Conclusion: Using a modular design approach, the innovative prosthesis for the TMJ (Patent M.Mesnard & A.Ramos) presented here provides the surgeon with a range of five modules. The additive manufacturing has already been used successfully to produce finished parts in industries such as aerospace, dentistry... It will eventually be possible to produce the temporal prosthesis component that is tailor-made [5] [6].

AN EXPERIMENTAL STUDY OF MECHANICAL BEHAVIOR OF POLY (LACTIC ACID) FOR STENT APPLICATION

Tianyang Qiu [1,*]Rebecca Elliott [1]Alessandro Schiavone [1]Liguo Zhao [1]Mo Song [2]

[1]Wolfson school of mechanical and manufacturing engineering, [2]Department of materials, Loughborough University, Leicestershire, United Kingdom

Introduction and Objectives: Bio-resorbable polymeric stents are developed to open plaque-blocked arteries and then disappear within specific time period, which reduces the occurrence of thrombosis, in-stent restenosis and inflammation that may happen with the deployment of metallic stents[1]. The objective of this paper is to study the mechanical behavior of poly (lactic acid) (PLA), currently used for manufacturing commercial bio-resorbable stents, through processing and testing, with a focus on creep, stress relaxation and cyclic deformation behavior.

Methods: Standard dog-bone specimens were produced by compression molding, and then used to conduct series of tests in the tensile regime. Uniaxial tensile tests were performed at a range of strain rate (0.0001 ~1) to obtain the essential material behavior. Creep tests were conducted at two constant stresses (30 and 40MPa), and stress-relaxation tests were carried out under three constant strains (1%, 1.5% and 2%) for 200 minutes. Cyclic tests were performed to understand the deformation behavior under cyclic loading. For load-controlled tests, three stress ratios (0, 0.2 and 0.5) were considered while maintaining the maximum stress level at 40 and 50MPa, respectively. For strain-controlled tests, two strain ratios (0.2 and 0.5) were considered while maintaining the maximum strain level at 2% and 3%, respectively. In addition, a multiple-step cyclic test (see Table 1) was carried out by increasing the peak strain level at each cycle while maintaining the minimum stress level at 0.1MPa.

Results: The tensile results showed that the strain rate has an effect on the stress-strain behavior of PLA, demonstrating the time-dependent deformation nature of the material. An increase of strain rate led to enhanced stress response. The creep curve under 40MPa stress showed all three stages of creep deformation (primary, secondary and tertiary), but the specimen fractured after only 3 hours of loading. The stress relaxation curves showed a rapid stress reduction at the early stage, followed by a gradual stress loss stage and the final saturation stage. Under load-controlled conditions, the cyclic stress-strain loops showed the strain ratcheting behavior, resulting in the accumulation of strain with the number of cycles. Load ratio had an effect on strain ratcheting. Under strain-controlled condition, the stress-strain loops indicated a decrease of peak stress with the number of cycle due to stress relaxation. The multiple-step cyclic test results showed the capacity of plastic deformation at variable strain ranges, which is very limited (see Figure 1) when compared to metallic stent materials.

Figure:

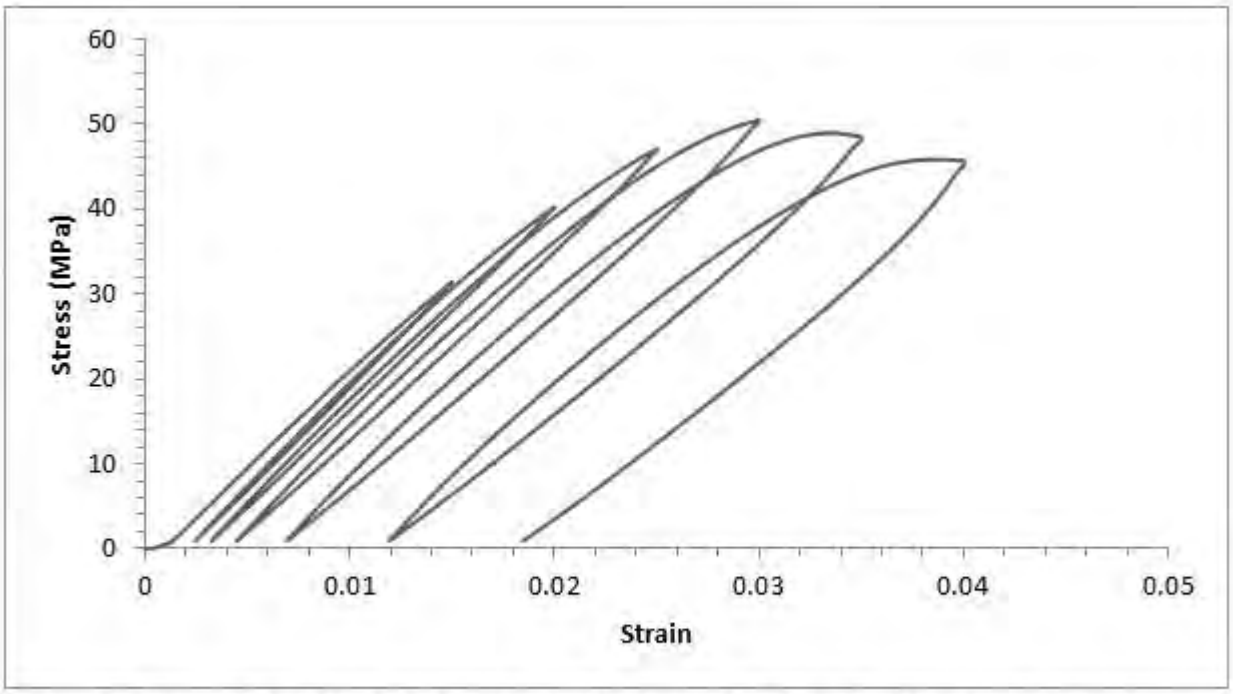

Figure 1, Stress-strain loops of PLA under multiple-step cyclic load with increasing maximum strain for each cycle (strain rate: 0.0001/s).

Conclusion: In conclusion, PLA is a brittle material that lacks significant plastic deformation behavior for stent application, as evidenced from various mechanical testing results including tensile, creep, stress-relaxation and cyclic tests. Further development of P(L)LA, through novel material processing, testing and even modelling, is required in order to improve the ductility of the material for successful stent applications.

Table:

Number of cycle	1	2	3	4	5	6
Peak strain in each cycle	1.5%	2%	2.5%	3%	3.5%	4%

BIOMECHANICAL FUNCTION OF A PREGNANCY COMPRESSION BELT. THREE-DIMENSIONAL HIP JOINT KINEMATICS: A CASE STUDY

Merilyn Lock [1] Michael Cole [2] Paul Grimshaw [3,*] Loisa Sessman [4] Malin Tapper [5]

[1]School of Medical Sciences, University of Adelaide , Adelaide , [2]School of Exercise Sciences, Australian Catholic University , Brisbane , [3]School of Mechanical Engineering , University of Adelaide , Adelaide , Australia, [4]School of Business and Engineering, Halmstad University , [5]Physiotherapy , Halmstad , Sweden

Introduction and Objectives: Pregnancy-related pelvic girdle pain (PPGP) and low back pain (LBP) are common problems and can result in functional impairment for those who are affected. The prevalence of PPGP and LBP has been reported at around 45% during pregnancy and 25% after pregnancy (Wu et al., 2004). Although the exact causes of PPGP and LBP are not clear, they are thought to be multifactorial including biomechanical factors affecting the sacroiliac joints (SIJs) and the pubic symphysis (Kanakaris et al., 2011; Vermani et al., 2010). A review by Aldabe et al. (2012) found an association between PPGP and altered motor control and pelvic mobility in six out of seven high quality case-controlled studies. Stability of the pelvic joints is maintained by muscular forces acting perpendicular to their longitudinal axis (Arumugam et al., 2012). Pelvic compression belts (PCBs) are thought to augment this effect through application of external compression. Electromyographical studies have shown that PCBs alter neuromuscular control of hip and pelvic muscles during unilateral stance in subjects with SIJ pain (Jung et al., 2013). Recent studies evaluating the effects of PCBs in pregnant women have shown improvements in impaired balance and falls risk scores (Cakmak et al., 2014). Additionally, finite element modelling has shown altered SIJ movement and an associated decrease in strain in sacrospinous and sacrotuberous ligaments with the use of a PCB (Sichting et al., 2014). Clarification regarding the general effects of PCBs on hip and pelvis mechanics is necessary to understand their effectiveness. A review by Arumugam et al. (2012) indicated a need for in-vivo analysis of SIJ kinematics with the use of PCBs. As such, the objective of this study was to assess three-dimensional (3D) hip biomechanics in a healthy female subject during a series of movements with and without a PCB.

Methods: A 10-camera 3D optoelectronic analysis system (Vicon, Oxford, UK; 150 Hz) was used to assess the movement patterns of one healthy female subject with and without the use of a newly developed PCB (patent pending). A series of five trials (n=5 trials) for four everyday activities (walk, step, sit to stand and unilateral lift with 10% of body weight) were examined using 16 anatomical joint markers that were positioned in accordance with the Plug-in Gait model. The belt was placed covering the SIJs bilaterally. Perceived level of compression was measured using a modified Borg CR10 visual analogue scale to elicit a score of 6-7. Raw data was low-pass filtered at 10 Hz using a 4th order Butterworth routine. Three-dimensional (x, y and z) displacement, velocity and acceleration for the left and right hip joints were compared for all trials between the two conditions. During this study, it was assumed that changes in pelvic joint kinematics should result in an associated change in hip joint kinematics.

Results: See Table 1

Conclusion: Remarkable similarity was seen in the x, y and z joint position traces between the 'with belt' and 'no belt' conditions. Average vertical displacement (not shown in Table 1) in the 'with belt' condition was slightly larger during the sit to stand and walk, and smaller during the step and lift. There is insufficient data to draw any conclusions whether any differences may be a result of altered sacroiliac kinematics. The limitations of this study include the use of only one, non-pregnant subject with no history of PPGP or instability. Nevertheless, the results of this study are important as the lack of difference between these conditions may suggest that this type of testing is not sensitive enough to detect changes in pelvic joint kinematics due to the effects of a PCB. Alternatively, the effects of PCBs that have been found in previous studies may be due to neuromuscular changes, biofeedback or reasons other than changes in joint kinematics.
Future research may include controlled studies looking at hip and pelvis biomechanics of female subjects with and without PPGP during bilateral and unilateral movements.

Table:

Test/Condition	Walk	Step Left Foot First	Lift With Left Hand	Sit-to-Stand
No Belt				
Max	900.56	1123.38	902.58	898.66

DEFORMATION PATTERNS OF CRACKED ARTICULAR CARTILAGE UNDER COMPRESSION

Yasir Al-Saffar [1 2,*] Belinda Pingguan-Murphy [1] Walter Herzog [2]

[1]Biomedical Engineering, University of Malaya, Kuala Lumpur, Malaysia, [2]Human Performance Lab, University of Calgary, Calgary, Canada

Introduction and Objectives: Osteoarthritis (OA) is a common joint disease that is characterized by progressive degeneration of cartilage [1]. Among the earliest characteristics of OA is the presence of micro-fractures on the cartilage surface [2]. These micro-fractures are thought to affect the tissue mechanical properties and chondrocytes' mechanical environment [3]. While some research has started looking at possible causes of cracks in cartilage, the mechanical behaviour of cracked cartilage has not been investigated. This study aims to determine the effects of cracks on the mechanical behaviour of cartilage and its deformation pattern.

Methods: *Experimental design:*

Split line patterns of tibial articular cartilage of New Zealand white rabbits were identified using India-ink. A compression test of the cartilage at a constant rate of displacement was used to compare the mechanical properties between intact cartilage and cartilage with a defined crack. Using a custom designed 0.75 mm wide blade, a consistent full thickness crack was produced perpendicular to the cartilage surface and oriented perpendicular to the split line patterns in an attempt to induce the highest possible amount of structural damage to the cartilage [2].

Sample preparation and loading protocol:

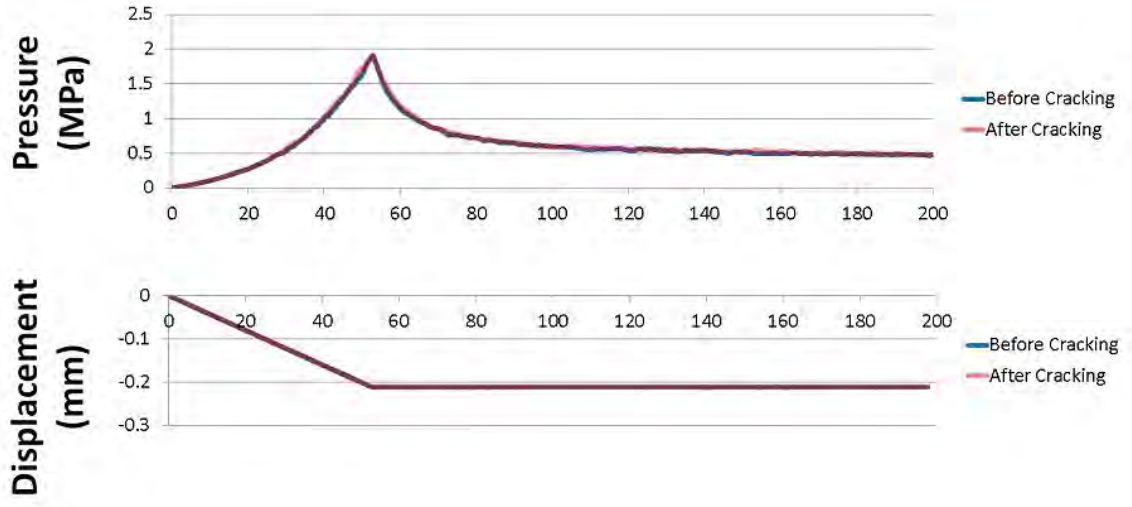
Rabbit knee joints were dissected. Soft tissue was carefully removed from tibiae to allow secure mounting of samples in dental cement. PBS was used at all times to keep samples from drying. Once the cement was set, samples were mounted on an MTS machine for 2 compression tests. The first compression test involved lowering an indenter (2 mm diameter) towards the sample surface at a speed of 4 μm/s until reaching a force of 6 +/-0.5 N (1.75-2 MPa) where it was held steady for 20 min to measure the stress relaxation behaviour of the cartilage sample. The indenter was then removed and the tissue was allowed to recover for one hour. For experimental group cartilages, a defined crack was made at the end of the 1 hr rest period by replacing the indenter with a cutting blade. A second compression, identical to the first, followed and stress relaxation measurements were performed.

Cartilage tissues were then fixed in the loaded state and prepared for histology. Mechanical and histological differences between intact and cracked samples were quantified.

Results: The split line patterns of tibiae were found to be consistent. Control and experimental group cartilages recovered to the initial thickness at the end of the rest period. The depth of indentation for the second compression test was similar to that of the first for each sample and for the intact and cracked group cartilages. Among the cracked samples, the difference in displacement between the first and second compression ranged from 0.6% to -0.7%. Comparing the first stress relaxation curve of each sample to its corresponding second curve showed almost identical properties for control and cracked samples (fig.1).

On histology, the induced crack was difficult to identify as it closed during compression and only an S-shaped fine line was visible under polarized light microscopy. A striking feature observed at the compression site in control and cracked samples was the reorientation and crimping of collagen fibres under the applied load. The cracked samples showed a distinctly different pattern of collagen fiber reorientation under compression as a small triangular area on either side of the crack experienced less crimp than further away from the crack.

Figure:



Caption: Fig.1: Example for first and second stress-relaxation curves overlapping for experimental samples.

Conclusion: The presence of a single crack did not result in detectable changes in the mechanical properties of the cartilage in terms of strain and stress relaxation behaviour. This result indicates that the cartilage's structural organisation can compensate for minimal structural damage as produced by the artificial crack, and hence may help slow the progression of OA in real life. The closure of the crack under compressive load may partially explain the preserved mechanical behaviour, and may be attributed to the swelling pressure maintained by proteoglycans. Polarized microscopy shows a distinct pattern of collagen fiber deformation in the cracked compared to the control group samples. The presence of reduced crimp at the crack's edge might indicate stress release. The difference in collagen reorientation between intact and cracked samples may provide crucial insight into the load distribution in early OA cartilage that contains cracks, and may help identify how cracked cartilage degenerates.

IMAGE-BASED FINITE ELEMENT MODELING OF THE ACHILLES TENDON:

THE ROLE OF FASCICLE MORPHOLOGY AND MUSCLE FORCES IN NON-UNIFORM TENDON DISPLACEMENTS

Geoffrey Handsfield [1,*] Joshua Inouye [1] Laura Slane [2] Darryl Thelen [3] Wilson Miller [4] Silvia Blemker [1]

[1]Biomedical Engineering, University of Virginia, Charlottesville, VA, [2]Radiology, [3]Mechanical Engineering, University of Wisconsin, Madison, [4]Radiology and Medical Imaging, University of Virginia, Charlottesville, VA, United States

Introduction and Objectives: The Achilles tendon is an important tendon with a complex structure. It is composed of three to four fascicles, each controlled by a different muscle of the triceps surae group [1]. These fascicles twist 90° [2] and are capable of sliding past one another [3]. Reduced sliding of the Achilles fascicles appears to increase with aging and may be associated with tendinopathy [3,5]. Recent advances in ultrasound imaging have enabled measurement of fascicle sliding *in vivo*, as demonstrated by non-uniform tissue displacements within the Achilles tendon. These studies have shown evidence of fascicle sliding in controlled single joint tasks [4] and in walking [5]. The results of these experiments are challenging to interpret due to the complex 3D morphology of the tendon. For example, it is not clear whether it is complex fascicle geometry and/or differential muscle forces that give rise to non-uniform displacements in the tendon. The purpose of this study is to create an MRI based finite element model of the Achilles tendon fascicles to investigate the role of muscle forces and fascicle sliding on tendon tissue displacements. The specific goals are to i) build a finite element model from ultrashort echo time (UTE) MRI of the Achilles tendon, ii) predict the muscle forces necessary to replicate tissue displacements observed in the literature, and iii) use the model to understand the interactions of muscle forces and fascicle sliding on tendon displacements and strains.

Methods: We developed a novel UTE MRI approach for high contrast, high resolution imaging of the Achilles tendon. The pulse sequence, which we refer to as SUTE&TIE (Subtraction Ultrashort TE & Tendon Intensity Enhancement), obtained images with a 3D spoke-radial k-space acquisition strategy. Two complete sets of 3D images were acquired, one at an ultrashort echo time (TE: 0.08ms) and the other at a short echo time (TE: 2.5ms). Field of view was 300x300x300 mm^3 and spatial resolution was 0.8mm isotropic. Short TE images were subtracted from UTE images to maximize tendon intensity and contrast. A healthy 27 year-old female (height: 1.63m, mass: 52 kg) was scanned with this sequence on a 3T MRI scanner using a flexible RF coil wrapped around the ankle, which was manually placed in 25° of plantarflexion.

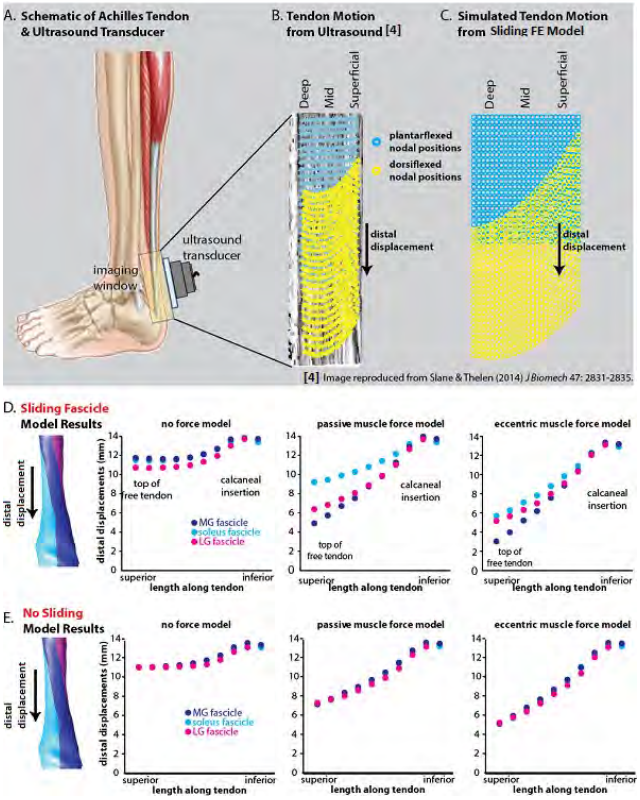
A finite element model of the Achilles tendon was created from axial image views. The tendon was subdivided into three fascicles associated with the triceps surae muscles and consistent with literature [1,6]. Two models were created—one that enabled sliding between fascicles, another with no inter-fascicle sliding. Fascicles were modeled as Neo-Hookean materials with a coefficient of 45MPa. Meshing and finite element analysis were implemented in AMPS software.

The calcaneal insertion was prescribed to rotate 25° about ankle joint center. Passive and active muscle forces on each fascicle were chosen such that the model predicted Achilles tissue displacements that were consistent with previous measurements of tendon displacements during passive and eccentric dorsiflexion experiments [4] (Fig. 1 A,B,C).

Results: Physiologically reasonable muscle forces were capable of replicating differential displacements for the “sliding” model but not the “no sliding” model. Distal displacements were inversely related to muscle forces applied to the fascicles

(Fig. 1D). Tissue strains in the MG fascicle were higher than those in the soleus fascicle for both passive and eccentric conditions. In the “no sliding” models, neither passive nor eccentric muscle forces induced differential displacements between fascicles (Fig. 1E).

Figure:



Caption: Sliding fascicle FE models replicate in vivo ultrasound results of Achilles motion (A-C). Physiological force conditions cause different displacement of the Achilles fascicles for sliding models (D) but not for no sliding models (E).

Conclusion: In this model, muscle forces and sliding tendon fascicles were necessary to replicate previously measured *in vivo* tissue displacements in the Achilles. The modeled differential tissue displacements were associated with differential fascicle stretch, with the greatest stretch in the MG fascicle. This high stretch may be due to high passive forces in the MG muscle or differences in the effective tissue compliance between fascicles. Musculotendon changes such as cross-linking of collagen between tendon fascicles and changes in muscle strength and neural activation may be the physiological mechanisms that reduce differential tendon displacements in aging subjects and runners. Further work is needed to verify these hypotheses and suggest clinical interventions to prevent tendinopathy.

AS-0394

A VISUAL ASSESSMENT OF HOW LOADING RATE AFFECTS THE FAILURE MECHANICS OF TYPE I COLLAGEN FIBRILS

Samuel P. Veres [1 2,*] Neil C. Chambers [2] Tyler W. Herod [2]

[1]Saint Mary's University, [2]Dalhousie University, Halifax, Canada

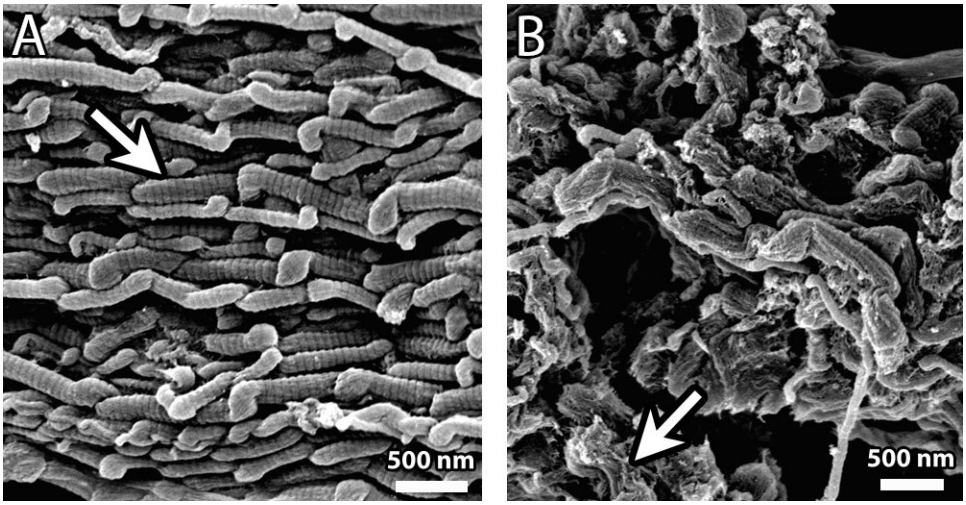
Introduction and Objectives: Overload damage to tendons can occur over a variety of strain rates, ranging from low rate injuries during lifting tasks to high rate injuries during sports activities. Because crosslinking within tendons—the major determinant of their mechanical response—varies with *in vivo* load, functionally distinct tendons may behave differently when overloaded at differing rates. In this study we present a detailed nanostructural account of the damage that occurs to individual collagen fibrils when tendons are ruptured at strain rates varying from 1 to 100%/s. We show that changes in damage morphology with strain rate are tissue specific, varying significantly between low *in vivo* load digital extensor tendons, and high *in vivo* load flexor tendons.

Methods: Digital flexor (n = 4) and digital extensor tendons (n = 4) were dissected from the forelimbs of 4 adult steers and subdivided lengthwise to produce several parallel samples. One sample from each tendon underwent crosslink analysis using hydrothermal isometric tension testing (HIT), as described previously [1]. Samples from the same tendon were assigned to the following test groups: control, 1%/s rupture, 10%/s rupture, and 100%/s rupture. All samples were first preconditioned using ten loading cycles to 10% strain. Control samples received preconditioning only. Samples in the rupture groups were pulled to rupture at their assigned strain rate (1, 10, or 100%/s). The molecular stabilities of the control and ruptured samples were analyzed using differential scanning calorimetry (DSC), conducted as described previously [2]. Collagen fibrils within control and ruptured tendons were visually assessed at magnifications of up to 90,000X using scanning electron microscopy (SEM).

Results: Extensor tendons ruptured at 1%/s showed extensive regions of well-aligned fibrils with longitudinally repeating kinks. Many of the kinked fibrils in these samples had lost their native D-banding. Extensors ruptured at 10%/s also contained aligned, kinked collagen fibrils, however, most had intact D-banding (Fig). In contrast to the 1 and 10%/s extensors, the extensors ruptured at 100%/s contained irregularly kinked and highly contorted fibrils that appeared to have undergone significant elastic recoil. Rather than a uniform loss of D-banding as in the 1%/s rupture samples, many of the irregularly kinked fibrils appeared shredded, having lost lateral cohesion among the structural subunits throughout their cross-section (Fig). At all strain rates, the damage caused to fibrils in flexor tendons was distinct from that caused to extensors. Compared to extensors, fewer regions of kinked fibrils were found in flexors that had been ruptured at 1%/s. Where kinked fibrils were found, none had lost their D-banding, indicating a greater resistance to molecular packing disruption. No plastically deformed fibrils were observed in flexors ruptured at either 10 or 100%/s, indicating a more brittle mode of failure at these higher strain rates. DSC data supported our ultrastructural observations. Compared to control extensors, endotherm onset temperatures were significantly lower in the 1%/s ($p = 0.015$) and 100%/s ($p = 0.046$) rupture samples, but not in the 10%/s rupture samples ($p = 0.23$). For flexor tendons, onset temperature was significantly lower in 1%/s rupture samples compared to controls ($p = 0.027$), but no difference was observed for either the 10%/s ($p = 0.98$) or

100%/s (p = 0.40) samples. Comparison of only the control extensor and flexor samples using HIT showed that significant architectural differences exist between these two tendon types, which may underlie their differing nanoscale responses to overload. HIT confirmed that crosslinking in flexor tendons was significantly more advanced than in extensor tendons. Compared to extensors, flexors had a significantly higher denaturation temperature (p = 0.0014), indicating greater lateral constraint among collagen molecules, and temperature of maximum force generation (p = 0.015), indicating the presence of significantly greater levels of thermally stable crosslinking.

Figure:



Caption: (A) Damaged collagen fibrils caused by medium speed (10%/s) extensor tendon rupture. Damaged fibrils are highly kinked, but most retain their D-banding (arrow). 25,000X. (B) Damaged collagen fibrils caused by high speed (100%/s) extensor tendon rupture. Damaged fibrils are irregularly kinked, contorted, and often shredded (arrow). 20,000X.

Conclusion: This study provides the first description of how plastic deformation of collagen fibrils varies in tendons with both strain rate and tendon type. While fibril plasticity is maintained over two decades of loading rate in low *in vivo* load extensors, fibril plasticity is lost at higher rates in high *in vivo* load flexors. The different responses to strain rate of collagen fibrils within these two tissues may affect healing potential and remodeling ability.

BIOMECHANICAL PROPERTIES IN A TENDON PATHOLOGY MODEL: A ROLE FOR PROTEOGLYCANS

Rachel Choi [1,*] Joshua Martin [1] Else Jacobsen [2] Margaret Smith [3] Andrew Dart [2] Christopher Little [3] Elizabeth Clarke [1]

[1]Murray Maxwell Biomechanics Laboratory, The Kolling Institute of Medical Research, Sydney Medical School, University of Sydney, St Leonards, [2]Camden Veterinary Hospital, University of Sydney, Camden, [3]Raymond Purves Bone and Joint Research Laboratories, The Kolling Institute of Medical Research, Sydney Medical School, University of Sydney, St Leonards, Australia

Introduction and Objectives: Tendons are vulnerable to overuse and injury at work and in leisure. An often painful degenerative cascade will follow and can progressively weaken the previously healthy tendon to the point of acute rupture. While ruptures are reparable, 20% of Achilles tendon repairs experience re-rupture[1] and long-term outcomes from surgery are unsatisfactory in approximately 33% of cases[2]. No current treatments can restore the structure of degenerated tendons.

Our previous research using a focal tendon injury model confirmed that pathological tendons have decreased ultimate tensile strength (UTS) and elastic modulus. These changes extended throughout the tendon (up to 10cm from the injury site), and were associated with similar widespread increases in proteoglycans and associated glycosaminoglycans (GAGs). This indicates that “healthy” tendon tissue used in surgical repairs is in fact mechanically deficient. The aim of this study was to determine whether the accumulation of proteoglycans are responsible for the reduced modulus and UTS in pathological tendons, by assessing tendons with enzymatically reduced GAG levels.

Methods: The superficial digital flexor tendon (SDFT) was unilaterally hemi-transected (pathological) in six horses (n=6). Three control horses were sham-operated unilaterally, with the contralateral as a non-operated control (n=6, no differences found between sham-operated and non-operated controls). Animals were sacrificed after six weeks. Replicate samples (~25x1x1mm) from each tendon were harvested and allocated to three groups: (i) no treatment (*ex vivo*), (ii) incubated for 18 hours at 37°C in Tris-acetate buffer alone, or (iii) incubated in buffer with chondroitinase ABC (0.3 units/ml to remove GAGs). Specimens were biomechanically tested to failure in tension and then papain-digested for measurement of GAG content with spectrophotometry.

Biomechanics data were normalised to measured specimen cross-sectional area and gauge-length to calculate elastic modulus and UTS. The relationship between modulus, UTS and GAG content was analysed using mixed models and ranking correlation (correcting for non-independence).

Results: Ex vivo comparison of pathological versus control tendons confirmed decreased modulus (-39%, $p<0.01$) and UTS (-38%, $p<0.01$), and elevated GAG content (51%) in pathological tendons. Chondroitinase digestion reduced this GAG content to 50% ($p<0.01$) of ex vivo levels, and partially returned modulus and UTS to 73% ($p<0.01$) and 72% ($p<0.01$) of normal, respectively. GAG content was negatively correlated with both modulus ($p<0.01$) and UTS ($p<0.01$) when correcting for incubation treatment and pathological versus normal tendons.

Figure:

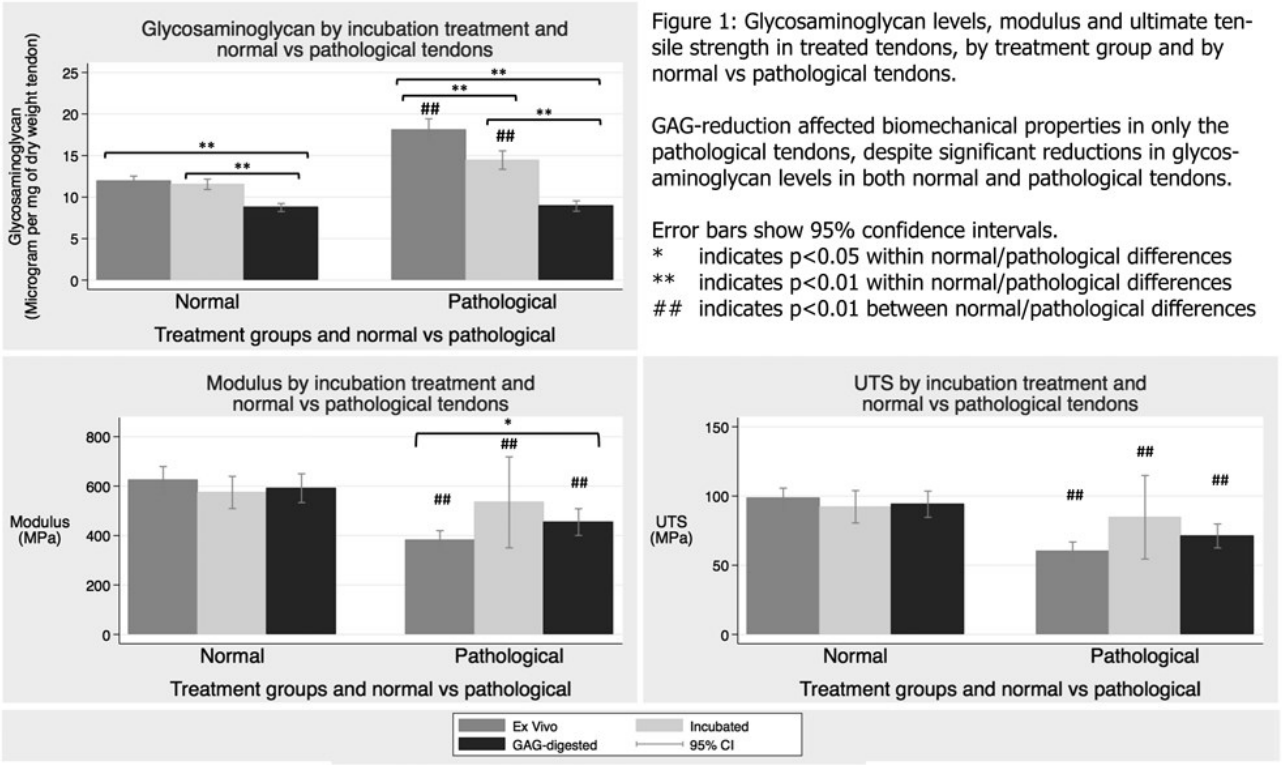

Figure 1: Glycosaminoglycan levels, modulus and ultimate tensile strength in treated tendons, by treatment group and by normal vs pathological tendons.

GAG-reduction affected biomechanical properties in only the pathological tendons, despite significant reductions in glycosaminoglycan levels in both normal and pathological tendons.

Error bars show 95% confidence intervals.
* indicates p<0.05 within normal/pathological differences
** indicates p<0.01 within normal/pathological differences
indicates p<0.01 between normal/pathological differences

Conclusion: These data demonstrate that increased proteoglycan, and specifically the chondroitin sulfate glycosaminoglycans in diseased tendons directly affects and contributes to altered biomechanical properties. Preventing proteoglycan-accumulation *in vivo* could spare the biomechanical properties of tendons undergoing degenerative changes, thus reducing incidence of rupture. Surgical repairs may also have improved outcomes if the accumulation of proteoglycans can be reversed.

AS-0396

FATIGUE DAMAGE TO POSITIONAL AND ENERGY-STORING TENDONS AT THE NANOSCALE LEVEL OF THE COLLAGEN FIBRIL

Samuel P. Veres [1 2,*] Tyler W. Herod [2] Neil C. Chambers [2]

[1]Saint Mary's University, [2]Dalhousie University, Halifax, Canada

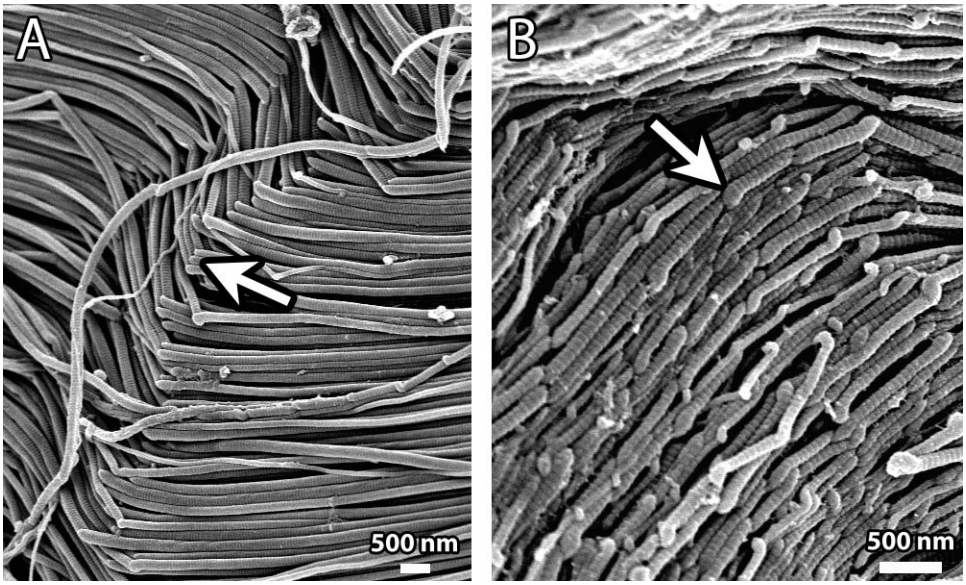
Introduction and Objectives: The accumulation of microscale fatigue damage in tendons resulting from excessive cyclic loading has been studied previously, providing a good description of what is known as “microdamage”. In this study we moved beyond microdamage, revealing the accumulation of fatigue damage to individual nanoscale collagen fibrils in two functionally distinct tendons: digital flexors and extensors. We identified two distinct forms of nanoscale fatigue damage, and show that these accumulate much faster in low *in vivo* load extensors compared to high *in vivo* load flexors.

Methods: Digital flexor tendons (n = 4) and extensor tendons (n = 4) dissected from the forelimbs of 4 adult steers were subdivided lengthwise to produce several parallel samples. One sample from each tendon underwent crosslink analysis, as described previously [1]. Samples from the same tendon were assigned to the following test groups: control, rupture, 500 cycle fatigue, and 1000 cycle fatigue. All samples were first preconditioned using ten loading cycles to 10% strain, and all tests were at a strain rate of 10%/s. Control samples received preconditioning only. Samples in the rupture group were pulled to rupture and their ultimate tensile strengths were calculated. 500 cycle fatigue samples were cyclically loaded 500 times to 30% of their ultimate stress, determined via the paired rupture sample from the same tendon. 1000 cycle fatigue samples were cyclically loaded the same way, but for 1000 cycles. After their respective mechanical interventions, the molecular stabilities of the control and fatigue samples were analyzed using differential scanning calorimetry (DSC), conducted as described previously [2], and their internal collagen fibril architectures were visually assessed at magnifications of up to 90,000X using scanning electron microscopy (SEM).

Results: Crosslinking in flexor tendons was significantly more advanced than in extensor tendons, as revealed by both denaturation temperature ($p = 0.0014$) and temperature of maximum force generation ($p = 0.015$) during hydrothermal isometric tension testing. Under SEM, control extensor tendons showed well-aligned, straight fibrils of diameter 141 ± 44 nm (40 fibrils), with clearly defined D-banding. Control flexor tendons were quite different: fibrils were significantly smaller ($p < 0.0001$) measuring 70 ± 30 nm in diameter (31 fibrils), and were often covered in dense filamentous webbing. In extensor tendons that had undergone both 500 and 1000 cycles of loading, collagen fibrils showed two characteristics identified as nanoscale forms of fatigue damage. First, highly localized fibrillar folds were observed, marked by a sharp discontinuity in fibril orientation caused by laterally aligned fibril kinks (Fig). Second, fibrils with longitudinally repeating, but non-aligned kinks were observed (Fig). In stark contrast, flexor tendons that had undergone 500 and 1000 cycles of loading showed little to no accumulation of fatigue damage, with minor infrequently observed fibrillar folds being the only architecture difference between the fatigue and control samples. DSC assessment of molecular stability in the control samples corroborated HIT findings: compared to extensor tendons (n = 5), flexor tendons (n = 5) had significantly higher endotherm onset temperatures ($p = 0.027$) and lower full-widths at half-maximum ($p = 0.003$) indicating that flexor tendons were composed of collagen molecules with both greater thermal stability and homogeneity. Compared to control tendons,

none of the metrics measured (onset temperature, peak temperature, full-width at half-maximum, specific enthalpy of denaturation) changed significantly with cyclic loading in either the flexor or extensor tendons, indicating that early fatigue damage, while clearly visible under SEM, does not affect enough molecules to be detectable via bulk tissue measurement.

Figure:



Caption: (A) Fatigue damage type I: Fibrillar folds (arrow) were commonly seen in cyclically loaded extensor tendons, but rarely seen in cyclically loaded flexor tendons. 6,000X. (B) Fatigue damage type II: Fibrils with longitudinally repeating, but non-aligned kinks (arrow) were commonly seen in cyclically loaded extensor tendons, but not flexors. 13,000X.

Conclusion: This study provides the first description of fatigue damage accumulation at the nanoscale level of individual collagen fibrils in functionally distinct tendons. Striking differences in fatigue damage to high and low *in vivo* load tendons are found, possibly arising from observed differences in collagen crosslinking and fibrillar architecture. Our findings may be important to understanding the architectural changes that tendons must undergo during development or physical training, and may have relevance to the optimal selection of allograft tissues.

DYNAMIC MECHANICAL PROPERTIES OF THE BOVINE PERIODONTAL LIGAMENT

Iman Zoljanahi Oskui [1] Ata Hashemi [1,*]

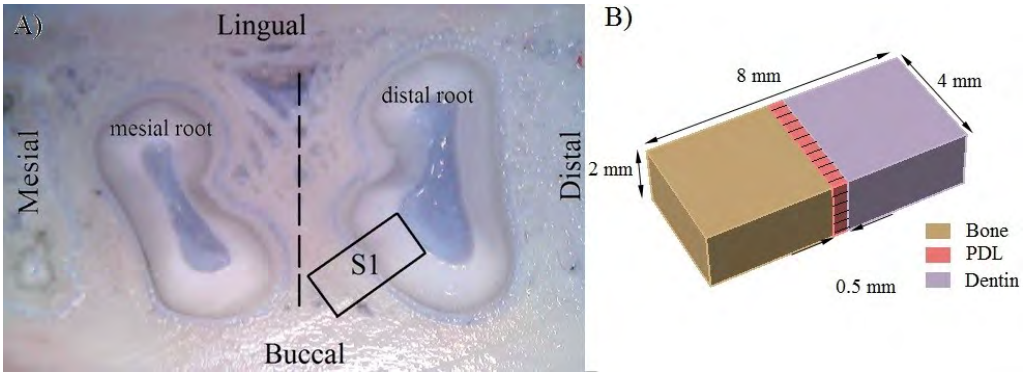
[1] Faculty of Biomedical Engineering, Amirkabir University of Technology, Tehran, Iran, Islamic Republic Of

Introduction and Objectives: Periodontal ligament (PDL) has a major contribution to tooth-bone attachment [1] and also absorbs and distributes the occlusal forces on alveolar bone [2]. Owing to nonlinear and viscoelastic behavior of PDL [3], exploring its dynamic mechanical properties is necessary [4, 5]. To best of our knowledge these dynamic mechanical properties are not experimentally determined. Hence, in current study, results of tensile and compressive dynamic tests on bovine PDL are presented. Wide range of loading frequencies is applied to PDL to capture how it affects storage and loss modules in tension and compression.

Methods: Transverse sections with a thickness of 2 mm are cut from left lower bovine mandible (Figure 1.A). On these sections, eight samples of 4 mm * 8 mm dimensions are extracted from tooth-PDL-bone interface zone (e.g. S1 in Figure 1) for dynamic mechanical tests. Special attention is given to alignment of collagen fibers with longitudinal direction of the samples (Figure 1.B). These samples are imaged under light microscope and resultant images are used to measure PDL length. Our measurements showed an initial length of 0.5±0.1 mm for PDL. Subsequently, samples are mounted on TTDMA testing device (Triton Technology Inc.) such that dentin and bone are attached to jaws of testing machine. Since bone and dentin are much stiffer than PDL, any tensile or compressive force applied to the sample is transferred to PDL. Load-controlled tensile test with dynamic force of 2 N in frequency range of 0.01 to 100 Hz. Compressive tests with the same magnitude and frequencies are repeated. During the test, samples were submerged in PBS.

Results: Storage modulus is increased with elevation of frequency in either tension or compression. For a given frequency, compressive storage modulus is approximately twice of storage modulus in tension. In tensile tests, loss modulus showed an insignificant enhancement while the frequency is increased till 20 Hz and drops beyond this threshold. The same trend is seen in compressive tests with the threshold of 0.5 Hz.

Figure:



Caption: Figure 1. A) Transverse section of bovine mandible, B) Schematic of testing sample.

Conclusion: Dynamic mechanical behavior of the PDL shows different trends in tension and compression, implying that mechanical behavior of PDL is governed by collagen fibers in tension and liquid phase in compression.

MEASUREMENT OF THE EFFECTS OF 'KINESIO-TAPING' ON IN VIVO THORACOLUMBAR FASCIA MOVEMENT USING 3D ULTRASOUND: METHODOLOGICAL DEVELOPMENT AND RELIABILITY

Shihfan J. Tu [1,*] Roger Woledge [1] Dylan Morrissey [1 2]

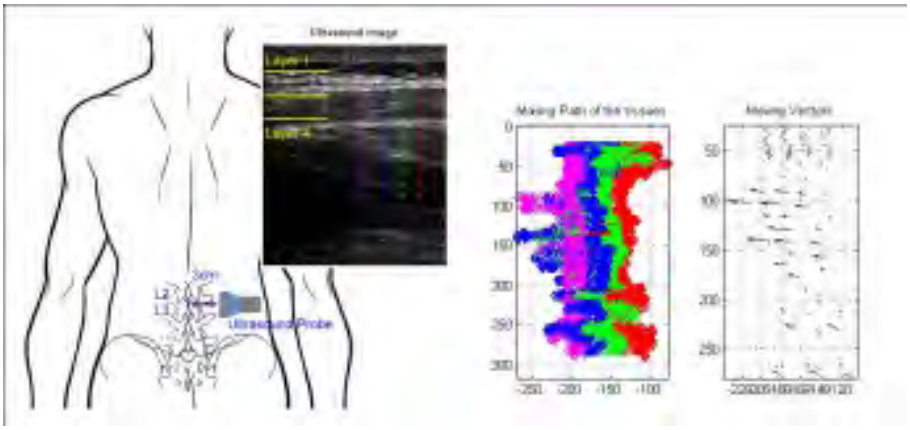
[1]Sports and Exercise Medicine, Queen Mary University of London, [2]Physiotherapy Department, Bart's Health NHS Trust, London, United Kingdom

Introduction and Objectives: Therapeutic taping techniques are increasingly used to treat low back pain (LBP) [1, 2, 3], albeit with variable effects and unclear mechanisms. Changes in thoracolumbar fascial thickness, structure and shear strain are associated with LBP [4, 5], however methods for quantifying in vivo fascia properties are inadequate. We therefore aimed to develop a reliable in vivo measurement technique to enable exploration of taping mechanisms.

Methods: Ultrasound videos of known orientation and position were taken of 9 normal participants (male and female, aged 27.3 ± 2.04, BMI 22.98 ± 3.10) while performing velocity-guided lumbar flexion with and without taping. An automated algorithm using cross-correlation to track contiguous tissue layers across sequential frames, in two planes, was developed and applied to two movements of each subject in each taping condition. Reliability was assessed using the intra-class correlation coefficient (ICC 2, 1), limits of agreement (LOAs) were calculated for each assessment and systematic differences tested with a Student's t-test.

Results: The mean movements of thoracolumbar tissue during lumbar flexion before and after taping (figure 1) showed strong reliability within subjects ICC both when subjects were moving without tape applied (ICC = 0.82) and with Kinesio-taping applied (ICC = 0.82). No significant differences was found (No tape, p = 0.32, t = 1.00; tape, p = 0.90, t = -0.13). Intra-observer analysis revealed acceptable LOAs for both measurements when subjects were taped and not taped. The study was not powered to reveal differences between taping conditions, and none was revealed, however a sample size calculation suggested that 80 subjects would be required at 80% power and 5% significance levels. It must be noted these were normal subjects rather than those with pain.

Figure:



Caption: Ultrasonography tracking analysis. (A) The Ultrasound probe was placed 3 cm lateral to the midpoint of a line joining L2 and L3 spinous processes. In the tracking programme, multiple tracking targets (middle area between 4 red

dots) were drawn. (B) Movements in each position were tracked and recorded as a route map. (C) A vector field plot based on the route map was calculated to quantify tissue movements in each plane. Blue vectors indicate in-image movement direction and amount. (Plot unit = pixels)

Conclusion: Movement of relative thoracolumbar fascia, muscle and fatty tissue and underlying tissues could be reliably quantified during lumbar flexion in vivo using real-time ultrasound. The reliability was similar for both taped and untaped conditions. Next steps include validity analysis and testing in subjects with low back pain to investigate possible mechanisms of taping therapies.

Table: Table: Intra-class correlation coefficient and limits of agreement

	Analysis 1	Analysis 2	P value	ICC	$MEAN_{diff}$	SD_{diff}	Lower LOA	Upper LOA
without taping	2.15 ± 2.76	1.91 ± 2.3	0.32	0.82	0.23	1.97	-3.63	4.09
with taping	1.76 ± 1.78	1.78 ± 2.53	0.90	0.82	-0.02	1.69	-3.33	3.29

DIFFERENCE IN TRAINED VS. UNTRAINED ON THE MATERIAL PROPERTIES OF SKELETAL MUSCLE

Matthew Salzano [1]Erica A Bell [1,*]Kayla D Seymore [1]Jamie E Hibbert [1]Anthony S Kulas [2]Zachary J Domire [1]

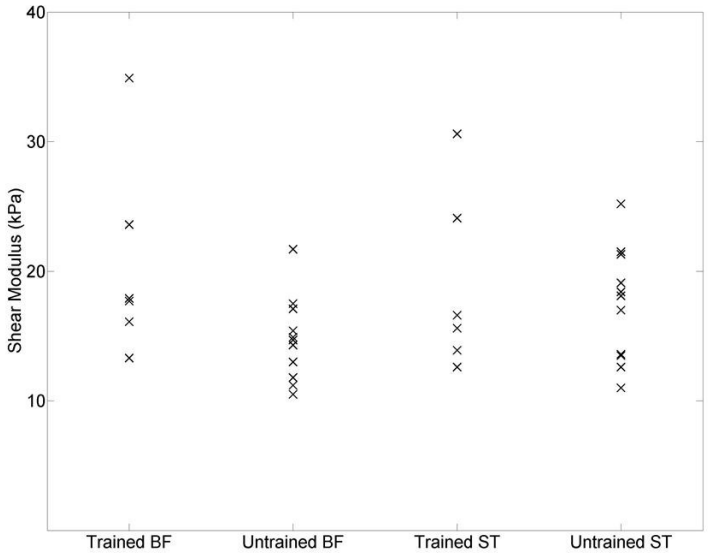
[1]Kinesiology, [2]Health Education & Promotion, East Carolina University, Greenville, United States

Introduction and Objectives: It is known that the extracellular matrix (ECM) of muscles cells plays a role in the lateral transmission of force through the whole muscle [1]. With exercise training, muscle adapts through hypertrophy and increased strength. In order for ECM to remain undamaged as a result of the muscular strength gains, its strength should also increase. ECM could become stronger by laying down more collagen and becoming bigger or by changing material properties via increased cross-links. However, existing research is conflicting on the effect training has on ECM stiffness. Endurance training was found to have no effect on the passive stiffness, measured *in vitro*, in the soleus of young rats [2]. Two studies disagree with this, showing that endurance training increases rat muscular stiffness and human joint stiffness, both measured via quick release tests [3,4]. These two studies also show that plyometric training [4] and resistance training [3] result in decreased joint and muscular stiffness, respectively. The opposite effect of resistance training on joint stiffness was found in human hamstrings [5]. The purpose of this study is to examine the effect of training on muscle material properties through comparison of ultrasound elastography measurements between elite and recreational athlete hamstrings as a representation of trained and untrained muscle, respectively. We hypothesize that modulus will be higher in the trained muscle compared to the untrained muscle.

Methods: This study used 6 elite sprinters and jumpers (3 male, 3 female) and 11 recreationally active (RA) individuals (4 males, 7 females). RA was defined as performing strength and/or cardio training for at least 5 hours per week. All subjects were free of previous injury and completed an informed consent form approved by University IRB. Ultrasound elastography measurements were taken from the mid-belly of the biceps femoris long head and semitendinosus muscles using an Aixplorer SuperSonic Imagine. Stiffness measurements were taken with a 3 mm diameter region of interest from the middle of the readable data within the Q-box. Stiffness levels were then plotted on Cleveland dot plots to compare differences between groups for each muscle.

Results: Elastography measurements show that the elite athletes had significantly higher modulus in their biceps femoris muscles than the RA individuals (avg. kPA: 20.6 vs. 14.7, respectively; $p<0.05$). There was no significant difference in stiffness values within the semitendinosus muscle between the elite athletes and RA subjects (avg. kPa: 18.9 vs. 17.4; $p>0.05$).

Figure:



Caption: Figure 1. Trained vs. Untrained Modulus

Conclusion: The results of this study support our hypothesis that modulus in trained muscle will be higher when compared to untrained muscle. The cross-sectional nature of this study limits the ability to infer training as the cause for higher modulus. It possible that genetics plays a role, and elite athletes are predisposed to this condition, allowing for quicker and larger strength gains. The lack of information regarding the range of training volume in RA also makes it difficult to make conclusions about training effects on muscle modulus. Future work in this area could examine differences in modulus through a training protocol or by recording training volume and strength measurements. While limitations to this study exist, our work supports the idea that muscle modulus can be increased through training.

Table:

	Elite BF	RA BF	Elite ST	RA ST
Average:	20.6	14.7	18.9	17.4
Std. Deviation:	7.8	3.2	7.0	4.4

THE PROBABILITY OF FINDING 0D STATISTICAL SIGNIFICANCE IN 1D TRAJECTORY ANALYSIS

Todd Pataky [1,*] Jos Vanrenterghem [2] Mark Robinson [2]

[1]Department of Bioengineering, Shinshu University, Ueda, Japan, [2]Research Institute for Sport and Exercise Sciences, Liverpool John Moores University, Liverpool, United Kingdom

Introduction and Objectives: One-dimensional (1D) kinematic and force trajectories are often summarized using 0D metrics like local extrema. One problem with this approach is that analysis of 0D metrics ultimately yields probability values which are based on classical 0D models of randomness like the 0D Gaussian distribution. Thus analyses which set a threshold for significance (α) control the likelihood that random 0D data, not random 1D data would reach that threshold. The purpose of this study was to estimate the probability with which random 1D data reach the 0D threshold for significance. Much higher 1D probabilities would imply that 0D thresholds bias analyses of 1D trajectories.

Methods: *Trajectory roughness*: We estimated the average temporal derivative λ of nine separate public 1D kinematics/force datasets from the ISB data archives and from simtk.org using an unbiased procedure [1]. Analyses below consider the full range of estimated λ values.

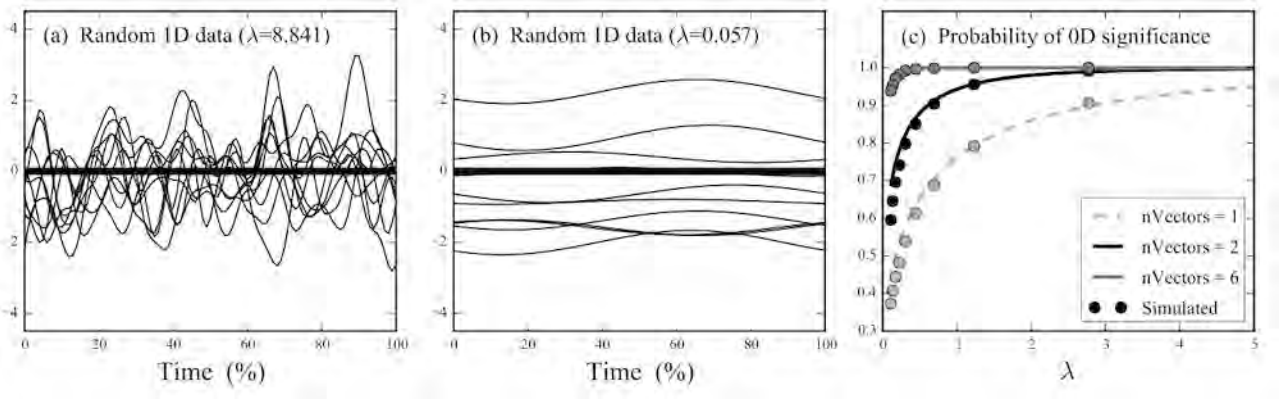
Theoretical probabilities: For simplicity we considered just a simple two-sample experiment design with N=10 observations per group; note that more complex designs like ANOVA would lead to greater divergence between 0D and 1D results. Basic t tables show that the critical t value (t*) for this two-sample design is t*=1.734 at α=0.05; this implies that random 0D Gaussian data would produce a t value greater than 1.734 with a probability of 5%. We computed the probably that random 1D data would reach t* as a function of λ using Random Field Theory (RFT) [2] and the open-source software: One-Dimensional Statistical Parametric Mapping (www.spm1d.org) [3].

Probability validations: We validated the aforementioned RFT probabilities by simulating 100,000 separate two-sample t tests using random 1D trajectories with controlled λ (Fig.1a,b). We repeated these 100,000 simulations across the range of λ values observed in the public datasets, and we also repeated these simulations for four separate cases: (1) scalar trajectories, (2) single three-component vector trajectories, (3) two three-component vector trajectories, and (4) six three-component vector trajectories. For conceptual purposes Case 4 could be interpreted as an experiment which measures three-dimensional joint angles from the hip, knee and ankle for both the left and right limbs.

Results: *Trajectory roughness*: Across the nine public datasets the average temporal derivative ranged from λ=0.057 to λ=8.841 (Fig.1a,b). The median value was λ=1.232.

Probabilities: For the median roughness, RFT predicts that 1D data would reach the 0D threshold for significance with a probability of 41.0%. This implies that the effective Type I error rate for 0D procedures is α=0.41 and not the presumed α=0.05. For two, three and six three-component vector trajectories, that probability increased to 79.4%, 95.8% and 99.9%, respectively (Fig.1c). This implies that, for experiments involving two or more vector trajectories, one is effectively guaranteed of observing 0D significance even when there is actually no difference between two groups. Simulations of random scalar and vector 1D trajectories validated the estimated probabilities (Fig.1c).

Figure:



Caption: (a,b) Random 1D trajectories for different smoothness values; λ is the average temporal derivative (change in signal per percent time). (c) Analytical probability that random 1D trajectories will reach 0D significance (solid lines) and simulation values (dots).

Conclusion: This study suggests that classical models of 0D randomness may substantially underestimate the probability with which random 1D trajectories produce particular results. In particular, the current results suggest that the effective Type I error rate (α) of 0D analyses can actually be well over 90% in common Biomechanics experiments, an order-of-magnitude larger than the presumed α=0.05. Since reporting an experimental result obliges one to also report its p value (the probability with which random data would produce the same result), using a 1D model of randomness for 1D data analysis may ultimately yield more objective p values. In short, as compared to the traditional 0D Gaussian model of randomness, a model of 1D randomness may be more consistent with the experimental variability observed about mean 1D trajectories.

WHOLE BODY CENTER OF MASS VELOCITY AND DIRECTION DURING CHANGE OF DIRECTION TASK AT MAXIMUM SPEED

Daichi Yamashita [1,*] Yuki Inaba [1] Masaki Asakura [2] Yoshihiko Ito [1]

[1]Department of Sports Science, Japan Institute of Sports Sciences, [2]Athletic Performance, Deers Football Club, Tokyo, Japan

Introduction and Objectives: The ability to change of direction is important in competitive sports such as American football. To gain separation from an opponent, athletes need to run fast and change of direction quickly. Many studies have investigated biomechanical characteristics of the single foot during change of direction, however, it is difficult to achieve the required angle during a single step at high speed (Vanrenterghem et al., 2012). We compared the COM horizontal velocity and angle during straight run to change of direction over several steps.

Methods: Twelve male semi-professional and collegiate American football players (experience = 7.5 ± 4.8 years) participated in this study. They were instructed to perform two tasks: straight running (RUN) and sidestep cutting to 45° (CUT) at their fastest speed. For straight running, subjects ran for 15 yards. For CUT, subjects ran for 10 yards, then planted their left foot and change direction to the right at 45°, and continued running for 5 yards.

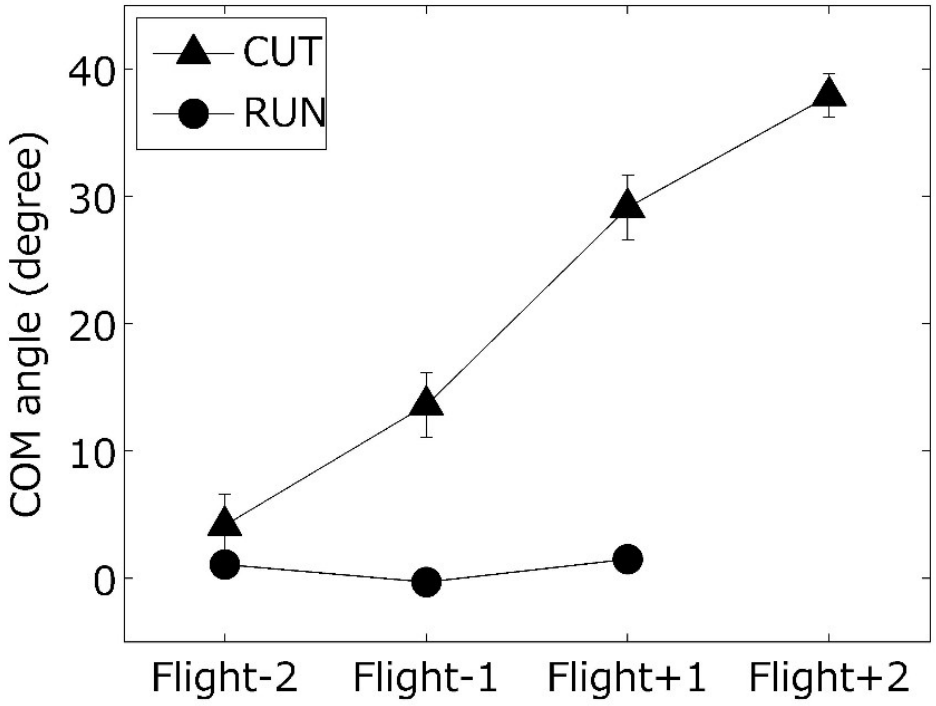
Three-dimensional coordinates of the anatomical landmarks were acquired using a 3D optical motion capture system with 20 cameras (250 Hz; Vicon, Oxford, UK). Thirty-one reflective markers were placed on each subject's body. The whole body centre of mass (COM) position was calculated as the weighted sum of the 14-segment model. The COM velocity and angle were defined using horizontal COM velocity vector at four flight phases; before the previous (right) foot strike (Flight -2) before the cutting (left) foot strike (Flight -1), after the cutting foot take-off (Flight +1) and after the next (right) foot tale-off (flight +2). Each flight phase was confirmed using each toe and heel markers.

Two-way repeated measures ANOVA were used to determine if differences exist between task directions (RUN and CUT) or flight phases (Flight -2, Flight -1, and Flight +1) for velocity and angle. Post hoc analyses were then examined with paired t-tests for comparison of the values measured at each flight phase between RUN and CUT. One-way repeated-measures ANOVA were conducted for velocity and angle during RUN and CUT. When the effect of flight phase was found, post hoc multiple comparison Tukey tests were conducted between flight phases ($p < .05$).

Results: A significant interaction was observed for velocity ($p < .05$). Compared to RUN, velocity was smaller during CUT at each flight phase ($p < .05$). Velocity was increased with flight phase during RUN ($p < .05$) but did not change during CUT.

A significant interaction was also observed for angle ($p < .05$). Compared to RUN, angle was greater during CUT at each flight phase (Fig.1). Angle was increased with flight phase during CUT ($p < .05$).

Figure:



Caption: Fig.1. Average COM angle at each flight phase (mean ± SD) during CUT and RUN.

Conclusion: These results showed that change of direction motion was started before the previous foot strike. Not only the cutting leg, but also the leg before and after cutting contributes change of direction more than a bit. This study provides important insight into the whole body COM control during change of direction at maximal speed.

MULTI-BODY OPTIMIZATION WITH KNEE JOINT CONSTRAINTS BASED ON THE STIFFNESS MATRIX

Vincent Richard [1 2 3,*] Giuliano Lamberto [4] Tung-Wu Lu [5] Valentina Camomilla [6] Aurelio Cappozzo [6] Raphaël Dumas [1 2 3]

[1]Université Claude Bernard Lyon 1, Villeurbanne, [2]Laboratoire de Biomécanique et Mécanique des Chocs, IFSTTAR, Bron, [3]Université de Lyon, Lyon, France, [4]Department of Mechanical Engineering, University of Sheffield, Sheffield, United Kingdom, [5]Department of Orthopedic Surgery, National Taiwan University, Taipei, Taiwan, Republic of China, [6]Department of Movement, Human and Health Sciences, Università degli Studi di Roma "Foro Italico", Rome, Italy

Introduction and Objectives: Estimation of joint kinematics using optoelectronic system and skin markers can be performed using a multi-body optimization (MBO) method [1]. With the intent to estimate the bone segments pose, MBO should compensate for the effect of soft tissue artefacts (STA), thanks to a multi-body model made of segments and articulated joints (represented by a set of constraints). When modelling the joints as simple mechanical linkages (hinge or spherical), the accuracy of the model-based kinematics is questionable [2]. Some studies have tried to improve the estimated kinematics by using a more detailed anatomical knowledge to model the joints [3,4]. Instead of a deterministic and non-physiological mechanical linkage, the present study proposes an alternative definition of the joint model thanks to a stiffness matrix introduced in MBO through a penalty-based method.

Methods: The knee stiffness matrix **S** reflects the coupling laws between passive forces and moments **F,** and joint angles and displacements of the tibia relative to the femur $\mathbf{U}= [\theta_1\ \theta_2\ \theta_3\ d_1\ d_2\ d_3]^T$ expressed in a joint coordinate system. This stiffness matrix satisfies the equation $\mathbf{F=SU}$. **S** has been experimentally obtained on a cadaveric subject by measuring the forces corresponding to a known displacement imposed by means of a robotic arm [5]. **S** was measured at 30° of knee flexion and was, thereafter, assumed to be constant, independent to knee flexion.

The principle of MBO is to minimize the squared distances between model-determined and measured skin marker positions. In the present study, this distance minimization was appended with the minimization of the joint deformation energy. The optimization problem for bone pose (**Q**) estimation was the following:

$\min f = 1/2[(\mathbf{\Phi}^m)^T \mathbf{\Phi}^m + w(\mathbf{U})^T \mathbf{SU}]$

subject to $\mathbf{\Phi} = 0$

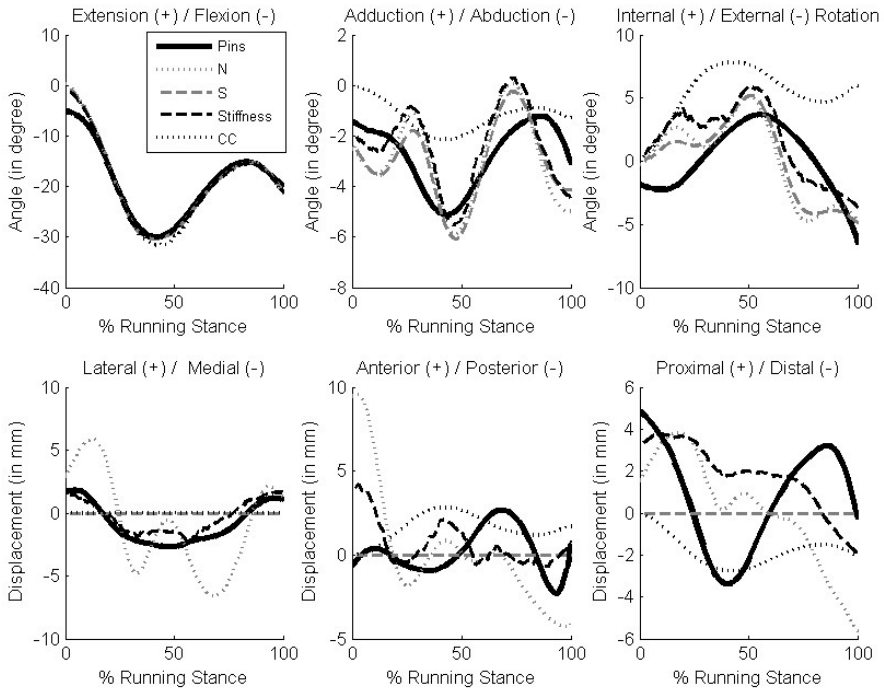
where $\mathbf{\Phi}$ represents the kinematic constraints (other than for the knee) and the rigid body constraints of the multi-body model and w is a weighting factor. In this study, $w = 1e^4$.

The resulting model-based kinematics (Stiffness) was compared in term of root mean square errors (RMSEs) to that obtained with the model-based kinematics obtained using more classical kinematic constraints (N: no constraint; S: spherical constraints) or constraining the degrees of freedom (DoFs) of the knee with direct coupling curves (CC) between them [6]. The method was tested *in-vivo* on data from 5 running trials of 3 subjects, measured with both skin markers and intra-cortical pins [7].

Results: RMSEs were generally limited for joint angles and displacements (under 6° and 4.9 mm, respectively). For flexion/extension, RMSEs were similar for all joint models (lower than 1.6°). More discrepancy between models was observed for internal/external rotation with 2.5°, 3.4° and 6° for S, Stiffness and CC models respectively. In terms of joint

displacements, the spherical model (S), although imposing null displacements showed the smallest RMSEs, while for both Stiffness and CC models, they were between 1.6 mm and 3.7 mm. The highest RMSEs were obtained without constraints (between 3.4 mm and 4.9 mm for N).

Figure:



Caption: Figure 1: Knee kinematics of the mean over the 5 trials of one subject

Conclusion: Joint models based on the stiffness matrix have already been used for spine kinematics but never for limb kinematics. The present MBO results seems encouraging in comparison with the more classical models of the knee (S, CC), even though assumptions have been made (e.g., constant stiffness matrix).

The proposed method is a penalty-based method where the choice for the weight factor w is critical. It is interesting to notice that such penalty-based method does not impede the joint displacements (as S do) nor prescribe them as a function of knee flexion (as CC do). Conversely, the six DoFs rely on the stiffness matrix coefficients, and, especially the extra-diagonal coefficients that stand for couplings. To that respect, the implementation of a knee flexion dependent stiffness matrix may provide improvement. Such MBO can be a promising method for STA compensation.

ASSESSMENT OF THE AGREEMENT BETWEEN THE SPATIO-TEMPORAL WALKING GAIT PARAMETERS FROM THE OPTOGAIT PHOTOELECTRIC SYSTEM AND THOSE FROM FORCE PLATES AND MOTION CAPTURE

Aoife Healy [1,*] Sara Behforootan [1] Nachiappan Chockalingam [1]

[1] Centre for Sport, Health and Exercise Research, Staffordshire University, Stoke On Trent, United Kingdom

Introduction and Objectives: Assessment of spatio-temporal walking gait parameters can be used to identify pathology and asymmetry in clinical populations. Instruments used to calculate these parameters include force and pressure plates and motion capture systems. Due to the high cost of some of these instruments and the space they require they may not be easily accessible to clinicians. Optogait is a portable system which consists of transmitting and receiving bars which contain LEDs; as a person walks between the bars their feet cause interruptions in the communication between the LEDs and this information is used to calculate the gait parameters. While recent research has examined the validity of the Optogait to another portable gait assessment system (GAITRite) [1, 2] no studies have compared the gait parameters calculated from Optogait to those from force plate and motion capture data. The aim of the study was to assess the level of agreement of spatio-temporal walking gait parameters calculated using a photoelectric system (Optogait) to those calculated from force plate and motion capture data (AMTI + Vicon).

Methods: Ten healthy participants (8 males and 2 females; mean age ± standard deviation: 30 ± 8 years) walked at their self-selected speed (1.33 ± 0.2 ms^{-1}) while simultaneously recorded by the two systems. The 5m Optogait system (sampling at 1000Hz; Microgate, Italy) was set up together with two force plates (AMTI OPT464508 sampling at 1000Hz; AMTI, USA) and a 14 camera Vicon motion capture system (sampling at 100Hz; Vicon, OMG, UK) for simultaneous capture. Reflective spherical markers were placed on anatomical landmarks of the participant, for use with the Plug-in-Gait Model. The force plates detected the initial foot contact and foot off gait events (using a minimum force threshold of 20N) while the movement pattern of the toe marker was used to identify the subsequent foot contact of the gait cycle. Three trials (each consisting of 1 gait cycle) were recorded with the mean values of step length and time, stride length, stance phase, swing phase, gait cycle, speed and cadence for left foot data used for statistical analysis. Agreement between the two systems was examined using 95% limits of agreement by Bland and Altman [3] and paired t-tests were used to detect any systematic differences between the systems.

Results: Six of the eight gait parameters were significantly different ($p \leq 0.05$) between the systems (Table 1); with results for gait cycle, stance phase and stride length significantly higher (0.01 s, 0.02 s and 0.01 m higher respectively) for the Optogait while cadence, speed and swing phase were significantly lower (1 step/min, 0.01 ms^{-1} and 0.02 s lower respectively). Results for 95% limits of agreement showed good agreement between the two measurement systems (Table 1).

Conclusion: Consistent with previous research findings the Optogait system reports longer stance phase and shorter swing phase times than other measurement systems. This is due to the fact that the LEDs within the bars are raised 3mm with respect to the floor; thereby the measurement of stance phase time starts prior to the foot contacting the floor and the measurement of swing phase starts after the foot has left the floor. While a systematic difference between the two

measurement systems were evident for the majority of the gait parameters all parameters showed good agreement based on the 95% limits of agreement and the differences are considered small enough to be acceptable for clinical purposes.

Table:

Gait parameter	Optogait	AMTI + Vicon	95% LOA
Cadence (steps/min)	116 ± 9	117 ± 9*	-2.51 - 0.69
Gait cycle (s)	1.04 ± 0.08	1.03 ± 0.08*	-0.01 - 0.02
Speed (ms^{-1})	1.327 ± 0.2	1.335 ± 0.2*	-0.02 - 0.01
Stance phase (s)	0.65 ± 0.06	0.63 ± 0.06*	0.01 - 0.04
Swing phase (s)	0.39 ± 0.02	0.41 ± 0.02*	-0.04 - -0.001
Step length (m)	0.68 ± 0.05	0.68 ± 0.05	-0.01 - 0.01
Step time (s)	0.52 ± 0.04	0.52 ± 0.04	-0.01 - 0.02
Stride length (m)	1.37 ± 0.1	1.36 ± 0.11*	-0.01 - 0.01

Caption: Mean ± standard deviation of spatio-temporal gait parameters for both systems with 95% limits of agreement (*significant difference between the two measurement systems ($p \leq 0.05$); LOA: limits of agreement).

THE ROLE OF LOWER LIMB JOINTS IN ENERGY ABSORPTION DURING DESCENT OF STAIRS AND SLOPES

Helene Pillet [1,*] Boris Dauriac [1] Coralie Villa [1 2] Xavier Bonnet [3] Francois Lavaste [1 2]

[1]LBM/Institut de Biomécanique Humaine Georges Charpak, Arts et Metiers ParisTech, Paris, [2]CERAH, INI, Woippy, [3]R and D Department, Proteor, Dijon, France

Introduction and Objectives: The role of lower limb joints during locomotion has classically been addressed by inverse dynamic calculation of the lower limb joints powers. This approach, focused on the function of each joint, fails in synthetizing the overall efficiency of the gait pattern. Indeed, the action of lower limb joints can be opposite, for instance, during the push off phase of gait when the ankle is generating power while knee and hip are absorbing [1]. As an alternative, the individual limb method (ILM) proposed by Kuo et al. allows a direct and simple quantification of the global mechanical work needed during gait [1]. Previous work compared the total mechanical work performed by each limb computed from both methods for able-bodied walking at different velocity on level ground [2]. Growing differences were identified during the collision period when the walking velocity increases.

When going down (stair or slope), potential energy must be dissipated. Even if previous works have addressed the quantification of joint powers independently in each condition, no study has sought to compare how negative work is made to absorb this energy according to the walking condition.

The aim of the present paper is to calculate the mechanical work performed by able-bodied subjects during the stance phase when walking downslope and downstairs using both ILM and inverse dynamics method (ID).

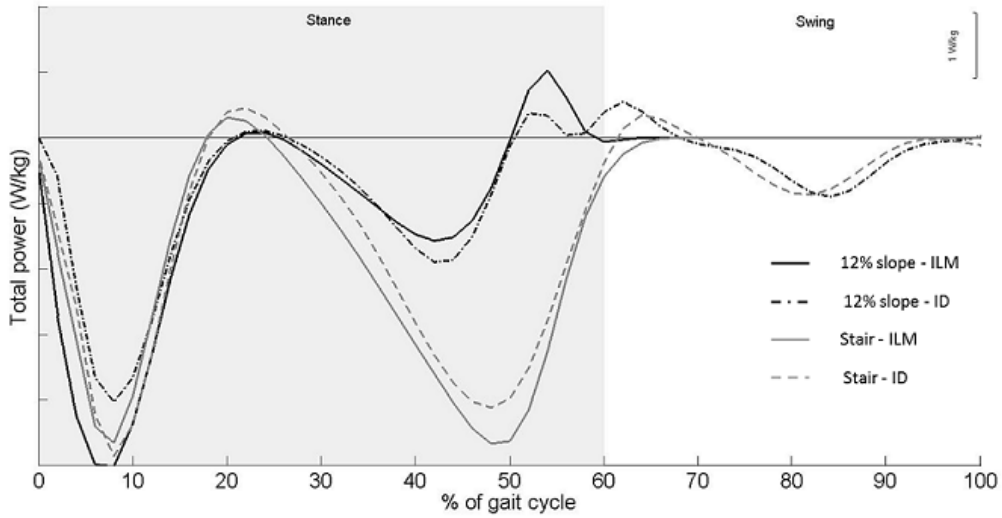
Methods: Thirteen asymptomatic subjects participated in the study (average age: 39.08 (±16.14) years). The protocol was approved by the local ethics committee. Data collection included a whole body motion capture with a Vicon system and force plates measurements during walking in three conditions: level ground, slopes (5% and 12% inclined) and stair (4 steps). Data processing consisted in calculating the center of gravity of the body and lower limb joints powers using the modeling described in [3] as well as the mechanical power by the ILM [1]. This second method intrinsically separates the contribution of each lower limb. Mechanical work was then computed by integration of the mechanical power provided both by the ILM and the sum of joint powers from ID to evaluate the dissipated energy during the stance phase.

Results: For one limb, the negative mechanical work obtained by ID underestimates the negative mechanical work obtained by the ILM (Figure 1, Table 1); this is particularly emphasized for the slope descent. Inverse dynamics consider segments as rigid bodies, which suggests that the remaining amount of work could be performed by soft tissue [2]. Another bias of the method is to limit the calculation to lower limb contributions. In slope, in particular, it could be useful to take into account the powers of upper body joints.

More than one third of the negative work is provided by the ankle during stair descent, which is consistent with the specific role of the ankle at strike. To ensure sufficient energy absorption, forefoot contact is required and results in increased mobility of the ankle. Depending on the stiffness of the ankle, this pattern will not be always be possible and the energy absorption would have to be made differently. The knee contributes to more than the half of the negative work performed in stairs as well as in slopes. The quantification of this negative energy can have implication in the design and the setting

of microprocessor-controlled prosthetic knee, which are able to mimic this behaviour by dissipating energy through a hydraulic system. These kind of knees must be fine tuned to avoid compensatory motion, which can have deleterious effect on residual and contralateral joints.

Figure:



Caption: Figure 1: Total mechanical power of one lower limb over the gait cycle for stair and 12% slope descent calculated from individual limb method (ILM) and inverse dynamics method (ID).

Conclusion: The original results presented here gives reference data of mechanical power performed during stair and slope descent. They could have interesting prospects in prosthetic knee and ankle design and should be completed by a temporal analysis of the contribution of the different joints to the mechanical power absorption, which would be essential for the correct adaptation and coordination between different walking conditions.

Table:

Conditions	Negative mechanical work (J/kg)		Contribution of each joint (% of total negative mechanical work from ILM)		
	ILM	ID	Ankle	Knee	Hip
Stair descent	-1.62 (0.08)	-1.47 (0.13)	37% (9%)	59% (8%)	1% (0.5%)
12% slope descent	-0.92 (0.15)	-0.65 (0.13)	27% (7%)	51% (17%)	18% (5%)

Caption: Table 1: Average (SD) negative mechanical work over the entire stance phase for one limb given by each method (ILM and ID) and percentage of the total negative mechanical work provided by each joint of the lower limb.

HIGHER FREQUENCY CHARACTERISTICS OF INITIAL LOADING DURING DROP LANDINGS CAN BE MASKED BY SOFT TISSUE VIBRATION ARTEFACT

Mark J. Lake [1,*] Rachel Gardener [1]

[1]Research Institute for Sport and Exercise Science, Liverpool John Moores University, Liverpool, United Kingdom

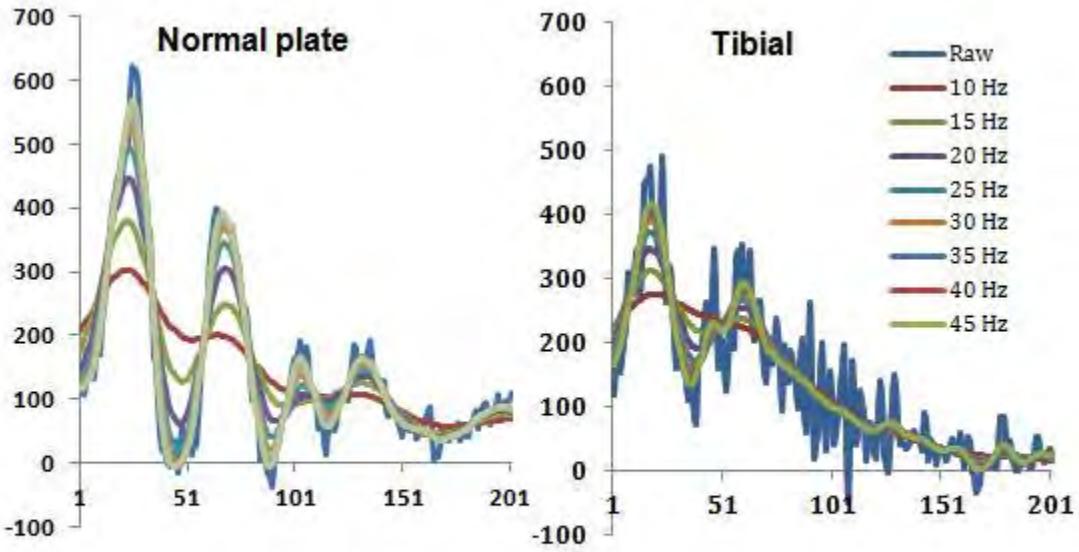
Introduction and Objectives: There is a need to improve biomechanical techniques that attempt to measure lower limb loading and movement profiles during tasks, such as drop jumping, that are used to screen for the risk of knee ligament injury [1]. Injury risk factors have focused on the initial ground contact phase of landing and turning movements [e.g. 2], but during this period there are oscillations of the lower limb soft tissues which can distort the biomechanical data. Low-pass filtering (e.g. 10-15Hz) of lower limb kinematics during drop landings removes some of this oscillatory behavior but it is not known whether high frequency signal characteristics (>15Hz) of joint movements and loading are also removed in the process. This study examined initial lower limb loading variables during drop landings with shank motion captured using markers on two skin-mounted plates; one over soft tissue (calf muscles) and the other over bone only (tibia). We investigated the influence of plate/soft tissue vibration and data filtering on loading variables including those associated with knee ligament injury risk (early peak knee abduction moments).

Methods: Twelve young male and female subjects performed two sets of ten controlled, single leg drop (40 cm) landings onto a force platform. In a mixed order of presentation, one session used a standard shank cluster (normal) of markers on a curved plate tightly mounted over the lateral calf (mass = 34.3 g), while the other session utilized a lighter, individually moulded plate (tibial) (mean mass = 17.4 ± 2.4 g) tightly fitted over the anterio-medial surface of the distal part of the tibia [3]. To capture possible high-frequency motion characteristics, the kinematics were sampled at 1000Hz using a six-camera opto-electronic system (Oqus 300, Qualisys, Sweden). A range of low-pass cut-off frequencies (10-45Hz) were initially used to estimate the signal frequencies present. Two-way ANOVA's were used to explore the relative importance of marker plate location and filter cut-off (15Hz or 35Hz) on loading variables during early ground contact such as peaks in angular velocities and internal knee joint moments ($p<.05$).

Results: Landing conditions (touchdown foot velocity) and initial loading (vertical ground reaction force (vGRF) peak) were not significantly different between the two sets of landings. This suggested that a direct comparison between the biomechanical data of the two shank marker plate mountings was possible.

For both plate conditions motion of the shank had signal content up to approximately 35Hz with the normal plate providing much larger and extended oscillatory behavior (see figure 1.). Due to the soft tissue vibration, the peak shank flexion velocities for the normal plate were 7-19% larger than the corresponding peak values when using the tibial plate. The tibial plate typically produced data that peaked earlier with a more damped oscillation (see figure 1). For both plates, extensor and abduction knee joint moment peaks were substantially increased using the 35Hz filter by 18% and 47%, respectively. The normal plate significantly increased knee extensor moments and tended to increase abduction moments for both filtering approaches.

Figure:



Caption: Figure 1: Shank angular flexion velocity (deg./sec) for the first 200ms

Conclusion: The substantial oscillations observed with the normal soft tissue plate had frequencies between 15Hz and 35Hz which corresponds to the range of vibration frequencies of the triceps surae muscle group after landing [e.g. 4]. Therefore, it can be reasonably assumed that soft tissue vibration was the main reason for increased values for peak segmental transients and knee joint moments during the early landing phase compared to the same data using the tibial plate. The tibial plate, which was minimally influenced by soft tissue movement, clearly demonstrated significant high frequency signal components above 15 Hz and up to 45Hz in some cases. These higher frequencies (masked by soft tissue vibration using the normal plate) agree closely with the frequency content of the vGRF during landing in this study and tibial acceleration measurements during running using bone pins [5]. The findings suggest that, unless the influence of soft tissue vibrations during initial landing can be minimised and higher frequency motion characteristics are retained in the data, injury risk factor variables determined during this phase should be treated with caution.

AGE AND GENDER INFLUENCE BICYCLE (DIS)MOUNTING KINEMATICS

Rosemary Dubbeldam [1,*] Chris Baten [1 2] Paul Straathoff [3] Hans Rietman [1 3] Jaap Buurke [1 2]

[1]Roessingh Research and Development, [2]Faculty of Electrical Engineering, Mathematics and Computer Science , Department of Biomedical Signals and Systems, [3]Faculty of Engineering Technology, Department of Biomechanical Engineering, University of Twente, Enschede, Netherlands

Introduction and Objectives: In the Netherlands, senior citizens continue to ride their bicycles well into old age. However, elderly cyclists have a high risk of being involved in a single-cycling accident, a cycling accident where no other party is directly involved: About 12000 elderly cyclists require medical attention each year. Most of these accidents occur at low cycling velocities and 20% occur during (dis)mounting the bicycle. Knowledge of bicycle and cyclist kinematics during (dis)mounting may provide insight in fall mechanisms. So far, accident analysis studies did not distinguish between mounting and dismounting a bicycle and no studies reported on corresponding bicycle or cyclist kinematics. This study aims to analyse bicycle and cyclist (dis)mounting kinematics and relate these findings to age, gender and fall-history.
Methods: Cycle measurements were performed outdoors. Fourteen young (18-40 years) and 33 elderly (65-82 years) cyclists were asked to get on the test-bicycle, cycle normally for about 400 m stop and wait, continue cycling for 400 m and get off the bicycle at a certain point (Fig. 1). Of the elderly cyclists, 15 had reported a fall with their bicycle in the last year. Bicycle and cyclist motions were recorded with 10 Inertial Measurement Units (IMU's). FUSION software (LABVIEW) was used to assess kinematic parameters during the (dis-)mounting phase. The mounting phase was defined from the moment the first foot was lifted from the floor till cyclic leg motion occurred, as was observed by plotting the left and right thigh angular velocity. Vice-versa defined the dismounting phase. The maximum angle, angular velocity and angular acceleration were calculated for the bicycle roll (around longitudinal axis), bicycle sway (around vertical axis), bicycle steer, cyclist left and right thigh (around transverse axis) and cyclist sternum roll (around longitudinal axis). The cycling velocity was calculated by integrating the longitudinal acceleration from the IMU accelerometer signal on the bicycle frame. By means of a linear regression model, the relationships between kinematic parameters and age, gender and fall-history were studied.
Results: All cyclists reached a cycling velocity of at least 5 km/h by the end of the mounting phase. Elderly cyclists tended to reach 5 km/h around 50% of the mounting phase while younger cyclists reached this velocity around 90% of the mounting phase. The spreading of the kinematic parameters within the older and young group was large: many older cyclists performed similar to the young cyclists. However, significant group differences were observed and significant relationships between age, gender and fall-history and cycling kinematics were assessed in the linear regression analysis. During mounting, older cyclists have 60% higher thigh angular accelerations compared to the younger cyclists (2907 vs. 1816 deg/s^2). Female cyclists have 40% higher thigh angular accelerations compared to male cyclists. Furthermore, older cyclists demonstrated 20% higher bicycle sway angular accelerations, and females demonstrated lower steer angular velocities. The older cyclists with a fall-history demonstrated 25% higher sternum angular velocities compared to older cyclists without a fall history.

Older cyclists needed about 1 second more time to dismount their bicycle compared to young cyclists (4.6 vs. 3.6 sec). During dismounting, female cyclists have 50% higher thigh accelerations compared to male cyclists, but the female cyclists showed 40% lower bicycle yaw angular accelerations compared to male cyclists. The older cyclists with a fall-history demonstrated 30% lower maximum steer angles compared to older cyclists without a fall history.
During the waiting task, these differences in dismounting thigh acceleration increase to 75% for elderly and 90% for females compared to young and male cyclists respectively.

Figure:

Caption: Figure 1. Older cyclist mounting test bicycle

Conclusion: Differences in bicycle and cyclists kinematics were observed between young and older cyclists but also between males and females. The higher thigh accelerations observed for older and female cyclists may be related to their higher risk of being injured during (dis)mounting compared to young and male cyclists which have been reported in accident analysis studies.

PERFORMANCE OPTIMIZATION AND ERROR ESTIMATION OF AN OPTICAL MOTION CAPTURE SETUP FOR MEASURING SMALL DISPLACEMENTS ON THE FOOT WITHIN A FULL BODY MEASUREMENT VOLUME

Patric Eichelberger [1,*] Nicole Lutz [1,2] Yvonne Brülhart [1] Leonore Joanna Bösch [1] Fabian Krause [3] Heiner Baur [1]

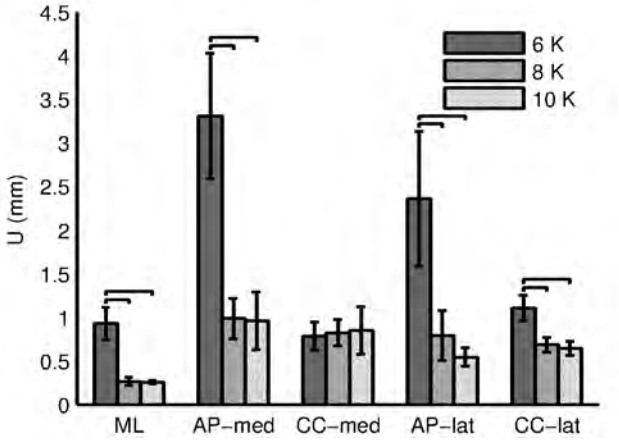
[1]Bern University of Applied Sciences, Health, Discipline Physiotherapy, Bern, Switzerland, [2]University of Salzburg, Department of Sport Sciences & Kinesiology, Salzburg, Austria, [3]University of Bern, Inselspital, Department of Orthopaedic Surgery, Bern, Switzerland

Introduction and Objectives: Foot function can clinically be assessed by the navicular drop [1], a compound measure for the talonavicular joint motion that is often taken in static conditions. It has been found that other factors than static foot posture play a role in dynamic foot mobility [2]. Therefore, a new foot model for dynamic navicular drop measurement using optical 3D motion capturing has recently been developed. The aim of this study was the optimization of an existing full body measurement setup in order to allow simultaneous foot assessments and the estimation of accompanying instrumental errors to have a quantitative landmark in the optimization process.

Methods: The examined setups consisted of six, eight or ten symmetrically arranged cameras (Vicon Bonita, 200 Hz, Vicon Motion Systems, Ltd., Oxford, UK) resulting in a measurement volume of (5.5 · 1.2 · 2) m^3 in all cases. Spatial region of interest for performance analysis (ROI_{PA}) was given by two force plates centrally placed in the measurement volume. Temporal ROI_{PA} was defined as the interval between left initial contact and left toe off event. For the reference object two spherical markers with a diameter of (16.14 ± 0.05) mm and an inter-center distance of (95.53 ± 0.02) mm were placed at both ends of a rigid rod. The reference object was either placed with its longitudinal axis in medial-lateral (ML), anterior-posterior (AP) or cranial-caudal (CC) direction on the left foot. AP and CC configurations were measured with reference object mounting on the foot's lateral and medial side respectively. Ten trials per reference object mounting position were captured and standard deviations (SD) from the measured marker distances calculated. The average SD from ten trials was defined as precision, the relevant performance quantity under consideration of displacement measurements. Measurement uncertainty served as outcome and was calculated as U = 2·SD (95.5% CI). Following checking for normal distribution (Kolmogorov-Smirnov), outcome differences between examined camera setups were analyzed with paired t-tests.

Results: Measurement uncertainties for the initial 6-camera setup ranged from 0.78 mm to 3.31 mm. This interval decreased for the 8-camera setup (0.26 mm to 0.99 mm) and was stable when further switching to ten cameras (0.26 mm to 0.96 mm). The relative change in measurement uncertainty ranged from +9% to a reduction of -77% for the final 10-camera setup compared to the 6-camera setup. The changes of the CC-med configuration never showed statistical significance ($p < 0.05$). All other changes were significant when switching from six to eight and from six to ten cameras. Switching from eight to ten cameras never turned out to be significant.

Figure:



Caption: Measurement uncertainty with error bars (+/- SD) for all measured conditions with horizontal brackets indicating significant differences ($p<0.05$)

Conclusion: Adding two or four cameras to the initial 6-camera setup didn't influence the uncertainty in the CC-med configuration, whilst all other configurations profited from an uncertainty decrease. In the 6-camera setup, the uncertainty was more inhomogeneous for the different configurations compared to the 8-camera and 10-camera setup. Comparing six and ten cameras, ML, AP-med and AP-lat showed with (-70 to -77)% similar uncertainty improvements, whereas the uncertainty in CC-lat only decreased by 42%. In the final 10-camera setup, the smallest uncertainties were observed for ML (0.26 mm) and the highest for AP-med (0.96 mm). The estimations are spatially and temporary limited to the force plates when the foot is in stance phase. The use of ten cameras led to an optimized system performance for displacement measurements on the foot within a full body measurement volume. Relating the findings to navicular drop values of normal feet (about 8 mm), relative instrumental errors can roughly be estimated to lie between 3% and 12%, which is considered as an acceptable error range. In accordance to the requirement to keep the full body measurement volume for routine gait analysis unchanged, it is expected that the maximum measurement performance has been reached. As already reported by other authors, the influence of the laboratory setup on measurement performance was clearly demonstrated and the importance of systematic instrumental error assessment before clinical measurements is underlined.

UNILATERAL FOOT PRONATION INCREASES IPSILATERAL SHANK INTERNAL ROTATION AND CONTRALATERAL KNEE ADDUCTION MOMENT OF INDIVIDUALS WITH KNEE OSTEOARTHRITIS DURING THE STANCE PHASE OF GAIT

Renan Alves Resende [1] Kevin Deluzio [2] Renata Noce Kirkwood [3] Renato Guilherme Trede Filho [1,*] Angélica de Fátima Silva [1] Mayra Fernandes de Souza Orlandi [1] Sérgio Teixeira Fonseca [4]

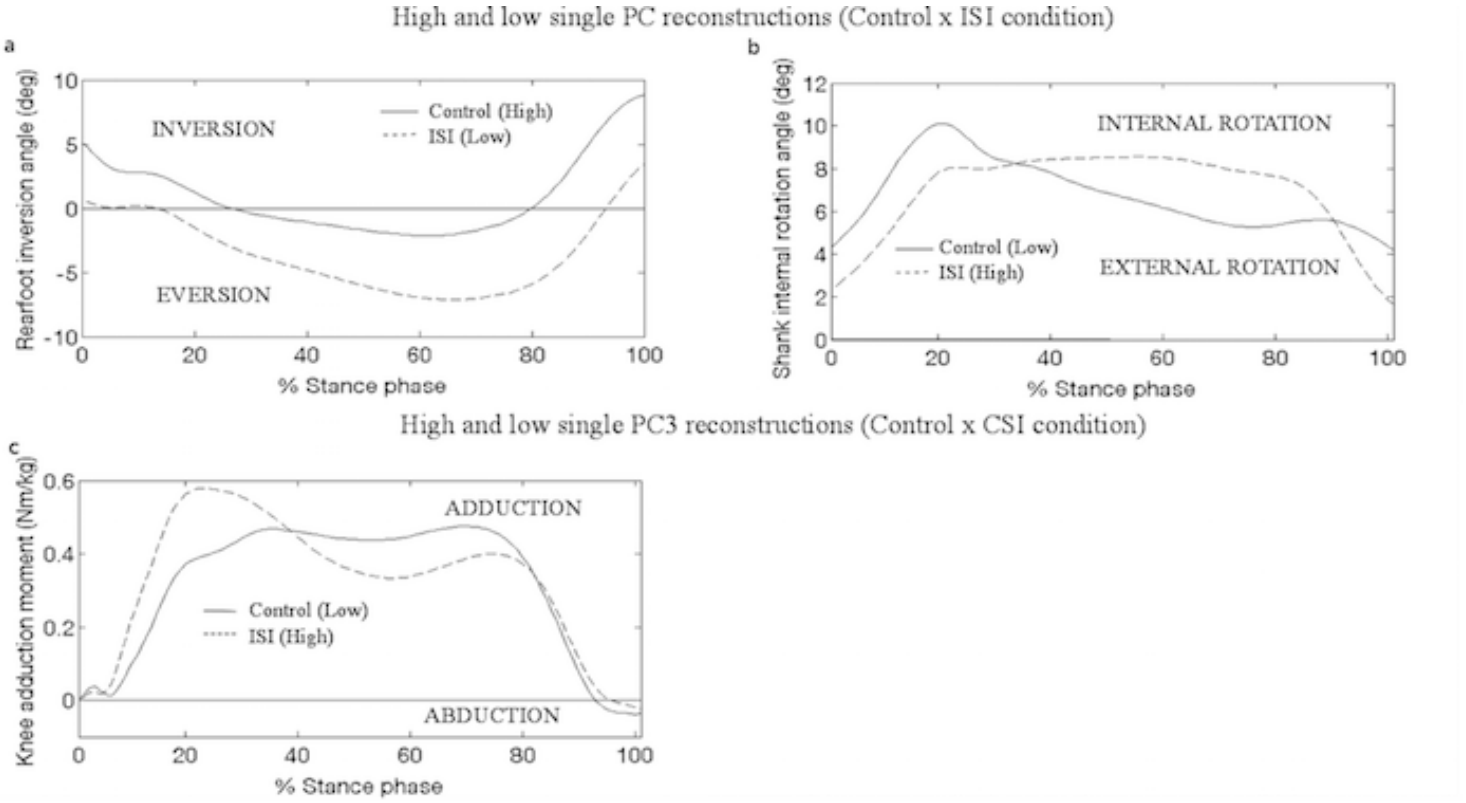
[1] Physical Therapy, Universidade Federal dos Vales do Jequitinhonha e Mucuri, Diamantina, Brazil, [2] Mechanical and Materials Engineering, Queen's University , Kingston, [3] Kinesiology and Physical Education, Wilfrid Laurier University, Waterloo, Canada, [4] Physical Therapy, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil

Introduction and Objectives: Increased shank internal rotation[1] and knee adduction moment[2] during the stance phase of gait increase knee osteoarthritis (OA) progression. In healthy young individuals, unilateral foot pronation increases shank internal rotation of the ipsilateral lower limb and knee adduction moment of the contralateral lower limb[3]. In addition, individuals with knee OA demonstrate increased foot pronation[4]. Therefore, this study investigated the effects of unilateral foot pronation on the biomechanics of lower limbs during the stance phase of gait of individuals with knee OA.

Methods: Kinematic and kinetic data of 20 participants (13 females) with knee OA on one or both knees were collected while they walked wearing flat sandals and laterally wedged sandals (10º medially inclined on the forefoot). Three conditions were investigated: (1) control condition - the participant walked wearing flat sandals; (2) ipsilateral side inclined condition – wedged sandal on the knee OA side and a flat sandal on the contralateral side; 3) contralateral side inclined condition - flat sandal on the knee OA side and wedged sandal on the contralateral side. The right lower limb biomechanics were analyzed for both conditions. Principal Component Analysis was used to compare differences between conditions on rearfoot eversion, shank internal rotation and knee adduction moment. The scores of the principal components retained for analysis were compared between conditions using one-way repeated measures analysis of variance (ANOVA) with pre-planned contrasts between the control condition and the two other conditions.

Results: Participants had an average age, mass and height of 67 years (SD 8.3), 87.9 kg (SD 18) and 170 cm (SD 8), respectively. Table 1 presents the results of this study. Gait waveforms represented by high (+ 1 standard deviation) and low (- 1 standard deviation) principal component scores for each significant principal component are shown in Figure 1.

Figure:



Caption: Control, ipsilateral side inclined and contralateral side inclined conditions differences demonstrated by the ANOVA. Shown in the figures are the waveforms that represent high and low principal component (PC) scores for the indicated measure and PC. In all cases, the waveform that represents the PC score (i.e. high or low PC score) that characterizes the ipsilateral side inclined (ISI) or the contralateral side inclined (CSI) conditions is shown as a dashed line; the solid line is the waveform that represents the control condition PC score. The rearfoot inversion angle PC1 (a); shank internal rotation angle PC2 (b); knee adduction moment PC3 (c).

Conclusion: The coupling mechanism between foot pronation and shank internal rotation also occurs in individuals with knee OA. Increased shank internal rotation accelerates knee OA progression, which suggests that these patients could benefit from proper evaluation and treatment of increased unilateral foot pronation. The increased knee adduction moment on the contralateral lower limb may be a compensation for the smaller knee adduction moment caused by lateral wedges on the ipsilateral lower limb[5]. Therefore, foot motion should be evaluated in individuals with knee OA and the use of lateral wedges to reduce knee adduction moment on the ipsilateral lower limb should consider the possible deleterious effects on the contralateral lower limb.

Table:

Measure	PC	Variance explained (%)	*p-value*	Effect size	Interpretation of differences between conditions
Rearfoot inversion angle	1	78.9	<0.001	0.79	ISI condition had greater rearfoot eversion throughout stance.
Shank internal rotation angle	2	3.6	<0.001	0.70	ISI condition had greater shank internal rotation during late stance.
Knee adduction moment	3	8.0	0.002	0.63	CSI condition had greater knee adduction moment in early stance.

Caption: Principal components (PCs) that demonstrated differences between conditions. Percentage of variance explained and an interpretation of each PC are also provided. ISI: ipsilateral side inclined; CSI: contralateral side inclined.

THE RELATION OF LEG STIFFNESS ON PERFORMANCE IN CUTTING MANEUVERS

Sina David [1,*] Igor Komnik [1] Johannes Funken [1] Ralf Müller [1] Thomas Dupré [2] Wolfgang Potthast [1]

[1]Institute of Biomechanics and Orthopaedics, German Sport University Cologne, Cologne, [2]Karlsruhe Institute for Technology, Institut of Sports and Sports Science, Karlsruhe, Germany

Introduction and Objectives: Leg stiffness is an important component of fast sprinting or good jumping results.[1, 2] Until now, it is unclear if leg stiffness also influences the performance in fast running and sprinting including directional changes. The spring mass model is usually used to determine the absorption and generation of mechanical energy during the stance phases of walking, running and jumping. By investigating cutting manoeuvres with 90° and 180° turning angle, it is hypothesized, that higher leg stiffness also decreases the duration of the manoeuvre. Therefore the purpose of this study was to investigate the relation between leg stiffness and the performance during 90° and 180° cutting manoeuvers.

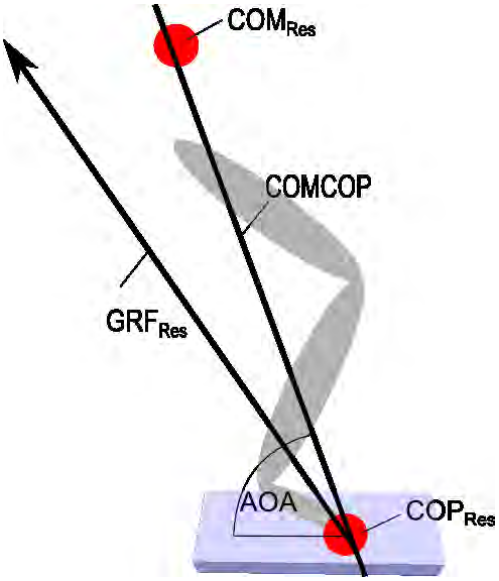
Methods: Eight healthy elite soccer players (Height: 1.79 ± 0.06m, weight: 79.5 ± 6.7 kg, age: 23 ± 3.3 years) wearing the same shoe (Under Armour Blur Carbon IV) were investigated with a 12 camera Vicon motion capturing system (200 Hz), fullbody marker set and two Kistler force plates (1000 Hz) which were covered by natural turf. They had to perform five valid trials for each, 90° and 180° cutting manoeuvres and four meter acceleration runs each at maximal effort. The approach distance of three meters and was covered by artificial turf.

Data was calculated by an Anybody AMS lower body model with 3 degrees of freedom (DOF) in the hip and knee joint respectively. Time histories of ground reaction force (GRF), center of mass (COM) and center of pressure (COP) were normalized to the contact time of the outside leg in 90° and 180° cutting manoeuvres. In sprinting, stance time of the contact leg was used for normalization. The resulting GRF (GRF_{RES}), COM (COM_{RES}) and COP (COP_{RES}) were calculated, COM_{RES} and COP_{RES} were used to define a vector between COM_{Res} and COP_{Res} (COMCOP). The GRF_{RES} was then projected on COMCOP. The total displacement of COM_{RES} in direction of COMCOP (COM_{COMCOP}) during contact time and the maximum GRF projected on COMCOP ($MaxGRF_{COMCOP}$) were calculated. The leg stiffness is the $MaxGRF_{COMCOP}$ divided by the maximum COM_{COMCOP} displacement. Further parameters are the maximum force produced to change the COM direction (Max_{DC}) which is $\sqrt{(GRF_{x^2}+GRF_{z^2})}$ for the acceleration runs, $\sqrt{(GRF_{x^2}+ GRF_{y^2})}$ for the 90° cuts and for the 180° cuts GRF_x.

Results: No correlation between leg Stiffness and any other parameter was found for acceleration runs. There are only moderate correlations between the force-dependent and the velocity-dependent parameters (p=.001 to .018; r=.388 to .543). In contrast, there is a high correlation between leg stiffness and $MaxGRF_{COMCOP}$ (p<.001; r= .829) and Max_{DC} (p< .001; r=.760). Moderate correlations between leg stiffness and ground contact time (GCT) (p<.001; r=-.671) and runtime (p<.001; r=-.554). Ground contact time decreases with higher $MaxGRF_{COMCOP}$ (p<.001, r=-.717). A shorter GCT is related to shorter runtimes (p<.001; r=.836) and higher MinCOMVel (p<.001; r=-.818).

For 180° cuts leg stiffness is moderate related to GCT (p=.007; r=-.442) and the velocity-dependent parameters (p=.006 to 0.008; r=.435 to .446). Runtime increases with a higher Max_{DC} (p=.001; r=.513)(Table 1).

Figure:



Caption: Figure 1: Schematic illustration of parameters

Conclusion: While there is a high correlation for leg stiffness and runtime in sprinting, there is no detectable relationship of leg stiffness within acceleration sprints. This may be caused by a larger AOA, and therefore higher joint angles compared to sprinting. During 90° cutting manoeuvres, leg stiffness becomes more influential, due to the necessity to change the body's orientation within a small time interval. This is also supported by the correlation of Max_{DC} and runtime, where a higher Max_{DC} leads to a shorter runtime. Contrary to the expectations, there are only moderate to small correlations within the 180° cutting values. This may be caused by a higher complexity of the movement (e.g. gaining back orientation, balance, joint stability etc.) and the role of the inner leg. Other influences on 180° direction changes like the role of countermovement in terms of energy storage[3] are also discussed. In order to further understand the movement strategies encountered in cutting manoeuvres, the role of joint stability and behaviour of muscles in the lower extremity should be investigated.

Table:

	Acceleration run	90° turning leg	180° turning leg
Leg Stiffness (kN/m)	6.55 ± 2.80	4.66 ± 1.23	8.36 ± 2.55
Max GRF_{COMCOP} (N)	1979 ± 198.77	1779.56 ± 226.73	1698.88 ± 166.56
Max_{DC} (N)	1971.49 ± 198.62	1050.25 ± 140.59	1074.68 ± 113.37
MaxCOMVel PRE (m/s)	6.57 ± 0.45	3.47 ± 0.40	4.34 ± 0.50
MaxCOMVel POST (m/s)	7.09 ± 0.44	4.27 ± 0.43	3.99 ± 0.50
MinCOMVel (m/s)	5.51 ± 0.34	1.82 ± 0.22	0.18 ± 0.97
GCT (s)	0.13 ± 0.01	0.38 ± 0.06	0.58 ± 0.17

RELATION BETWEEN PREOPERATIVELY DETERMINED STATIC LEG AXIS AND DYNAMIC KNEE ADDUCTION MOMENTS IN WALKING AND STAIR CLIMBING

Johannes Funken [1,*] Kai Heinrich [1] Ralf Müller [1] Michael Knye [1] Rüdiger Schmidt-Wiethoff [2] Wolfgang Potthast [1 2]

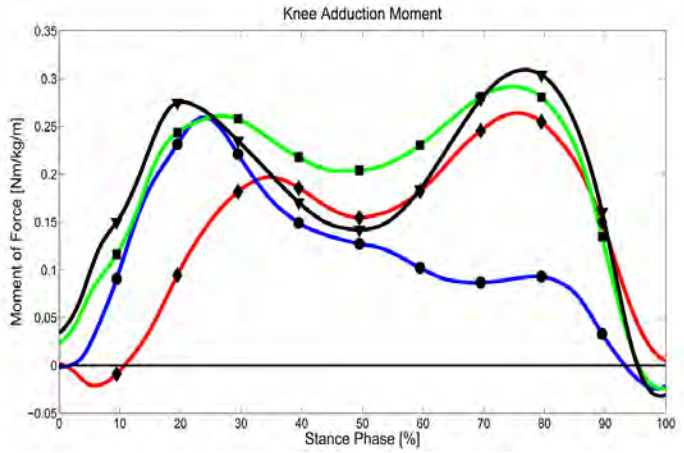
[1]Institute of Biomechanics and Orthopaedics, German Sport University Cologne, Cologne, [2]ARCUS Clinics, Pforzheim, Germany

Introduction and Objectives: Osteoarthritis is considered to be the most common joint disease in adult human. The varus moment of the knee (knee adduction moment, KAM) is a surrogate indicator for the loading of the medial knee compartment and an accelerated progression of gonarthritis [1,2]. High tibial osteotomy (HTO) is a surgical procedure to reduce the KAM to a normal level [3] by realigning the leg axis and shifting the loading from the medial towards the lateral compartment. Over the last decades surgical planning was based on x-rays in a static upright position and virtually shifting the mechanical leg axis through the so called Fujisawa point [4]. Durable results are strongly related to the preoperative KAM [5]. As a consequence, a high correlation between dynamic KAM and static leg axis (SLA) is essential for a positive long-term outcome of a HTO. In the international literature only correlations between SLA and KAM in very slow walking or with self-selected/unknown speed were found (r: 0.65 – 0.79) [2,6,7]. Activities of daily living (AODL), however, cover a wide range of different movements. The aim of this study was to identify the correlation between preoperative KAM and the SLA in four AODL (slow/fast walking and stair ascending/descending). In the long run this will help to optimize surgical methods and ensure a better and more stable clinical result.

Methods: Ten patients (body mass: 84.6 ± 14.0 kg; body height: 1.79 ± 0.06 m) with upcoming HTO were asked to participate in a gait analysis including slow walking (WS) and fast walking (WF) (1.2 and 1.7 m/s), stair descending (SDown) and stair ascending (SUp). Kinematic data were captured using a 3D-infrared-camera system (Vicon Nexus, 100 Hz). Kinetic data in the walking conditions were captured with two force plates (Kistler, 1000 Hz). For stair climbing a custom made staircase with five steps was used. The second and the third step were instrumented with force plates. Inverse dynamic calculations for the lower limbs were executed using a biomechanical 3D multibody model (alaska, Dynamicus). Static leg axis was calculated from x-rays in a static erect position. Peak knee joint adduction moments were then normalized to body weight and body height and correlated (Spearman) to static leg axis. Additionally ground contact time was calculated as the time between Touchdown and TakeOff.

Results: Knee adduction moment curves show different chracteristics for each condition (Figure). However, mean peak adduction moments did not differ significantly from each other (Table). Mean varus angle was found to be 8.25 ± 2.35°. In fast walking more than half of the variance of the peak knee adduction moment cannot be explained by the static leg axis, which is the main parameter for HTO planning. In stair climbing the explanation of variance is very divergent between ascending and descending. Stair descending does not differ in ground contact time to slow walking and shows a similarly high explanation of variance. Stair ascending in contrast has the longest stance phase but only 34% of the KAM can be explained by the static leg axis. All correlations were significant ($p<0.05$). All Ground contact times were significantly different to each other ($p<0.01$), except WS to SDown.

Figure:



Caption: Green: slow walking, Black: fast walking, Red: stair ascending, Blue: stair descending

Conclusion: Two thirds of the peak KAM in an activity of daily living cannot be explained by the parameter HTO planning is fundamentally based on. The findings of this study indicate that preoperative planning based on static images might not be comprehensive and does not consider a wide range of daily activities. More movements of daily life should be analyzed with regards to the topic to underline the findings of this study. Future development of surgical planning might include preoperative gait analysis combined with model-based simulations to make HTO more individual and generate a more reliable long-term outcome.

Table:

	Peak Knee Adduction Moment [Nm/kg/m]	R^2 (SLA/ Peak KAM)	Stance time [s]
Slow walking	0.30 ± 0.08	0.81	0.71 ± 0.03 [a,b]
Fast walking	0.32 ± 0.09	0.45	0.59 ± 0.02 [a,c,d]
Stair ascending	0.29 ± 0.11	0.34	0.88 ± 0.10 [b,c,e]
Stair descending	0.28 ± 0.14	0.72	0.77 ± 0.11 [d,e]

Caption: Lower cases indicate a significant difference ($p<0.05$) between two conditions.

BIOMECHANICAL EVALUATION OF A MICROPROCESSOR CONTROLLED PROSTHETIC KNEE MECHANISM

Anthony Crimin [1,*] Anthony McGarry [1] Stephan Solomonidis [1]

[1]Bioengineering, University of Strathclyde, Glasgow, United Kingdom

Introduction and Objectives: Manufacturers of prosthetic components claim that transfemoral prostheses incorporating microprocessor controlled prosthetic knee joints (MCPK) facilitate a more natural gait and stability compared to non-microprocessor controlled knees (non-MCPK). Furthermore, it has also been suggested that the MCPK user may reduce their cognitive effort during ambulation (Hafner et al. 2007). However, limited biomechanical evidence exists to enhance the understanding of the difference between involuntary and voluntary control that the MCPK and non-MCPK may offer (Gerzeli et al. 2009).

The objective of this investigation was to determine whether a MCPK (Blatchford Orion), compared to a non-MCPK (Otto Bock 3R80), provided participants with enhanced swing phase response and stability during stance.

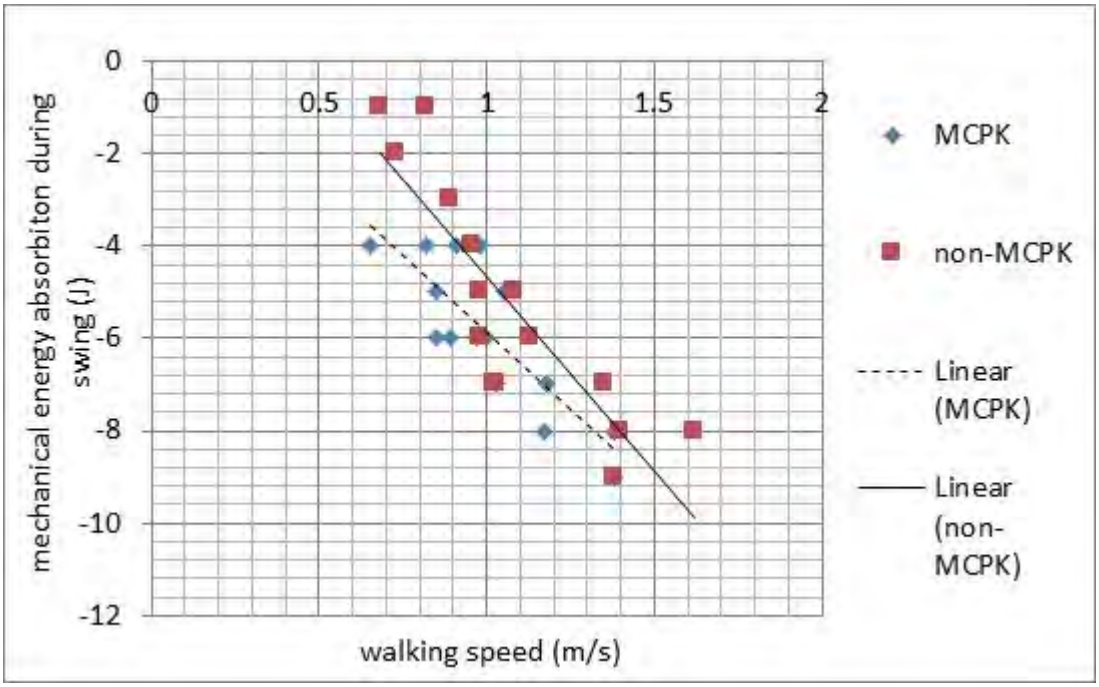
Methods: The Blatchfords Orion MCPK was compared in a crossover study with six trans-femoral prosthetic users ambulating with the Otto Bock non-MCPK. Participants were considered to be outdoor ambulators (four K3 and two K2) according the Medicare Functional Classification level (MFCL) (Hafner et al.2007).

The kinematics and kinetics of six trans-femoral prosthetic users were investigated during level ambulation; a seven degrees ramp ascent/descent and stair ascent/descent activities at their self-selected walking speed (SSWS). The knee swing response was evaluated through considering the magnitude of mechanical energy absorption. The assumption was made that the magnitude of the mechanical energy absorption is correlated with the magnitude of the knee damping. Hence, with this assumption it is therefore possible to evaluate the damping response indirectly as the SSWS varies when transgressing from level walking to ramp ascent.

Results: The results on initial contact during level walking and ramp activities indicated that the MCPK provides significant ($P<0.05$) additional knee stability when compared to the non-MCPK as the knee extension moment on initial contact was reduced during initial contact. This result was reasoned as the hip musculature extension moment was also significantly reduced for participant A, B and C during level ambulation on initial contact, indicating that when the participants used the MCPK they felt a reduced requirement to stabilise their knee. Additionally, in contrast to the non-MCPK the two K2 participants who displayed the most significant reductions did not use the handrail for support using the MCPK during ramp descent.

The mechanical energy absorbed by the knee during swing phase, and representative of the damping response illustrated that the MCPK damping response assisted the prosthetic users' natural cadence change. This result is illustrated by the respective correlation coefficient of $R=0.8$ and 0.9, of the mechanical energy absorbed around the non-MCPK and MCPK (figure 1). The linear correlation indicates that mechanical energy absorption, thus damping response is correlated with walking speed. Therefore, this results illustrate that the stance period measure utilised by the MCPK microprocessor enhances the swing phase response of the knee.

Figure:



Caption: Figure 1 The mechanical energy absorbed around the knee during level and ramp ambulation

Conclusion: During ambulation with the Orion knee, the user can directly influence the flexion and extension resistance experienced around the knee through controlling the toe load, as with the 3R80 knee. However, as the microprocessor control of the Orion knee determines the relative flexion and extension moment magnitude, this sensory information may be used to determine when the user is ready to move from stance to swing. This gives the user greater voluntary control over the Orion knee compared to the 3R80 knee as high knee resistance is maintained around the 3R80 knee when they transition from stance to swing. Hence, the stance stability of the Orion knee can be maintained until the user is ready to reduce their knee security. Finally, the results also indicate that the (K2) ambulators rather the unrestricted (K3) ambulators appeared to use this additional functionally offered by the MCPK.

AS-0413

THE INTER-DAY MEASUREMENT CONSISTENCY AND PRECISION OF HAMSTRING AND LEG MUSCULO-ARTICULAR STIFFNESS

Justin P. Waxman [1,*] Randy Schmitz [1] Sandra Shultz [1]

[1]Kinesiology, University of North Carolina at Greensboro, Greensboro, United States

Introduction and Objectives: Hamstring (K_{HAM}) and leg (K_{LEG}) musculo-articular stiffness are commonly examined for their relative contribution to athletic performance and injury risk. Because K_{HAM} and K_{LEG} are neuromechanical properties that can be modified through training, it is important to know the expected day-to-day variations that are inherent in these measures before proceeding with intervention strategies. Therefore, the objective was to examine the inter-day measurement consistency and precision of K_{HAM} and K_{LEG}.

Methods: K_{HAM} and K_{LEG} were assessed on 2 separate testing occasions, separated by 2-5 days, in 15 healthy college-aged individuals (6 male, 9 female; 21.5 ± 2.5 yrs, 1.7 ± 0.1 m, 69.3 ± 11.0 kg). Participants were recreationally active and free from lower-extremity injury. K_{HAM} was assessed via the free oscillation technique, whereby the leg is modeled as a single-degree-of-freedom mass-spring system and the damping effect imposed by the hamstring musculotendinous unit on oscillatory flexion/extension at the knee joint is quantified, following a brief manual perturbation. K_{LEG} was assessed via barefoot hopping on a force platform at a frequency of 2.2 Hz under 3 separate conditions (i.e. bilateral, left leg, right leg). Inter-day measurement consistency was determined using repeated-measures analysis of variance (ANOVA) and calculating intraclass correlation coefficients ($ICC_{2,k}$ model). Measurement precision was evaluated by computing the standard error of measurement (SEM) and 68% and 95% limits of agreement (68%LOA and 95%LOA, respectively).

Results: All results are presented in Table 1. K_{LEG} demonstrated good-to-excellent inter-day measurement consistency for all three hopping conditions ($ICC_{2,3}$ range: 0.87 to 0.94) whereas K_{HAM} demonstrated only moderate measurement consistency ($ICC_{2,5}$ = 0.71). Additionally, absolute measurement error (LOA) for K_{HAM} revealed a relatively large systematic bias (9.4% of test-retest mean value), with greater values observed on Day 2 (Figure 1). When comparing the 68% and 95% LOA to the dispersion of scores (i.e. ±1 SD and ±1.96 SD, respectively), unilateral K_{LEG} had the highest measurement precision (left = 45.8%, right = 40.9% of SD), followed by bilateral K_{LEG} (65.8% of SD) and K_{HAM} (83.1% of SD).

Figure:

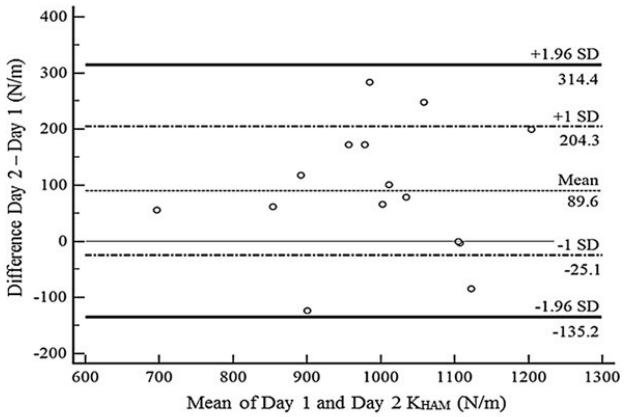

Figure 1. Bland-Altman plot showing the difference between values obtained on the first and second day of testing on the vertical axis, and the mean of the first and second day of testing on the horizontal axis, for each participant during K_{HAM} assessments. The thin dashed line represents the mean difference (bias) between testing days (Day 2–Day 1), while the thick dashed lines and solid lines represent the 68% and 95% limits of agreement, respectively. The mean difference is greater than zero, indicating systematic bias between the first and second day of testing.

Conclusion: The good-to-excellent inter-day measurement consistency observed for K_{LEG} indicates that K_{LEG} is a highly consistent measure when assessed during hopping at 2.2 Hz, and that K_{LEG} can be adequately assessed with little familiarization. In contrast, K_{HAM} demonstrated lower measurement consistency, and the systematic bias observed from the LOA analysis indicates the presence of a learning effect from Day 1 to Day 2. Thus, additional familiarization may be needed to obtain acceptable measurement consistency and precision when assessing K_{HAM}. Although K_{LEG} appears to be a highly consistent measure that can be adequately assessed with little familiarization, K_{HAM} displayed lower inter-day measurement consistency which was likely partially due to the presence of a learning effect (systematic error). As such, researchers interested in evaluating longitudinal changes in K_{HAM} should allow for adequate familiarization to the assessment procedures and include a control group. Additionally, researchers may find these results helpful for sample size estimation or when comparing day-to-day measurement consistency using alternative testing procedures.

Table:

	Day 1 m(SD)	Day 2 m(SD)	$ICC_{2,K}$	SEM	Bias	68% LOA	95% LOA
K_{LEG} (kN/m)							
Bilateral	37.2(8.1)	35.2(8.0)	0.87	2.9	-2.0	±5.3	±10.3
Left Leg	25.5(4.1)	25.1(4.2)	0.94	1.0	-0.4	±1.9	±3.2
Right Leg	25.7(4.2)	24.6(4.6)	0.94	1.1	-1.1	±1.8	±3.6
K_{HAM} (N/m)	949.0(134.1)	1038.6(141.8)	0.71	76.3	89.6	±114.7	±224.8

THE RELATIONSHIP BETWEEN PERFORMANCE ON A SINGLE-LEG SQUAT AND LEAP LANDING TASK: MOVING TOWARDS A NETBALL-SPECIFIC ACL INJURY RISK SCREENING METHOD

Aaron S. Fox [1,*] Jason Bonacci [1] Scott McLean [2] Michael Spittle [3] Natalie Saunders [1]

[1]School of Exercise and Nutrition Sciences, Deakin University, Melbourne, Australia, [2]Human Performance Innovation Laboratory, University of Michigan, Ann Arbor, United States, [3]College of Sport and Exercise Science, Victoria University, Melbourne, Australia

Introduction and Objectives: Screening methods that identify those at-risk of suffering an anterior cruciate ligament (ACL) injury are vital for the development of targeted ACL injury prevention strategies. The majority of ACL injury risk screening methods [1-3] utilise simplistic bilateral landing tasks, which have been shown to not adequately represent sport-specific movements [4,5]. The single-leg squat may be a useful screening movement for netball as it closely resembles the lower limb position of a leap landing; a high-risk task within the sport [6]. The purpose of this study was to determine the relationship between performance of a single-limb squat and a netball leap landing, in order to examine the utility of a single-limb squat as a netball-specific ACL injury risk screening method.

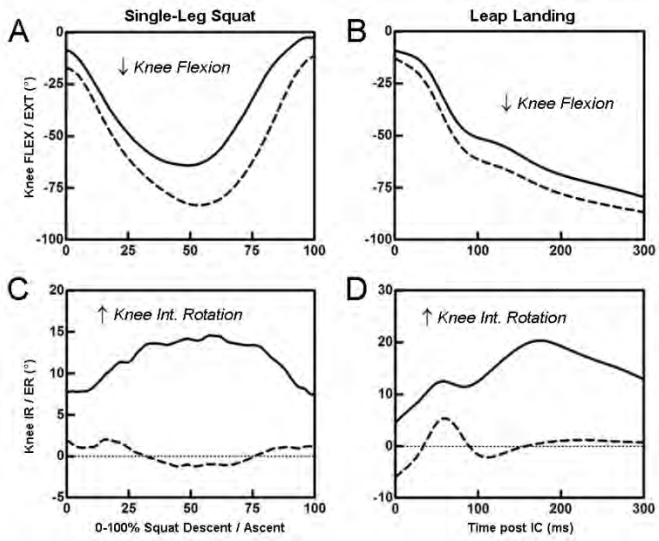
Methods: Twenty-five female netball players (23.7 ± 3.3 years; 170.9 ± 8.0 cm; 68.2 ± 9.0 kg) performed a single-leg squat task and ten trials of a netball leap landing task. The squat required the performance of one repetition on a single-limb. The leap landing involved a six-metre run-up, followed by a single-limb take-off and land on the contralateral limb while catching a pass. Three-dimensional hip and knee joint rotations and external joint moments were calculated from lower extremity kinematics and ground reaction force (GRF) data for both tasks. For the squat, data were extracted from the initiation of the squat descent to the end of the squat ascent. For the landing task, data were extracted from initial contact (IC) to 300 ms post IC. A vertical GRF threshold of 10N was used to detect IC.

Principal patterns (PP) in biomechanical data from both tasks were identified by submitting extracted joint rotation and moment waveform data to principal component analysis (PCA). Patterns were extracted for the variables of hip flexion/extension ($H_{FLEX/EXT}$), adduction/abduction ($H_{ADD/ABD}$), and internal/external rotation ($H_{IR/ER}$); knee flexion/extension ($K_{FLEX/EXT}$), adduction/abduction ($K_{ADD/ABD}$), and internal/external rotation ($K_{IR/ER}$); ankle dorsiflexion/plantarflexion ($A_{DF/PF}$), inversion/eversion ($A_{INV/EVE}$), and ankle internal/external rotation ($A_{IR/ER}$); and H_{FLEX}, H_{ADD}, H_{ER}, K_{FLEX}, K_{ABD}, K_{ER}, A_{DF}, A_{EVE}, and A_{ER} moments. Principal pattern scores (PP-Scores), which measure the degree to which the shape of the waveform corresponds to each PP [7], were computed and used for subsequent analyses. Pearson's correlation coefficients (r) were calculated to identify significant correlations ($p < 0.01$; $r > 0.60$) between squat and landing PP-Scores.

Results: Reduced peak K_{FLEX} and increased K_{IR} during the squat was indicative of reduced K_{FLEX} ($r = 0.62$) and increased KIR ($r = 0.95$), respectively, during landing. Figure 1 illustrates the relationship between K_{FLEX} and K_{IR} during the squatting and landing tasks. Larger squat K_{ADD} moment was also indicative of increases in K_{IR} during landing ($r = -0.82$). Increased H_{IR} during the squat was associated with greater landing H_{IR} ($r = 0.63$). Greater frontal and transverse plane knee motion during the squat were associated with greater landing frontal plane knee motion ($r = 0.74$) and peak K_{ABD} ($r = -0.63$), respectively. Greater transverse plane knee motion and A_{EVE} during the squat were indicative of increases in peak K_{ADD}

and K_{ABD} moments (r = -0.71 and 0.65, respectively) during landing; while increases in frontal plane knee motion and K_{ADD} moment during the squat were associated with greater landing K_{ADD} moments (r = 0.67 and 0.73, respectively). Greater K_{ER} moment during the squat was associated with larger peak K_{ER} moments during landing (r = 0.71).

Figure:



Caption: Figure 1: Effect of high (solid) and low (dashed) knee flexion and knee internal rotation PP-Scores during the squat on knee flexion (A & B) and knee internal rotation (C & D) during landing.

Conclusion: Strong associations were evident between matching joint rotations and moments between tasks, particularly at the knee (see Figure 1). A reduction in peak knee flexion during the squat was indicative of reduced knee flexion during landing. The presence of large frontal and transverse plane motion and moments at the hip and knee also transferred across tasks. The presentation of these biomechanical patterns during a single-leg squat may be useful indicators of athletes who perform leap landings with poor lower limb mechanics. Considering this type of landing is responsible for many ACL injuries in netball [6], the single-leg squat may have utility as a simplistic screening method for ACL injury risk in netball athletes.

SAGITTAL PLANE LANDING KINEMATICS IN ATHLETES WITH AND WITHOUT PATELLAR TENDINOPATHY

Rodrigo Scattone Silva [1,*] Ana Luisa Granado Ferreira [1] Theresa Nakagawa [1] Luccas Garcia [1] José Mourão dos Santos [2] Fábio Serrão [1]

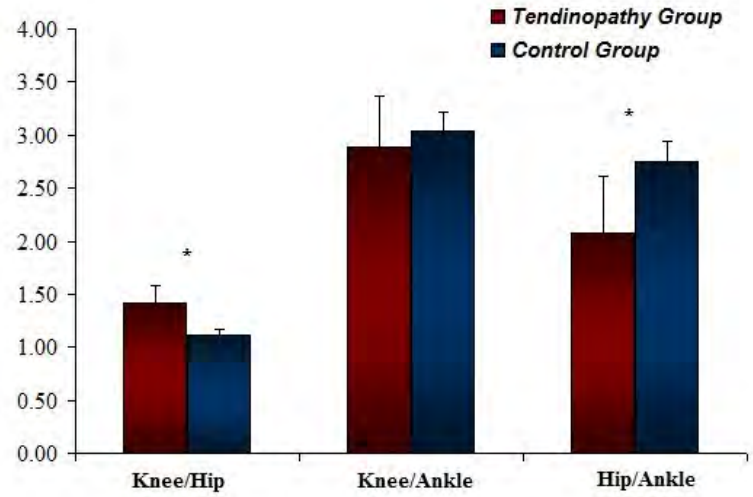
[1]Department of Physiotherapy, [2]Department of Medicine, Federal University of São Carlos (UFSCar), São Carlos-SP, Brazil

Introduction and Objectives: Patellar tendinopathy is highly prevalent in athletes engaged in sports that involve repeated jump-landings and it is considered one of the most common causes of anterior knee pain in the athletic population. Frequent application of high patellar tendon forces and poor landing biomechanics are believed to be some of the main causative factors of patellar tendinopathy [1]. Previous research has shown that asymptomatic subjects with patellar tendon abnormalities have altered jump-landing mechanics in comparison to controls without such abnormalities [2,3]. It has been demonstrated that, when landing from a horizontal jump, athletes with patellar tendon abnormalities perform hip extension, whereas athletes without tendon abnormalities perform hip flexion [2,3]. In fact, this altered hip joint movement pattern during landing was the primary risk factor that predicted both the presence and the severity of a patellar tendon abnormality [3]. However, research involving landing mechanics of athletes with symptomatic patellar tendinopathy is still scarce. The purpose of this study was to compare the sagittal plane lower limb kinematics during jump-landings between athletes with and without patellar tendinopathy.

Methods: Young male athletes, 18 to 30 years of age, were recruited from local volleyball, basketball and handball teams. They were submitted to an ultrasonographic evaluation of both patellar tendons by an experienced radiologist. Subjects presenting current symptoms in the patellar tendon during tendon-loading tasks for at least 3 months and presenting patellar tendon abnormalities [4] were included in the patellar tendinopathy group (TG; n = 7). Asymptomatic subjects without patellar tendon abnormalities were included in the control group (CG; n = 7). The Qualisys Motion Capture system with 8 cameras (Qualisys Medical, AB, SWE) was used to evaluate lower limb kinematics while the athletes performed drop vertical jumps from a box. The symptomatic lower limb was evaluated in the TG and, in case of bilateral symptoms, the most symptomatic limb was evaluated. The athletes of the CG were matched to the athletes of the TG regarding anthropometric variables and evaluated lower limb. For the kinematic evaluation, fourteen passive markers were positioned on anatomical landmarks and 3 clusters were positioned on the athlete's thigh, shank and posterior aspect of the shoe. The athletes performed 3 repetitions of a drop vertical jump task from a 31-cm box. They were instructed to drop from the box in a bipodal stance and immediately perform a maximal vertical jump to reach a ball, which was hanging from the ceiling at the maximal height the athlete could reach. The Visual3D (C-Motion, MD, USA) software was used for data processing. Mean values from the 3 repetitions of the landing phase of the task were considered for analysis. The landing phase of the task comprised the period between foot contact and peak knee flexion. The variables of interest were the peak angles of hip and knee flexion, peak ankle dorsiflexion, as well as the knee/hip, knee/ankle and hip/ankle ratios during the landing phase of the task. Independent t-tests were used for statistical analysis with a significance level of 5%.

Results: Results showed that the TG presented smaller peak hip flexion during landing when compared to the CG. No group differences were observed for peak knee flexion or ankle dorsiflexion (**Table 1**). Additionally, the TG presented a greater knee/hip ratio ($P < 0.001$) as well as a smaller hip/ankle ratio ($P = 0.009$) when compared to the CG (**Figure 1**).

Figure:



Caption: Figure 1. Sagittal plane peak angle ratios of the hip, knee and ankle during drop vertical jumps in subjects with and without patellar tendinopathy (mean and SD). * Significant difference between groups (P < 0.01).

Conclusion: The landing pattern of the athletes with patellar tendinopathy involved less hip joint flexion in proportion to knee flexion and ankle dorsiflexion when compared to controls. It is likely that this altered jump-landing mechanics results in a less efficient energy dissipation strategy, with the hip joint offering a smaller contribution for ground reaction force dissipation. This landing pattern might result in excessive overload of the knee extensor mechanism, possibly having a significant influence in the development and/or perpetuation of patellar tendinopathy.

Table:

	Tendinopathy Group	Control Group	*P*-Value
Hip Flexion	63.19 ± 10.23*	77.89 ± 9.99	0.019
Knee Flexion	88.80 ± 11.70	86.13 ± 9.98	0.654
Ankle Dorsiflexion	31.37 ± 6.35	28.49 ± 3.93	0.329

Caption: Table 1: Sagittal plane peak joint angles (deg) during drop vertical jumps in subjects with and without patellar tendinopathy (mean ± SD). *Significant difference between groups.

18F-NAF PET-CT: A MARKER FOR EARLY DETECTION OF BONE DEGENERATION AND REMODELLING IN THE LOWER LUMBAR SPINE

Justin Fernandez [1,*] Shasha Yeung [1] Andi Liu [1] Amanjeet Singh Toor [2] Ju Zhang [1] Vickie Shim [1] Thor Besier [1] Jacob Munro [2] Gerard Deib [3]

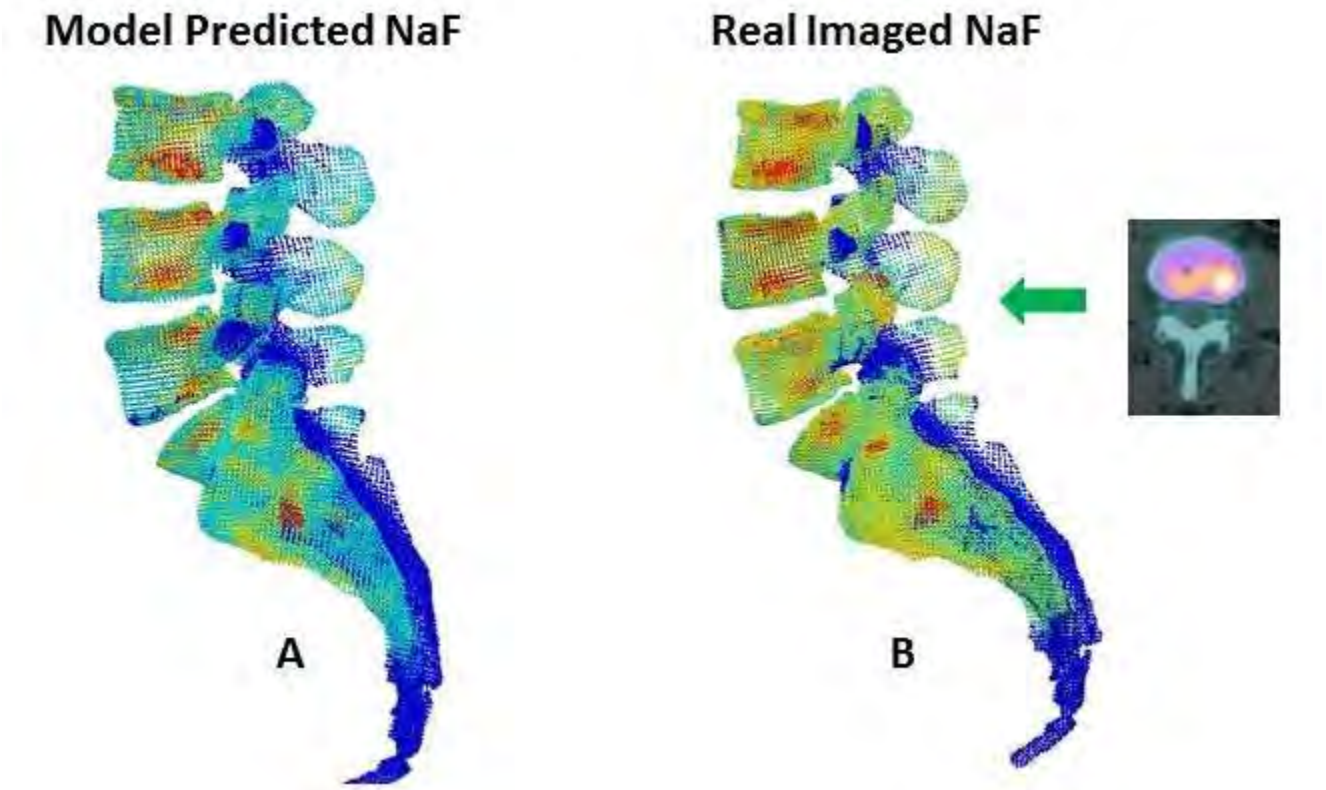
[1]University of Auckland, [2]Auckland City Hospital, [3]Mercy Private Hospital, Auckland, New Zealand

Introduction and Objectives: Chronic lower lumbar pain typically has multifactorial causes. Bone remodelling initiated by high stress has been identified as one potential source of pain [1] but there is little evidence to support this. Positron Emission Tomography (PET) is a functional imaging modality that offers an ability to measure bone metabolism for musculoskeletal disorders using a Sodium Fluoride (18F-NaF) trace marker [1,2]. While there is increasing use of 18F-NaF PET-CT for clinical diagnostics, there is no evidence to suggest that one of the major causes of vertebral endplate and spine facet degeneration, namely increased joint bone stress, correlates with NaF uptake. The primary objective of this study was to evaluate if patients who present with lower back pain have increased uptake of 18F-NaF in regions that correspond to high bone stress. The secondary objective was to see if there were any features of spine shape that are good predictors of increased bone stress and NaF uptake. These spine shape features may assist clinicians to identify suitable candidates for NaF imaging.

Methods: Twenty nine patients who presented with back pain had both CT imaging and 18F-NaF PET. Ethical approval was obtained by Mercy Private Hospital. The CT images were registered with the PET data to improve identification of NaF uptake. Those patients that showed significant NaF uptake were used to construct finite element models and compute Von Mises bone stress in the 3rd to 5th lumbar and sacrum using Abaqus. Extracted NaF uptake intensity was then mapped onto the finite element mesh for comparison between NaF intensity and bone stress. To evaluate spine shape, principal component analysis (PCA) was used to identify independent characteristics of shape; and partial least squares regression (PLSR) was used to correlate these shape modes with NaF intensity and stress in the spine.

Results: There were no significant age or BMI differences between males (age 48±19 yrs; BMI 27±4) and females (age 49±17 yrs; BMI 29±6). Of those subjects who presented significant NaF, 44% of their peak bone stress occurred in regions of high NaF uptake on average with some patients exhibiting up to 82% overlap between peak bone stress and high NaF. Further, PCA analysis revealed that the 3 key features of spine shape that influenced bone stress and NaF patterns were pelvic tilt, vertebral spine curvature and intervertebral disc spacing. A PLSR model was developed that linked these spine shape features to NaF intensity for use by both bioengineers and clinicians (as a pre-screening tool). A representative example of a PLSR model prediction of NaF intensity from shape, contrasted with the actual patient is shown in Figure 1. The model predicted the correct pattern and sites of peak NaF intensity near the vertebral endplates and at the spine facets. However, NaF intensity had errors up to 25% in magnitude near the NaF ‘hot-spots’.

Figure:



Caption: Figure 1: (A) Model predicted NaF uptake versus (B) real imaged NaF uptake. Red is a peak NaF 'hot spot'.

Conclusion: NaF offers a useful clinical modality to detect early signs of peak bone stress in the lower lumbar, which is linked to bone remodelling long before advanced pathology is observable. Standard structural modalities (CT and MRI) only reflect late adaptive bone changes with reliance on bone sclerosis and marginal vertebral remodelling. Given the high radiation exposure that NaF PET-CT presents to patients the results from this study may provide both clinicians and bioengineers with a pre-screening prediction tool for vetting suitable candidates and reduce unnecessary radiation exposure for healthy patients. This study showed that 44% of peak bone stress sites on average occurred in regions of high NaF uptake and up to 82% in some patients. This suggests that peak bones stress is one important factor associated with bone remodelling and identified by NaF tracers. It is important to interpret these results as a reflection of standing posture, which does not represent the complete array of tasks that constitute a daily loading stimulus. Inclusion of different tasks is likely to increase the overlap between peak stress and NaF. The population of spine models and NaF uptake readings from this study are currently being deposited in the open-source U.S. FDA funded Musculoskeletal Atlas Project (MAP) which is available for orthopaedic evaluation (www.launchpad.net/mapclient/).

SAGITTAL PLANE SPINE KINEMATICS DURING STOP-JUMP OF INDIVIDUALS WITH ADOLESCENT IDIOPATHIC SCOLIOSIS POST SURGICAL FUSION OF SPINE.

Rumit S. Kakar [1,*] Yumeng Li [2] Yang-Chieh Fu [3] Cathleen Brown-Crowell [2] Timothy Oswald [4] Kathy Simpson [2]

[1]Physical Therapy, Ithaca College, Ithaca, [2]Kinesiology, University of Georgia, Athens, [3]Health, Exercise Science, and Recreation Management, University of Mississippi, Mississippi, [4]Pediatric Orthopaedic Associates, Atlanta, United States

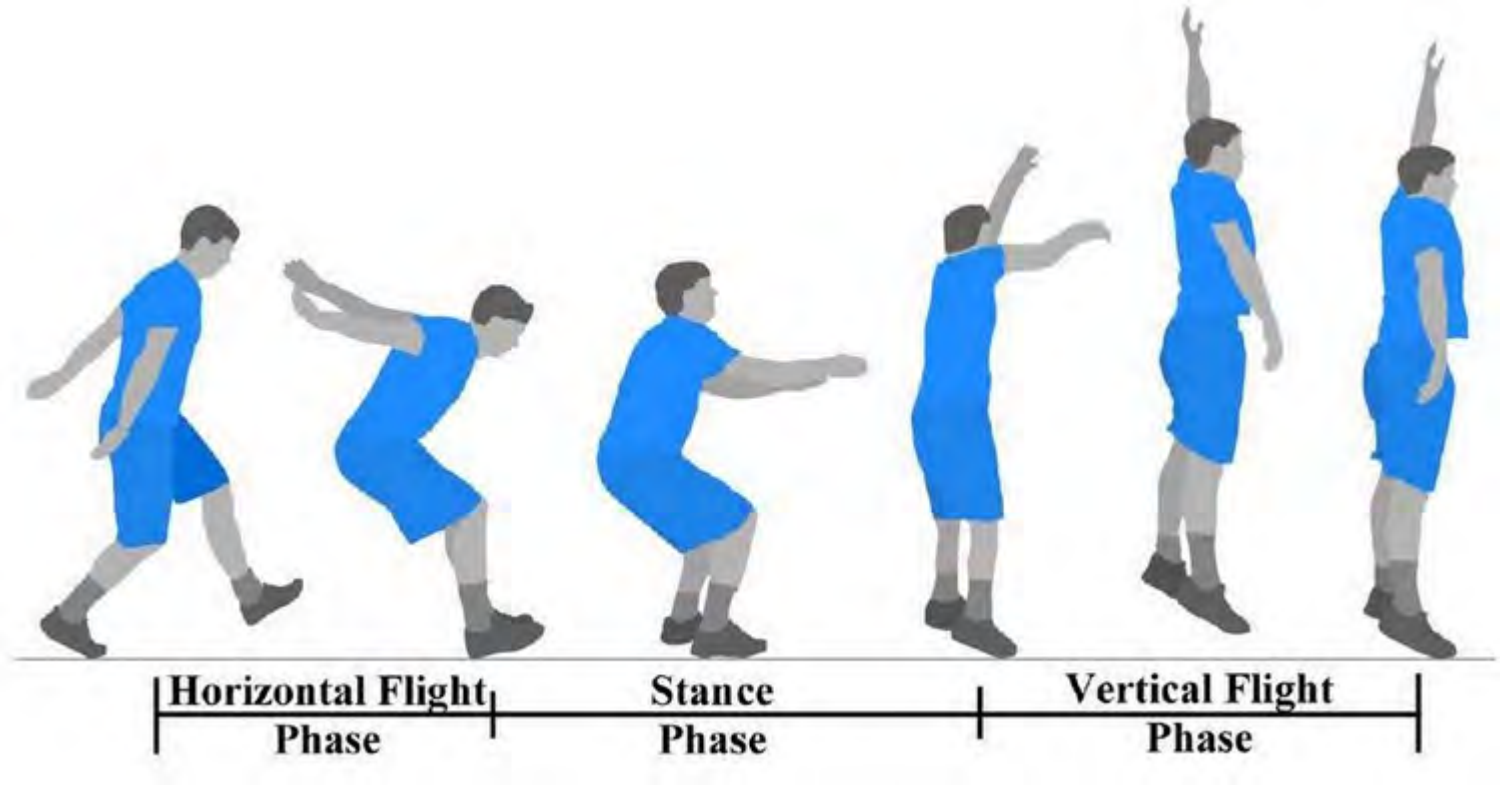
Introduction and Objectives: After spinal fusion, adolescent idiopathic scoliosis individuals (SF-AIS) often return to exercise and sport. However, the movements SF-AIS use to compensate for the loss of spinal flexibility at the fused segments during high-effort tasks like stop-jumps [1] are not known. The objective of the study was to compare the spinal kinematics in sagittal plane between SF-AIS and healthy controls (CON) groups during the stop-jump task. (Figure 1)

Methods: 10 SF-AIS (physically active; posterior-approach spinal fusion: 11 ± 2 fused segments; post-op time: 2 ± .6 yr); and 10 CON individuals, pair matched for gender, age (17.4 ± 1.3yr, 20.6 ± 1.5yr, respectively), mass (63.5 ± 12.2kg, 66.4 ± 10.9kg), height (1.69 ± 0.09m, 1.72 ± 0.08m) and level of physical activity participated. SF-AIS and CON performed 5 acceptable trials of the stop-jump task. Spatial locations of 24 retro-reflective spine and pelvis markers were recorded via a 7-camera motion capture system (240Hz). Analysis of covariance (jump height = covariate, $p < .05$) and 95% confidence intervals (95%CI) for the mean differences were used to compare the groups' sagittal plane, segmental angular displacements of the 3 spine segments (upper [UT: C7 to T8], middle [MT: T9 to T12], and lower segment [LT: L1 to L5]) and pelvis (PEL), along with relative angles UT-MT, MT-LT and LT-PEL, for the 3 phases of interest (horizontal flight: take-off to initial contact; stance: initial contact till take-off for vertical flight; and the 2nd vertical flight phase).

Results: Jump heights were not different between the two groups (mean difference: 0.013m; $p = .872$; 95% CI: -0.100m to .100m). For segmental angles during the stance phase, SF-AIS demonstrated significantly greater spinal flexion displacements of the MT (5.1°, $p = 0.009$) and LT (6.2°; $p = 0.012$) compared to CON. No other statistically significant group differences were observed for this, the two flight phases ($p > 0.104$) or any of the relative angles ($p = 0.208$-0.983). The mean difference between groups was less than 5° for most of the segmental and relative angular displacements (Table 1).

We expected that greater UT and LT angular displacements in stance phase would be displayed by the SF-AIS group to compensate for the lack of spinal motion in the MT, the segment that was fused entirely. SF-AIS did demonstrate significantly greater LT angular displacement in the compared to CON. However, not expected were the greater MT angular displacements of SF-AIS in this plane. Similar magnitudes of displacements for MT and LT and low MT-LT and LT-PEL relative angles, suggest a synchronous motion of the segments. The results supporting the predictions were contrary to those reported previously for spine kinematics in range of motion [2], gait [2-3] and side-stepping [4] studies. In the stance phase, use of LT extension range to also extend the MT as observed by their synchronous movement is one of the few compensatory adaptations used by SF-AIS during this movement that is different from CON. This adaptation likely helps achieve greater ranges of extension for the fused segments and, thus, in the spine as a whole.

Figure:



Caption: Figure 1: The stop-jump tasks and its phases.

Conclusion: Our findings suggest that these moderately-active SF-AIS individuals accomplish the performance goal of a successful jump largely through low back flexion-extension, while the fused segments synchronously move with the LT as a unit. Although this compensatory adaptation observed in SF-AIS helps achieve the performance goal during physical activities, the atypical mechanics could be clinically demanding on particular core muscles, thoracolumbar mechanics and the lumbo-pelvic rhythm [5].

Table:

Segmental Angle	SF-AIS	CON	Mean difference (°)	95% CI of the mean differences (°)		*p* value
	Mean ± SD	Mean ± SD		Upper limit	Lower limit

ACTIVE TRUNK EXERCISES REQUIRE MORE MUSCLE ACTIVITY IN MATURE THAN IN YOUNG ADULTS

Stephanie Valentin [1,*] Theresia Licka [1]

[1]Movement Science Group, Equine Clinic, University of Veterinary Medicine Vienna, Vienna, Austria

Introduction and Objectives: Reductions in muscle strength [1], changes in motor control patterns [2] and muscle morphology [3] are known to occur with ageing. However, the effect of age on trunk muscle activity during active trunk exercises has not been widely investigated, even though spinal range of motion is known to reduce with age [4]. The aim of this study was to compare the age differences in activity of the rectus abdominis (RA), obliquus internus (OI), obliquus externus (OE), and erector spinae (ES) muscles during flexion and extension exercises performed in upright (U) and 4-point kneeling (4P) postures.

Methods: Twenty-four healthy participants (12 young, aged 18-25 years; 12 mature, aged 45-60 years) were included. Reflective markers were attached over the spinous process of the 11th thoracic vertebra (T11), the head, the left and right styloid processes, and lateral femoral condyles. Three-dimensional kinematic data were collected using 10 high speed cameras (Eagle Digital Real Time System, Motion Analysis Corp., 120Hz). Surface EMG electrodes (Delsys Trigno, 1200Hz) were attached over the left and right ES, RA, OE, and OI after skin preparation. Data were collected during three repetitions of 10s of flexion and extension movements in U and 4P. Participants were instructed to perform each movement to their end range and return to the starting posture in one fluent movement. Raw EMG data were resampled, rectified, zero-mean offset, and a 4^{th} order low pass Butterworth filter applied. Processed EMG data from 0.5s before movement onset and 0.5s after movement cessation (both based on vertical T11 movement) were included for analysis. EMG data were normalised to the maximally observed muscle activity from any trial and movement for each muscle, and the maximum and 1^{st}, 2^{nd}, and 3^{rd} quartiles (Q1, Q2, Q3) calculated for the concentric phase (conc) and eccentric phase (ecc) of muscle activity. Due to non-normally distributed data, each EMG parameter was compared between the young and mature groups using a Mann-Whitney U test.

Results: There were no significant differences in T11 vertical displacement between the age groups. In the young group, median values across all muscles, postures and movements ranged from 6.91 - 33.29% for Q1, 7.17 - 42.05% for Q2, 7.53 - 66.02% for Q3, and 10.96 - 86.78% for the maximum. In the mature group, these values were 9.39 - 36.67%, 11.19 - 53.87%, 12.24 - 74.98%, and 15.33 - 89.08% respectively. In 4P, there were no significant differences between the young and mature group for any movement, muscle, or parameter, except for RA right (flexion Q2 ecc; extension Q1, Q2, Q3 ecc; $p<0.05$) which showed significantly greater values in the mature group. In U flexion, significant differences were found between the young and mature group for all muscles, however this was only in conc for ES (ES left Q1 and Q2; ES right Q1; $p<0.05$), in the maximum and Q3 ecc for left and right RA and OE, and Q3 conc for OI right (all $p<0.05$). In all these cases, values were greater in the mature group. Also, in U extension, the mature group had significantly higher values (ES left all parameters; ES right Q1, Q2 conc; $p<0.05$).

Conclusion: Differences in trunk muscle activation were observed between healthy young and mature participants, although this was dependent on movement direction and posture adopted. Interestingly, in each significant finding, the

mature group scored higher normalised EMG values compared to the young group, indicating that mature adults require greater muscle activity based on a peak dynamic normalisation method in comparison to young adults to attain similar trunk displacement. In U, differences between the age groups were found in all muscles and across all phases (concentric, maximum, eccentric). However in 4P, which is a posture considered to be relatively novel, fewer significant differences occurred between the age groups, with only RA right in the eccentric phase showing significant differences. This unilateral finding may be related to the establishment of more marked laterality with age in commonly adopted postures.

BOTULINUM TOXIN TYPE-A INDUCED PARASPINAL MUSCLE WEAKNESS CAUSED LUMBAR SPINE DEGENERATION

Sang Kuy Han [1,*] Young Eun Kim [2] Keyoung Jin Chun [1]

[1]Advanced Biomedical and Welfare technology R&BD group, Korea Institute of Industrial Technology, Cheonan,

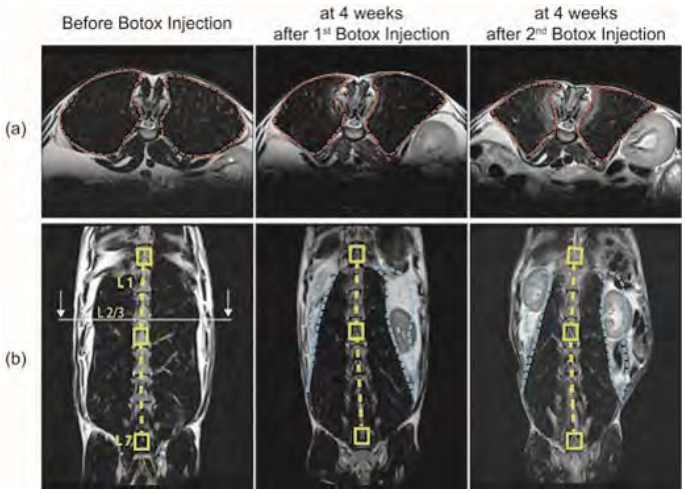
[2]Department of Mechanical Engineering, Dankook University, Yongin, Korea, Republic Of

Introduction and Objectives: The spine is a complex anatomic structure and provides mobility and strength. The health of the spine depends on the integrities and proper functions of structural components. Paraspinal muscles and spine are mutually dependent in a functional manner, as paraspinal muscles have a role to move and stabilize the spine. It has been generally speculated that paraspinal muscle weakness is related to spinal degeneration including intervertebral disc (IVD) failure. Since experimental approaches for examining the strength of paraspinal muscle in *in-vivo* is technically difficult, most of previous studies have been conducted using an *in vitro* experiment and a computational analysis, such as, a finite element modeling, for understanding of IVD biomechanics [1-2]. Recently, a series of studies employing botulinum toxin type-A (Botox) induced muscle weakness model has been reported to investigate the relationship between adjacent muscle weakness and the synovial joint health [3]. These studies systematically demonstrated that quadriceps muscle weakness caused the degenerations of articular cartilage in a patellofemoral joint. The purpose of this study was to investigate the effects of Botox induced paraspinal muscle weakness on the degeneration of lumbar spine in an *in-vivo* animal model. We hypothesized that the paraspinal muscle weakness directly induce the lumbar spine degeneration as it breaks force balance on each motion segment in the lumbar spine.

Methods: A skeletally mature New Zealand white rabbit was obtained (N= 4, average age = 19 months). Rabbits were anesthetized for receiving intramuscular botox injections at left and right sides of the lumbar spine from 1 to 3 (average total dose = 7 units/kg). One sixth of the total botox dose was injected into each site to equalize the effect of botox injection. The botox injection sites were visually monitored by X-ray during the injection process. This study was approved by ethical committee. MRIs were taken before and at 4 weeks after the botox injection (Siemens.,1.5 T) to analyze muscle cross-section area for quantifying paraspinal muscle atrophy and to measure lumbar spine alignment for assessing spinal degenerations.

Results: Botox injections produced paraspinal muscle atrophy which was measured by the decreases of the cross-section area of muscle in MRIs (Fig. 1a). The cross-section areas of paraspinal muscle between L2 and L3 decreased 36 ± 5 % at 4 weeks after the botox injection. From the additional observations of the rabbit with the second botox injection, the cross-section area of paraspinal muscle decreased 41% at 4 weeks after the 2nd injection. As a consequence of the decrease of the paraspinal muscle, the lumbar spinal alignment shown in the coronal view of the MRI has the progress of degeneration (Fig. 1b).

Figure:



Caption: Figure 1. An example of MRI data of the changes of the botox induced paraspinal muscle and lumbar spine from multiple botox injections. (a) Transverse view of MRI for the cross-section area of paraspinal muscle around lumbar 2-3. Red dashed lines indicate the paraspinal muscle. (b) Coronal view of MRI for the lumbar spine alignment. Yellow dashed lines indicate the changes of the lumbar alignment and blue dashed area indicate paraspinal muscle decreases after Botox injections. A cross-section line points where the cross-section area shown in (a) was set.

Conclusion: To our knowledge, this is the first study to understand the effect of paraspinal muscle weakness on the degeneration of lumbar spine in an *in-vivo* animal model. Based on our results, botox can be utilized for generating an *in-vivo* lapine model of paraspinal muscle atrophy. Furthermore, the temporal progress of paraspinal muscle atrophy caused the degeneration of the lumbar spine alignment. Since paraspinal muscles have a functional role to move and stabilize the spine, we speculated that the loss of a muscular force generation and the related instability in the structural lumbar spine units could cause a breakdown of the force balance system of the spine and the degeneration of the lumbar spine alignment. Although these speculations need to be further investigated in systematic experimental and computational studies, this study suggested that the structural integrity and health of paraspinal muscles directly affect the health of the lumbar spine. Further study will aim to investigate whether the paraspinal muscle weakness directly affects the spinal degenerations or the other independent factors are associated using the biomechanical and biochemical analyses.

AS-0421

A MULTI-OBJECTIVE OPTIMIZATION MODEL FOR ASSESSING SPINAL CURVATURE IN SCOLIOSIS

Simon Li [1]Daniel H. Chow [1,*]

[1]Department of Health & Physical Education, The Hong Kong Institute of Education, Hong Kong, Hong Kong

Introduction and Objectives: Previous studies have shown that the asymmetric postural adjustments had positive effect on the reduction of major spinal curvature in scoliosis [1]. However, those applications did not consider the probable negative effect on the minor region(s) of scoliotic curvature [2]. This study hypothesized that the optimal spinal loading could be achieved by controlled asymmetric load carriage for maximum correction of the affected region and minimum effect(s) on the unaffected region(s) in patients with scoliosis. The objective of this study was to develop an experimental protocol and formulate a multi-objective optimization (MOO) model [3] for determining the optimal asymmetric loading condition for scoliosis

Methods: Subjects with scoliosis were instructed to maintain a standardized and relaxed barefoot erect stance posture. A cross-chest asymmetric load was applied at the level of anterior superior iliac spines to each subject randomly at two sides (left and right) and in six different weights (0, 2.5, 5, 7.5, 10 and 12.5% of body weight). The spinal profile was palpated and identified by stickers adhered to the spinous processes [4]. Posterior-anterior view digital photos were taken to record the respective positions of the markers for determining spinal curvature. The mean spinal Cobb angles were determined [5]. Regression equations predicting the mean Cobb angles with respect to the applied load were set up. A MMO model was formulated to achieve the prioritized multiple goals of optimizing the maximum reduction in the major curvature and minimum effects on the unaffected regions(s). The subject specific optimal asymmetric loading condition was determined.

Results: Six young adults (mean age: 20.8 year, mean weight: 49.5 kg) in mild scoliosis participated in the study. The means of major and minor Cobb angles were 17.4^0 and 12.3^0 respectively. All of them had major curves at the thoracic region. Three had left curves and three had right curves. Different loads were applied to the left and right sides of the subjects. The mean Cobb angles with loading on the same and opposite sides of the major curves were 18.7^o ($+1.0^o$) and 14.2^o (-3.2^o) respectively. The effective side of the load determined by the MOO model was found to be on the opposite side of the major curve orientation. The optimal load determined by the MOO model was 3.2 kg (6.5% of BW). The predicted means of major and minor Cobb angles were 12.8^o and 13.3^o respectively. The predicted reduction in mean major Cobb angle was 4.6^o (26.4% of initial Cobb angle) and increase in mean minor Cobb angle was only 1.0^0 (8.1% of initial mean minor Cobb angle).

Conclusion: A cross-chest asymmetric load could be applied at the level of anterior superior iliac spines at the effective side opposite to the major curve orientation. The subject specific loading configuration could be determined by a multi-objective optimization model.

Lower Limb

AS-0422

LOWER EXTREMITY KINEMATICS DURING STOP-JUMP OF INDIVIDUALS WITH ADOLESCENT IDIOPATHIC SCOLIOSIS AFTER SURGICAL FUSION OF SPINE.

Rumit S. Kakar [1,*] Yumeng Li [2] Yang-Chieh Fu [3] Cathleen Brown-Crowell [2] Timothy Oswald [4] Kathy Simpson [2]

[1]Physical Therapy, Ithaca College, Ithaca, [2]Kinesiology, University of Georgia, Athens, [3]Health, Exercise Science, and Recreation Management, University of Mississippi, Mississippi, [4]1University of Georgia, Athens, GA; 2Univ. of Mississippi, USA; 3Pediatric Orthopedic Associates, Atlanta, United States

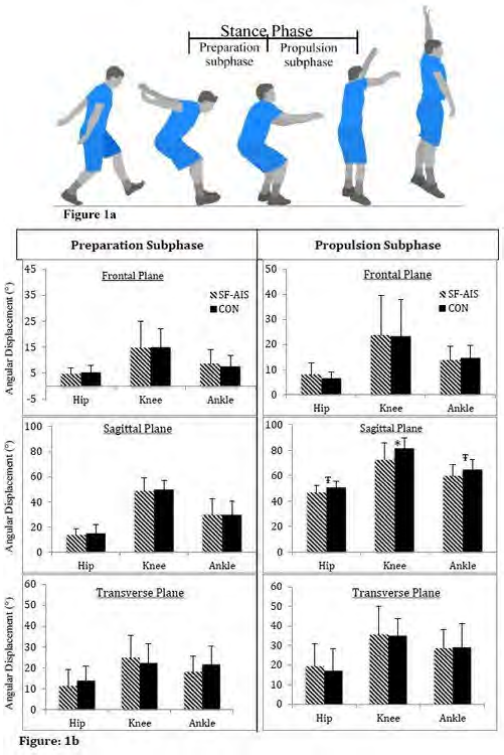
Introduction and Objectives: Spinal fusion for individuals with adolescent idiopathic scoliosis (SF-AIS) is aimed at correcting the three-dimensional deformity of the spine. However, whether atypical lower-limb kinematics are still demonstrated postsurgically or are affected by the rigidity of the spine during high-intensity physical activities is not known. It is also important from the rehabilitation point of view to understand if interlimb asymmetry is influenced by any residual, post-surgical curvature. Therefore, the objective of the study was to compare the lower extremity kinematics between SF-AIS and healthy matched controls (CON) and to compare the mechanics of the dominant and the non-dominant lower limbs within a group displayed during the stop-jump [1]. (Figure 1a)

Methods: The stop-jump task was performed by 10 SF-AIS (physically active; posterior-approach spinal fusion: 11 ± 2 fused segments; post-op time: 2.0 ± .6 yrs; and 10 CON individuals, pair matched for gender, age (17.4 ± 1.3yr, 20.6 ± 1.5yr, respectively), mass (63.50 ± 12.2kg, 66. 40 ± 10.9kg), height (1.69 ± 0.09m, 1.72 ± 0.08m) and level of physical activity participation (International Physical Activity Questionnaire). SF-AIS and CON performed 5 acceptable trials of the stop-jump. The locations of the 24 reflective markers placed on the pelvis and lower extremities were recorded via 7-camera VICON motion capture system. 2 (Group: SF-AIS or CON) × 2 (Limb: dominant or non-dominant) mixed-model ANOVA ($p < .05$) and Tukey's HSD posthoc test were used for peak angular displacements of hip, knee and ankle joints in the 3 planes of motion displayed in the stance phase (preparation and propulsion subphase; Figure 1a). Jump heights between the two groups were compared using a one-way ANOVA ($p < .05$).

Results: Jump height was not significantly different between the two groups (mean difference: 0.013m; $p = .872$; CI (-.100m to .100m)). For the preparation subphase, a tendency for Limb main effect was observed in frontal plane, with dominant limb knee ab/adduction displacement greater than the non-dominant (5.5° –5.7°; $p = .061$). No group effects were observed. For the propulsion subphase, SF-AIS demonstrated significantly lower knee extension angular displacement than CON ($p = .02$). Similar tendencies for hip extension (3.8°; $p = .055$) and ankle plantarflexion displacement (5.0°; $p = .084$) for SF-AIS also were exhibited (Figure 1b). No other significant differences were observed. For transverse plane displacements during the propulsion subphase, tendency for Limb main effect for SF-AIS and CON demonstrated that hip joint internal rotation was greater for the dominant than the non-dominant limb (8.1° and 5.9°, respectively; $p = .089$). Discussions: Results observed in the sagittal plane are partially in consensus with those reported for AIS during level walking [2]. Reduced sagittal plane kinematics can limit the maximum vertical jump heights. Jumps repeated multiple times during sports and other activities with atypical mechanics can potentially predispose SF-AIS to lower extremity injuries, although it was not reported in this study. The interlimb differences observed in both groups can

be attributed to the non-symmetrical nature of the task where the individuals tried to reach high with on one side. Spinal fusion surgery has been reported to reduce scoliosis associated pelvic misalignments thus improving lower limb mechanics in functional activities like walking [3]. Prolonged contractions of gluteus medius and semitendinosus on the dominant side of AIS individuals during walking, as that observed by Mahaudens et al. can also be potential explanations for the observed asymmetries in the limb kinematics [2].

Figure:



Caption: Figure 1a. Stop-jump task and the stance phase (preparation and propulsion subphase); Figure 1b: Angular displacements (°) of hip, knee and ankle joints in the two subphases of interest for the two groups, individuals with spinal fusion for adolescent idiopathic scoliosis (SF-AIS) and control (CON). * indicates significant difference between CON and SF-AIS groups ($p < .05$); ∓ indicates tendency for significant difference ($p = .05$-$.10$)

Conclusion: SF-AIS display mostly comparable lower limb kinematics to that of CON to prepare and propel their body vertically to a similar jump height without losing control during high-effort tasks such as the stop-jump. Clinically, it would be essential for a physician or a rehabilitation specialist to evaluate for any atypical lower extremity kinematics post-spinal fusion surgery whcih might have an safe participation in physical activities.

MECHANICAL PROPERTIES OF THE ACHILLES DO NOT RELATE TO STRENGTH OR TENDON SIZE

Stephen M. Suydam [1,*] Thomas Buchanan [2] Karin Gravare-Silbernagel [3] Daniel Cortes [4]

[1]Biomechanics, [2]Mechanical Engineering, [3]Physical Therapy, [4]Biomedical Engineering, University of Delaware, Newark, United States

Introduction and Objectives: Changes in tendon viscoelastic properties are commonly observed after injuries and during healing as a product of altered composition and structure. Continuous shear wave elastography (cSWE) is a technique to evaluate the elastic properties of soft tissue by means of the shear modulus[1]. Healthy tendon has not been previously quantified for elastic properties, nor have those properties been compared to functional or morphological measures. The aims of this study were to establish the range of shear modulus in healthy Achilles tendons, determine bilateral difference between tendons, and to show the independent nature of this measure through a lack of correlations to functional or morphological measures.

Methods: Twenty-nine subjects were evaluated for tendon health by a board certified therapist. Shear elastic modulus was measured at the free portion of the Achilles tendon using cSWE while the subjects lay prone on a plinth with their ankle in 10° of dorsiflexion. Ultrasound RF data was collected at 6450Hz while an actuator produced shear waves along the tendon. The ultrasound transducer was placed distal to the soleus myotendinous junction and the actuator was 3 cm proximal to the ultrasound probe, along the tendon. Six data sets were collected while the actuator was generating sinusoidal shear waves at each of 6 frequencies (323, 340, 358, 379, 403, 430Hz). The shear wave speed was determined in post processing with signal decomposition software. An optimization algorithm, using a Voigt model determined the shear elastic modulus with the frequencies and shear wave speeds as inputs from each of the 6 data sets. Maximum voluntary isometric contractions (MVIC) with the ankle at 90° were used to evaluate plantar flexion strength. The axial area of the free tendon was measured via B-Mode ultrasound. A Pearson's correlation determined if the shear modulus was related to the area or strength. A two, one-sided test of equivalence was used to determine if bilateral tendons were statistically equivalent. The desired detectable difference (δ) for the test of equivalence was determined by adding the possible variation caused by the measurement (mean modulus*average coefficient of variation within trial (CV)) and the minimal detectable change.

Results: The shear modulus values ranged from 37.8kPa to 67.4kPa, with a mean of 51.8kPa. The average bilateral CV was 7.2% for the shear modulus. The test of equivalence intervals δ was 6.0kPa which yielded a bilateral equivalence for the shear modulus ($p=0.009$). The average MVIC and area are located in Table 1. No significant correlations existed between the shear modulus of the Achilles tendons and the MVIC plantar flexion strength nor the axial area of the tendon. Tendon injuries are characterized by substantial changes in composition and structure which lead to altered tendon mechanical properties[2]. Since quantifying compositional and structural changes non-invasively is challenging, measurements of tendon viscoelastic properties can offer an alternative metric to evaluate tendon injuries and recovery. The bilateral symmetry and normative data permits this measure to be used to understand pathology and establish the severity of a case as compared to the contralateral limb. The CV between the two legs demonstrates that a 7.2%

variance bilaterally should be considered the minimum value before tendons within a subject are considered differing. Other clinical measures exist for pathological evaluation but the lack of correlation to the shear modulus from these existing metrics shows cSWE should be considered a unique method of diagnoses and recovery progress. Tendon thickening, determined through imaging techniques, and strength tests are excellent predictors of pathology and are effective diagnoses tools but may be missing the functional component.

Figure:

Caption: The arrangement of the ultrasound probe and actuator for cSWE. Note the ankle at 10 degrees dorsiflexion and the actuator 3cm proximal to the ultrasound probe.

Conclusion: The bilateral equivalence and the lack of correlation between shear modulus and clinical measures, such as strength and area, supports that cSWE has the potential to be an innovative tool for clinical evaluation.

Table:

	Mean		r
	Left	Right	(μ)
μ (kPa)	51.5	52.49	*
Area (cm^2)	0.49	0.48	0.26
MVIC (N-m)	132.2	138.5	0.01

Caption: The average shear modulus (μ), area and strength produced during MVIC. Note the lack of correlation of the area and strength to the shear modulus.

MEASUREMENT AND RECONSTRUCTION OF THE GEOMETRY OF THE DISTAL FEMUR USING ROBOTIC 3D ULTRASOUND

William C. Kerr [1,*] Philip Rowe [1] Stephen Gareth Pierce [2]

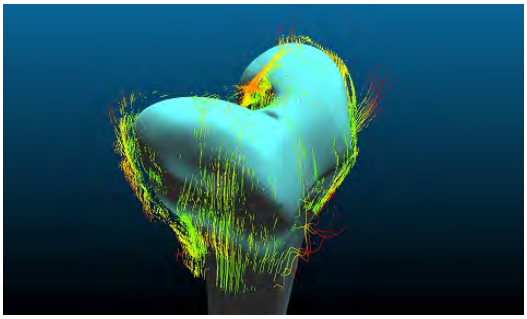
[1]Department of Biomedical Engineering, [2]Department of Electronic and Electrical Engineering, University of Strathclyde, Glasgow, United Kingdom

Introduction and Objectives: Currently, computed tomography (CT) is the preferred preoperative imaging method for guided knee arthroplasty systems, such as the Makoplasty. Ultrasound imaging has the potential to provide an alternative to CT in this capacity by offering comparable accuracies, while reducing cost and eliminating the risk of ionising radiation. A system was developed which allows for imaging of the bony surface of the distal femur; serving to establish a proof of concept for a full 3D knee imaging scheme.

Methods: An artificial distal femur was imaged using a 128 element 5MHz linear probe. Following a hemispherical path, the probe was manoeuvred around the specimen by a Kuka KR5 Arc HW 6 axis robot. Bespoke probe mounts and calibration parts were designed and manufactured, allowing the probe position and orientation to be known to the robot controller. These parts were tested for accuracy using a Faro Quantum touch probe with an accuracy of 0.055mm. Using synchronised probe position and ultrasonic data capture, a total of 1611 ultrasonic data acquisitions were performed using full matrix capture. The data were processed using the total focussing method (TFM), which provided 2D images. Surface contours were extracted from each image which were translated and transformed based on the positional data. This provided a 3D point cloud representing the outer surface of the specimen. The specimen was laser scanned using a Faro Quantum, providing an accurate comparison model for the ultrasonic data.

Results: The ultrasound-derived point cloud was inaccurate relative to the reference model, with a mean error of 3.60mm, a maximum error of 32.57mm and a standard deviation of 3.06mm. While the ultrasonic data mimicked the shape of the reference model, there was an offset between the two, with the shape of the ultrasonic data generally being larger. The 2D images suffered from sidelobes of significant intensity, resulting in inaccurate contour extraction. Additionally, calibration parts were found to be inaccurate, with the calibration spike found to be as much as 1mm shorter than the intended length.

Figure:



Conclusion: In principle, the system is functional, but is in need of significant improvement. The calibration parts will be redesigned and manufactured to a higher level of accuracy. In addition to this, the synthetic aperture focussing method (SAFT) will be investigated as an alternative to TFM. It is believed that the implementation of these improvements will provide a system capable of accurate bony surface imaging.

THE CHANGING MICROARCHITECTURE OF TRABECULAR BONE WITH HIGH STRAIN

Robert Wallace [1,*] Krishna Manda [2] Erika Sales [2] Pankaj Pankaj [2] Hamish Simpson [1]

[1]Orthopaedics, [2]Bioengineering, University of Edinburgh, Edinburgh, United Kingdom

Introduction and Objectives: Trabecular bone is a load bearing and shock absorbing material found at the ends of long bones, vertebrae and flat bones. Its complex micro-architecture and biphasic individual constituents hugely affect the macro mechanical behaviour of the bone which is largely unknown. Aging and bone disease can alter the micro-structure of the bone, which, in turn puts the bone at fracture risk. Although trabecular bone yields at small strains, large deformation analysis is necessary to understand the failure mechanisms and post-elastic nonlinear behaviour which facilitate orthopaedic implant designs.

In the current study we performed large compressive tests on trabecular bone samples from human femoral heads and assessed the microstructural indices. The specific aim of this study was to determine if there are any changes in the alignment or structure of the trabeculae during loading. Changes in the morphometry will elucidate how strain is distributed through the structure.

Methods: Human Femoral heads were harvested under ethical approval (2002/1/22) for the use of discard material in medical research. The femoral head was securely held in a submerged clamp to negate heat production as a core drill bit machined 10.64mm diameter samples. These were then cut parallel, using a Buehler Isomet low speed saw (Buehler, Illinois, USA) to a mean size of 12.15 (±0.65) mm.

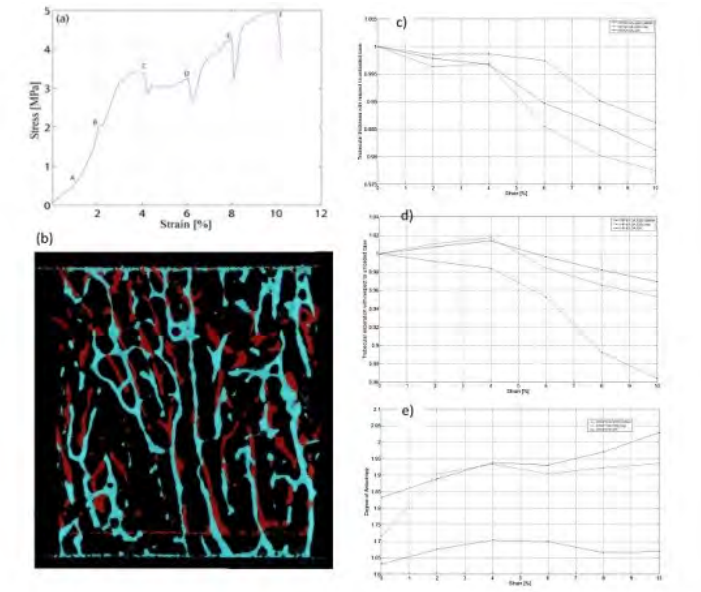
Samples were inserted into a compression stage mounted in a Skyscan 1172 microCT (SkyScan, Kontich, Belgium) and scanned at a preload of 5N. Load was applied at a rate of 0.01mm/s. In 3 cases, scans were conducted pre and post loading only (2 anterior, 1 posterior). In the remaining samples (2 central and 1 posterior) the samples were held and scanned at displacements equivalent to 2%, 4%, 6%, 8% and 10% strain. After full unloading, another scan was taken for all samples. A voxel resolution of 17.22µm was used for all samples.

A region of interest of 570 pixels (equivalent to a 9.8 mm circular shape) was used to determine; Percent bone volume (BV/TV, %), Structural model index (SMI), Trabecular Thickness (Tb.Th, mm), Trabecular Number (Tb.N), Trabecular separation (Tb.Sp, mm) and Anisotropy (DM) using CTan (SkyScan, Kontich, Belgium).

Results: In order to facilitate comparison the data for each specimen was normalised with respect to the preload. The data was analysed using an ANOVA (Tukey) with a p value < 0.05 indicating a statistically significant difference (SSD). BV/TV at 2% & 4% strain were SSD to 10%. SMI revealed SSD's between the post-load and 4%>10% strain, pre load and 2% strain were SSD to 10% strain. Trabecular thickness (Tb.Th) showed SSD's between the post-load and the preload – 6% strain, preload – 4% were also SSD to 8%, 10% and post-load. The trabecular number (Tb.N) showed SSD's between 10% strain and preload up to 6%, SSD's were also seen between preload up to 4% and 8%, 10% and post-load. Trabecular Separation (Tb.Sp) and Anisotropy did not show any significant differences during loading.

On all 6 samples, a paired t-test compared the values (not normalised) pre and post compression. SSD in BV/TV ($p = 0.049$) was found, implying that the bone does not return to the pre deformation structure. No other property displayed a SSD when comparing preload with post-load.

Figure:



a) Stress strain curve in uniaxial compression b) Reconstructed image at preload with 10% strain superimposed
c) Tracular thickness at increasing strain d) Trabecular separation at increasing strain
e) Degree on Anisotropy at increasing strain

Caption: Sample compression and morphometric analysis

Conclusion: During loading, the alignment of trabeculae was altered with respect to its original state, resulting in a change in the degree of anisotropy. The qualitative movement of trabeculae between unloaded and 10% strain is shown in Figure 1b. The central core, extracted coincident with the principal loading axis of the femoral head, had greater trabecular alignment than the peripheral cores. The trabeculae along this axis were observed to be denser, more aligned and approaching a more plate-like structure than those in the periphery. As we move away the periphery the BVTV differs up to 3 fold and the alignment of the trabeculae (DA) becomes increasingly random.

The SMI decreased during compression. However, this does not mean that the trabecular bone is becoming a plate-like structure, rather the trabeculae are coming closer together as was registered in the images.

Frequently, implants under load in the body are considered for finite element analysis. The morphometry/bone architecture for this analysis is assessed in unloaded situations. Our data indicates significant changes in architecture under load. If trabeculae are modelled as a continuum (as in most large scale models) the changing architecture would result in different properties under load than would be derived from the unloaded scan data. This may affect how the load around an implant is distributed. This problem is magnified when we look at the bone architecture peripheral to the principal loading axis of the femoral head.

MRI AND DTI ANALYSES COMBINED PROVIDE A POWERFUL TOOL FOR QUANTIFYING DEFORMATION ALONG HUMAN MUSCLE FIBERS IN VIVO

Uluc Pamuk [1,*] Agah Karakuzu [1] Burak Acar [2] Cengizhan Ozturk [1] Can A. Yucesoy [1]

[1]Institute of Biomedical Engineering, [2]Electrical and Electronics Engineering, Bogazici University, Istanbul, Turkey

Introduction and Objectives: Sarcomere is the basic functional element of skeletal muscle to produce muscle force. They are arranged in series within muscle fibers. Therefore, within muscles of human subjects in vivo, quantifying deformation along muscle fibers will provide invaluable information for characterizing muscle's function. Magnetic resonance imaging (MRI) analyses can quantify 3D tissue deformations in human muscles [1]. Diffusion tensor imaging (DTI) tractography allows visualizing orientation of muscle fibers [2]. With these analyses combined, we aimed at assessing fiber direction tissue deformations within the human medial gastrocnemius muscle as caused by knee angle changes.

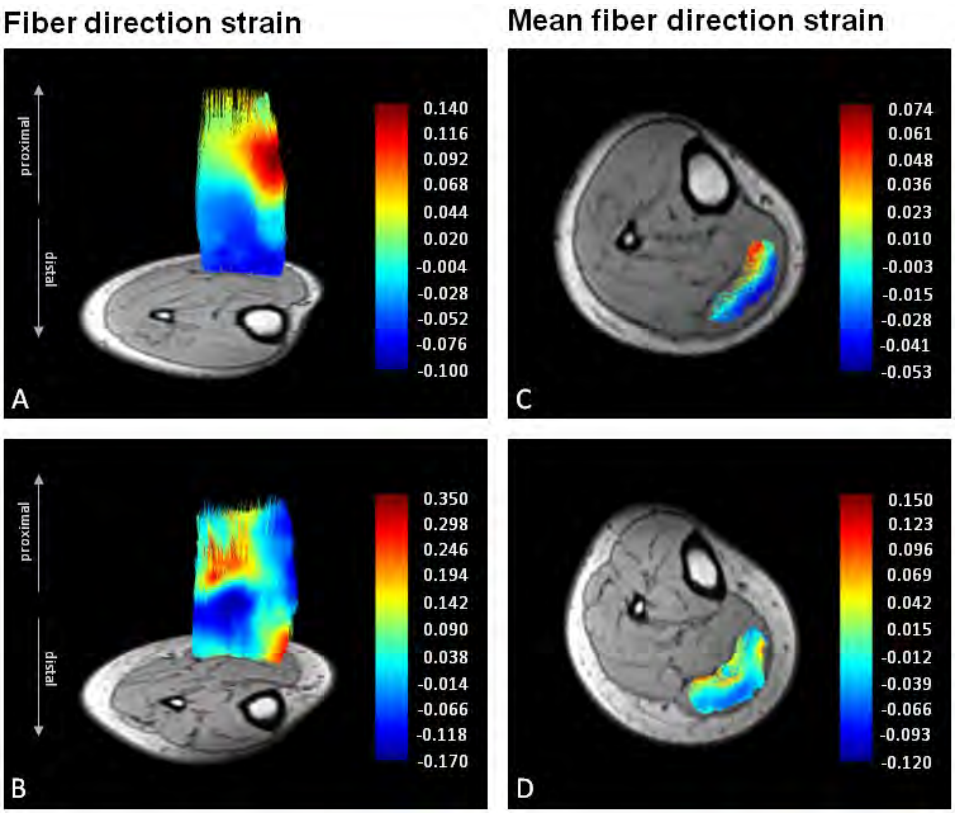
Methods: Healthy female subjects (n=5, age=27±1 years, height=159±4 cm, body mass=50±4kg) participated. Each subject was positioned prone within the MRI scanner with the ankle angle fixed at 90°. The knee was brought to flexion (140.8±3.0°) (undeformed state) and sets of 3D high resolution MR, and DT images were acquired. This was repeated at extended knee joint position (177.0±1.0°) (deformed state). The subjects were asked to stay relaxed at all times. Demons non-rigid registration algorithm [3] was applied to the MR image sets to quantify tissue deformations in global coordinates as caused by knee angle change. After Rician filtering the diffusion weighted images from noise, Split and Merge Tractography followed by 4th order Runga-Kutta integration [4] was applied to DTI data to determine medial gastrocnemius muscle fiber tracts. Strain transformation from global coordinates to local muscle fiber direction was used to quantify deformation along muscle fibers. Undeformed state images were also transformed by a synthetic rigid body motion (10˚ rotation in the axial, 3˚ rotations in coronal and sagittal planes and 4mm translation axially) imposed. Resulting fiber direction strains calculated were used as estimates of error strains.

Results: Mean error strains (for lengthening 0.2±0.1% and for shortening 3.3±0.9%) were small and were significantly different from mean fiber direction strains (for lengthening 8.7±8.5% and for shortening 7.5±4.6%) calculated for the pooled data from all subjects due to knee extension imposed. The figure shows for two subjects, examples of "serial" strain distributions along muscle fibers (panels A-B) and "parallel" strain distributions as mean fiber strain of groups of muscle fibers represented by each tract (panels C-D). Despite globally lengthened condition of medial gastrocnemius, serial strain distributions indicate lengthening and shortening (up to locally 116.7% and 23.3%, respectively) occurring simultaneously within the same muscle fibers. Mean fiber strains of different tracts are non-uniform (e.g., in panel D they range from -0.12 to 0.15; among all subjects from -0.21 to 0.19) indicating heterogeneity of parallel strain distributions within the axial cross sections of the muscle.

In sum, knee angle changes caused substantial tissue deformations to occur along the direction of muscle fibers of the medial gastrocnemius. These deformations involve both serial and parallel strain heterogeneity such that knee extension imposed can cause sarcomeres at different parts of the same muscle fibers to attain lengths corresponding not only to the descending limb of their length-force curves but also to the ascending limb. These findings are in concert with those of

previous modeling studies and coupled animal experiments [5]. In those studies it was shown that serial and parallel heterogeneity of sarcomere lengths ascribed to intermuscular mechanical interactions can change muscle's length range of force exertion, and the size of muscle force produced at various muscle lengths including muscle optimum length. These are key properties characterising mechanics of muscle in health and disease. Ability of inferring to such properties via physiologically relevant component of muscle tissue deformation is the strength of presently developed technique.

Figure:



Caption: Serial (A-B) and parallel (C-D) distributions of fiber direction strains. + and - values indicate lengthening and shortening, respectively.

Conclusion: The findings show that MRI and DTI analyses combined provide a powerful tool for quantifying deformation along human muscle fibers in vivo. Such a tool considering the muscle within the context of a fascial integrity with its surrounding muscular- and nonmuscular tissues could help substantially for a better understanding of normal and pathological muscle function as well as mechanisms of treatment techniques. However, the methods should be extended to assess muscle function in active conditions and during joint movement as well.

VALIDITY AND RELIABILITY OF ADULT PELVIC 3D RECONSTRUCTIONS USING LOW DOSE BIPLANAR X-RAYS

Ayman Assi [1 2,*] Bachir Ghostine [1 2] Christophe Sauret [2] Ziad Bakouny [1] Nour Khalil [1] Ariane Moniquet [2] Ismat Ghanem [1] Wafa Skalli [2]

[1]Laboratory of Biomechanics and Medical Imaging, School of Medicine, University of Saint-Joseph, Beirut, Lebanon, [2]Laboratoire de Biomécanique, Arts et Métiers ParisTech, Paris, France

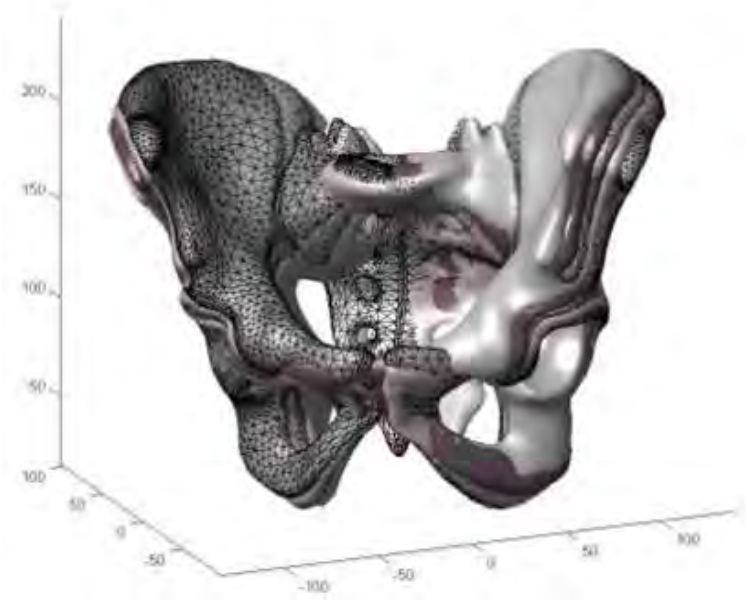
Introduction and Objectives: Pelvic 3D reconstructions are usually computed from CT-Scan acquisitions. However, this technique exposes the subject to high levels of radiation. A novel technique, the EOS® low dose biplanar X-Ray system, can be used to perform 3D reconstructions of skeletal structures such as the spine and the lower limbs [1,2,3]. Yet, the technique of 3D reconstruction of the pelvis, using this same system, is not fully validated, particularly when the pelvis is more or less rotated in the horizontal plane, which usually occurs because of malpositionning of patients during X-ray acquisition. The purpose of this study is to evaluate the validity and reliability of the main pelvic parameters using this new technique, in comparison with 3D reconstructions obtained by CT-Scan.

Methods: Helical pelvis CT-Scans (slice thickness: 0.6mm) of 6 adults (3 F and 3 M, age: mean 48 - SD 29) were considered. A three-dimensional reconstruction of each pelvis was obtained using the Avizo® software, by detecting the outlines of the pelvis on each slice and was considered as the reference. Lateral and Frontal Digitally Reconstructed Radiographs (DRRs) were computed from the CT-Scans, in order to simulate the lateral and frontal radiographs which would be obtained from a typical EOS exam. Then for each patient, axial rotation of the pelvis was simulated and the corresponding DRRs were calculated at 5°, 10°, 15° and 20°. The 3D reconstruction of each pelvis was obtained from each pair of X-Rays in each axial position, using the research version of the SterEOS® software (Figure 1). Four qualified observers repeated the 3D reconstruction 3 times each at each axial rotation. A total of 360 reconstructions in 3D were obtained (6 patients, 5 axial rotations, 3 operators, 3 times each).

Clinical parameters were calculated on the reference 3D scan and the biplanar X-ray reconstructions: pelvic angles (pelvic incidence, pelvic tilt, sacral slope), % of acetabular coverage of the femoral head (%ACFH), bicoxofemoral distance, frontal pelvic tilt, acetabular angles (abduction, anteversion, tilt) and center edge angle of the acetabulum (CEA). The bias was calculated as the mean difference between CT-based (reference) and biplanar X-Ray reconstructions. The 2SD of interobserver reliability was calculated in order to assess the 95% confidence interval (95%CI) of each pelvic parameter. The Intraclass Correlation Coefficient (ICC) was also used to evaluate the interobserver agreement.

Results: At 0° position, the bias was lower than 2° for all angles, lower than 3 mm for bicoxofemoral distance, and lower than 1% for the %ACFH. The 95% CI was lower than 2° for pelvic tilt and frontal pelvic tilt, between 2 measurement units (m.u.) and 4.5 m.u. for acetabular angles, pelvic incidence, %ACFH and bicoxofemoral distance, and higher than 5° for CEA. For rotated positions, the bias remained under 1.5° for pelvic angles but increased with the extent of axial rotation for CEA and acetabular angles, reaching 3.5° at 20° of rotation. The 95% CI increased with axial rotation and exceeded 7° in the 20° position for most of the studied angles. The ICC for all parameters and in all axial rotations was superior to 0.8.

Figure:



Caption: Fig 1- Superposition of 3D reconstructions obtained by SterEOS® research software for 0°, 5°, 10°, 15° and 20° of axial rotation for the same pelvis

Conclusion: Clinical measurements performed on 3D reconstructions of the pelvis from biplanar X-rays were shown to be accurate and reliable. A pelvic rotation of more than 15° significantly decreased the accuracy of CEA and acetabular angles. A pelvic rotation of more than 10° significantly decreased the reproducibility of pelvic angles, CEA and acetabular anteversion. The 3D reconstruction technique of the pelvis using biplanar X-rays was not affected by axial rotation when it did not exceed 10°, which is rarely exceeded by malpositionning of patients during X-ray acquisitions in clinical practice. Further research is underway in order to evaluate this technique on radiographs of children, where non-ossified portions of the pelvis could affect the visibility of bony landmarks and therefore the validity and reproducibility of 3D reconstructions.

IN VIVO MEASUREMENT OF BICEPS BRACHII AND TRICEPS BRACHII FASCICLE LENGTHS USING EXTENDED FIELD-OF-VIEW ULTRASOUND

Christa Nelson [1,*] Julius Dewald [1 2] Wendy Murray [1 2 3 4]

[1]Biomedical Engineering, Northwestern University, Evanston, IL, [2]Departments of PM&R and PTHMS, Northwestern University, [3]Sensory Motor Performance Program, Rehabilitation Institute of Chicago, Chicago, IL, [4]Edward Hines Jr. VA Hospital, Hines, IL, United States

Introduction and Objectives: Muscle architecture describes the number of muscle fibers and their orientation in relation to the axis of force generation. Muscle architecture is a determining factor of an individual muscle's active force-generating capacity [1]. A muscle's architecture can be quantified through measurement of specific parameters, including muscle volume, fascicle length, and the pennation angle of the fascicles. Due to the importance of muscle architecture for force generation, and consequently function, it is important to accurately measure these parameters. Architectural parameters have been shown to adapt to various conditions, such as with disuse, aging, exercise regimes, and in certain neurological conditions [1,2]. Fascicle length, in particular, is of interest, as it affects the excursion capacity of a muscle during passive and active range of motion [1]. Ultrasound is the most common imaging modality used for the *in vivo* measurement of muscle fascicle length [3]. However, due to the limited field-of-view for most ultrasound probes, static ultrasound is primarily used with muscles that have shorter fascicles and higher pennation angles, due to the ability to visualize the entire fascicle or estimate the length of a longer fascicle using trigonometric linear extrapolation.

Due to these limitations, extended field-of-view ultrasound (EFOV US) has been investigated as a method to visualize the entire muscle fascicle in one image [3]. In a gold-standard study, this method was both shown to be reliable and valid [4], and more accurate than the trigonometric method. The objective of this study was to use EFOV US to measure both biceps and triceps brachii fascicles under both active and passive conditions, determine the reliability of fascicle measurements, and evaluate the effect of joint position on fascicle length.

Methods: Biceps brachii (long head) and triceps brachii (lateral head) fascicle lengths were measured in both arms in N=11 healthy control subjects (6 female, 5 male, age range 23-71). Subjects were casted at the wrist and secured at the forearm, with the limb approximately in the horizontal plane (85° shoulder abduction, 0° shoulder rotation) and the wrist at 0°. Four EFOV US images were collected for each muscle in extended, mid-, and flexed elbow positions with the muscle relaxed, as verified by EMG. In the flexed posture, fascicles were also imaged during an isometric contraction. The level of torque held during isometric contraction was matched between limbs, and was determined as the maximum torque the subject could hold on the non-dominant limb for 10 sec., the approximate time of image acquisition. Image J was used to manually measure 4 fascicles in each image, with the best three images used for data analysis. The reliability of fascicle measurements was determined by calculating the intraclass correlation coefficient (ICC) for measurements within an image and across the three images. A two-factor repeated measures ANOVA (arm, position) was used to detect significant changes in fascicle lengths in different elbow postures. A two-factor repeated measures ANOVA (arm,

condition) was also used to detect any significant differences in fascicle lengths between the passive and active conditions.

Results: Fascicle measurements demonstrated excellent reliability for both muscles, with ICC values ranging from .831 - .949 for biceps brachii and from .812 - .919 for triceps brachii ($p<.0001$ for all values). As expected due to its anatomy, average biceps fascicles for all subjects *decreased* with elbow flexion (Fig. 1A), and average triceps fascicle lengths *increased* with elbow flexion (Fig. 1B). Changes in fascicle lengths between the different elbow postures were significant for both muscles ($p<.0001$). Measured biceps fascicles were significantly shorter in the active condition ($p=.015$), as were triceps fascicles ($p<.0001$).

Figure:

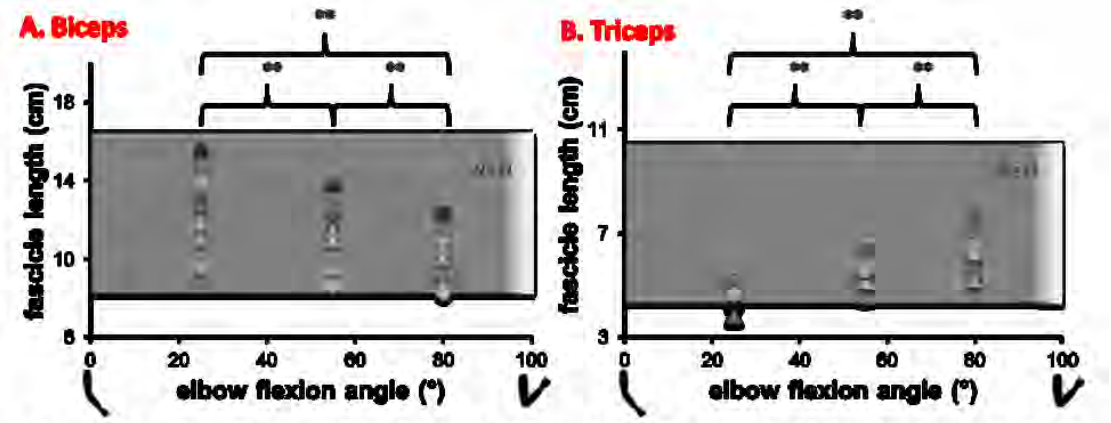

Figure 1. Biceps brachii long head (A) and triceps brachii lateral head (B) average fascicle lengths measured in N = 11 healthy control subjects using extended field-of-view ultrasound imaging. The shaded region in each plot represents fascicle measurements made in 5 male cadavers (Murray et. al 2000). Two-factor ANOVA detected a significant difference in fascicle lengths between positions ($p < .0001$) for both muscles.

Conclusion: Extended field-of-view ultrasound was used to measure muscle fascicles in biceps brachii and triceps brachii, under both passive and active isometric conditions. Fascicle lengths in healthy control subjects were consistent with published cadaver data [5], and significantly changed with position, as would be expected from each muscle's anatomy. Fascicle measurements were highly reliable for both muscles, with ICC values slightly higher for biceps brachii when compared to triceps brachii. Our data demonstrate the first known application of extended field-of-view US to measure longer fascicles in the upper extremity. Given the number of human muscles with fascicle lengths that are longer than the field-of-view of conventional ultrasound probes, this method is an important approach for the study of *in vivo* muscle function.

COMPARISON OF 2-D AND 3-D DIRECT INVERSION ALGORITHMS IN MR-ELASTOGRAPHY FOR DIFFERENT GEOMETRICAL STRUCTURES

Lyam Hollis [1,*] Neil Roberts [2] Pankaj Pankaj [3] Peter Hoskins [4]

[1]Cardiovascular Sciences, [2]Clinical Research Imaging Centre, [3]School of Engineering, [4]Medical Physics, University of Edinburgh, Edinburgh, United Kingdom

Introduction and Objectives: Magnetic resonance elastography (MRE) is a non-invasive technique to obtain *in vivo* material property measurements. Displacements resulting from a mechanically induced shear wave are characterized by a phase-encoding gradient in the MRI scanner. An inversion algorithm is utilised to obtain local estimates of wavelength which is related to the shear modulus of the material. This can be achieved by using a direct solution to the Helmholtz equation for planar shear waves. Such inversion can be performed on 2-d or 3-d datasets, yet in both instances the solutions are limited by the assumptions made to derive the Helmholtz equation. This study utilised finite element analysis (FEA) of MRE in order to compare measurements made using the 2- and 3-d inversion algorithms whilst varying the geometry of the region of interest and the material properties of the surrounding region.

Methods: All FEA simulations were performed using *Abaqus/Explicit* using geometries of size 80x80x50mm^3. In order to investigate the geometrical dependence of shear modulus measurements a cylindrical inserts with radii 10mm have been utilised. The length of these inserts has been varied from 2-50m. The shear modulus of the background material has been defined as 3kPa and the insert as 9kPa. Viscoelastic properties have been defined in both sections using the Kelvin-Voigt model of viscoelasticity with a shear viscosity of 1Pa·s in order to reduce the effects of reflections. The lower and side surfaces were fixed using symmetric boundary conditions whilst vibrations at 100Hz were applied as a concentrated force on nodal points on the upper surface.

To investigate the effects of the material properties of the shear moduli a cylindrical insert with a diameter of 30mm and a length of 20mm was inserted into the centre of the model. The cylindrical insert was split into two: the inner 10mm radius was defined as having a shear modulus of 9kPa whilst the shear modulus of the outer 5mm was varied from 2-9kPa. The shear modulus of the background was defined as 3kPa and viscoelastic properties were assigned to all regions using the Kelvin-Voigt model of viscoelasticity. Simulations were performed with the shear viscosity equal to 0.25 and 1Pa·s.

Once simulations had run displacement data was extracted from 2-dimensional planes through the centre of the model. The 2-d algorithm required displacements in one plane and from only the vibrational direction whilst the 3-d algorithm required data from 5 parallel planes spaced 1mm apart and in all three directions. Data was exported to *Matlab* where it was analysed using with the MRE inversion algorithms.

Results: Measurements from both the 2-d and 3-d inversion algorithms were consistent with one another when the geometry of the insert was varied. The measured values for the background were consistent with those prescribed and there was little variability across all geometries. This contrasted with the measurements of the insert which were dramatically underestimated for the small inserts yet suffered from a slight overestimation for the larger insert geometries (figure).

There was a slight difference in the 2-d and 3-d measurements when the effects of varying the material properties surrounding the region of interest were studied. In this instance the 3-d algorithm tended to obtain more accurate measurements in comparison to the 2-d. in both instances the measurements were dramatically underestimated when the surrounding region was prescribed with a low shear modulus (table). The results were similar for both prescribed values for the shear viscosity.

Figure:

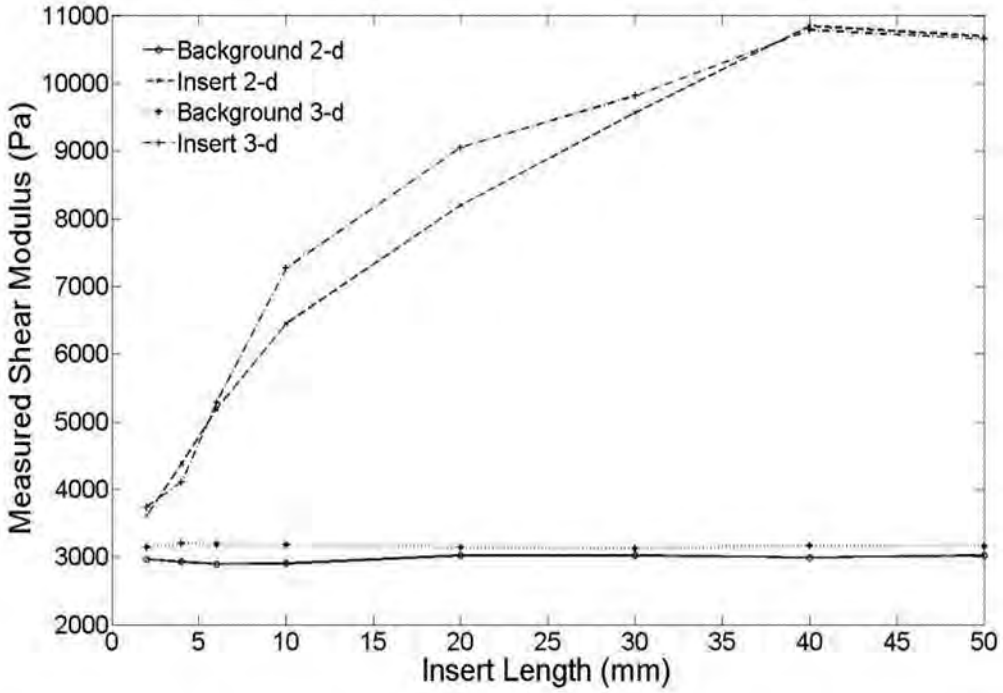

Figure: Comparison of measurements from the 2- and 3-d inversion algorithms when insert length is varied. True stiffness of the background is 3000Pa whilst the true stiffness of the insert is 9000Pa

Conclusion: This study demonstrated that measurements using both the 2-d and 3-d inversion algorithms were geometrically dependent. This suggests that whilst the direct inversion utilises local displacements to estimate local values for the shear modulus, wave propagation is dependent on the global material properties and as such this approach is limited. This implies that shear modulus measurements from different sized geometries are not directly comparable to one another. The study also showed that measurements are dependent on the material properties surrounding the region of interest. This suggests further limitations of the inversion algorithm with respect to the comparability of shear moduli from regions that have different surrounding materials. Although there was little difference between the 2-d and 3-d inversion algorithms it is likely that scattering and reflections are greatly reduced in modelling in comparison to the human anatomy and as such 3-d analysis is of greater importance *in vivo.*

A NOVEL APPROACH TO VISUALISE THE MORPHOLOGY OF PERICELLULAR MATRIX IN LIVE CARTILAGE

Eng Kuan Moo [1,*] Scott C. Sibole [1] Walter Herzog [1]

[1] Human Performance Laboratory, University of Calgary, Calgary, Canada

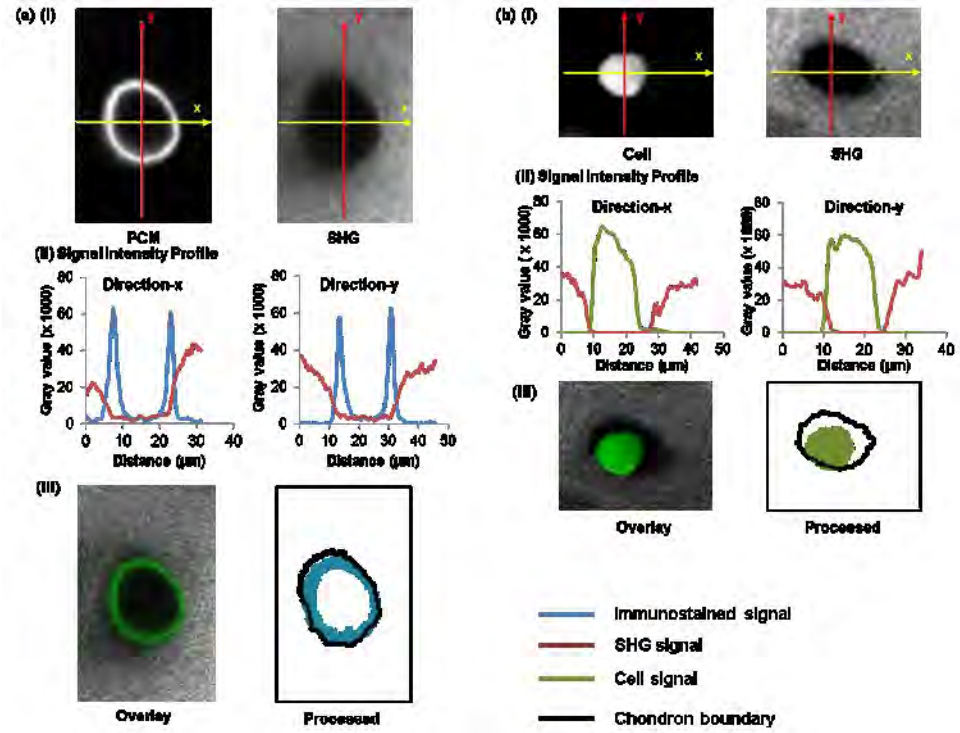
Introduction and Objectives: The pericellular environment of chondrocytes plays important roles in transducing mechanical signals from extracellular matrix (ECM) to the cells, as well as protecting cells from excessive deformation [1, 2, 3]. As a result, biosynthetic activities of chondrocytes rely heavily on the mechanical behavior of the pericellular matrix (PCM). Previous studies have investigated the morphology and mechanical behaviour of PCM through immuno-staining of collagen type VI, which is highly localized in the pericellular region [2, 3, 4]. However, immuno-staining requires tissue fixation and therefore, limits PCM observation to a single time point. Conversely, multi-photon microscopy allows imaging of collagen fibers in cartilage through second harmonic generation (SHG). SHG signal originates from the fibrillar structure of type II collagen fibers, which is non-centrosymmetric in nature [5]. As PCM is characterized mainly by type VI collagen that exists in microfibrillar form [2], this pericellular region lacks the appropriate structure to generate SHG signal. Therefore, SHG imaging may localize chondron (cell and PCM) in cartilage tissue. In addition, cell can be visualised through fluorescent staining. As such, simultaneous SHG imaging and live cell imaging can conceptually highlight PCM in live cartilage. Therefore, the purpose of this study was to establish a novel approach for imaging PCM in live cartilage, and to develop an image processing protocol for morphological analysis of PCM.

Methods: Cartilage explants extracted from porcine femoral groove were used. Two experiments were performed. In the first experiment, we localized PCM by the 'gold-standard' immuno-staining approach and identify the chondron boundary from SHG image based on the immuno-stained PCM image. Briefly, cartilage layer was fixed chemically overnight and frozen. Frozen cartilage was then cut into thick sections (40μm) and processed for immuno-staining by primary antibody (anti-collagen type VI raised in rabbit, Fitzgerald) and fluorescently-tagged secondary antibody (anti-rabbit raised in donkey, Fitzgerald). The sliced samples were then simultaneously imaged for SHG signals (Ex: 800nm; Em: 400nm) and immuno-stained PCM (Ex: 488nm; Em: 515nm). In the second experiment, cartilage explant was incubated in 8μM Calcein AM for 30min. The cartilage explants were simultaneously imaged for SHG signals and cell cytoplasm (Ex: 488nm; Em: 515nm). The fluorescent immuno-stained PCM and Calcein-stained cells were identified using 'Otsu' thresholding methods (ImageJ). SHG image were analyzed using active contour model (ImageJ, AB-Snake). The parameters of active contour model determined from immuno-staining experiment were used to define chondron boundary in live tissue experiment. PCM layer can be visualised by subtracting cell from chondron.

Results: Two-dimensional (2D) SHG image showed a dark ellipse (Figure 1a[i] and 1b[i]). This dark ellipse completely encapsulates the immuno-stained PCM layer (Figure 1a[i]), thus confirming our hypothesis that SHG microscopy can image chondron region. By trial and error, a gradient threshold of 10 at 150 iterations in active contour model produced satisfactory chondron boundary (Figure 1a[iii] right). When the SHG image is overlaid with the cell image, there exists a dark ring surrounding the cells, which suggests the PCM region (Figure 1b[iii] left). Using the same parameters of active

contour models, the chondron boundary in live tissue was determined, and the PCM region can be identified by subtracting live cell from the chondron (Figure 1b[iii] right).

Figure:



Caption: Figure 1. (a) (i)Immuno-stained PCM and the corresponding SHG image. (ii) Signal intensity profile of along x- and y-directions. (iii) Overlay of PCM and SHG images, and the processed binary image showing chondron boundary and PCM region. (b) (i) Calcein-stained chondrocyte and the corresponding SHG image. (ii) Signal intensity profile along x- and y-directions. (iii) Overlay of live cell over SHG image, and the processed binary image showing chondron boundary and live cell.

Conclusion: This study proposes a simple-to-use and novel approach for PCM imaging in live tissue. Through immuno-staining and SHG, we showed strong evidence of SHG capability in imaging chondron in live cartilage. By combining SHG imaging with live cell imaging, PCM was successfully imaged in live tissue. With the image processing protocol established in this study, future studies will focus on measuring the load-induced deformation of PCM and the role of PCM in transferring load from ECM to cells. As early osteoarthritis is related to softening of the PCM, this novel approach can enhance our understanding of the role of PCM in the pathogenesis of osteoarthritis.

IMPAIRED STATIC BALANCE IN CHILDREN WITH DEVELOPMENTAL COORDINATION DISORDER MAY BE EXPLAINED BY IMPAIRED CENTRAL AND PERIPHERAL CONTROL MECHANISMS

Merete B. Speedtsberg [1,*]Sofie B Christensen [1]Ken K Andersen [1]Derek J Curtis [2]Jesper Bencke [2]Bente R Jensen [1]

[1]Biomechanics and Motor Control Lab., Integrated Physiology, Department of Nutrition, Exercise & Sport, University of Copenhagen, Copenhagen N, [2]The Gait Analysis Lab., Department of Orthopaedic Surgery, Hvidovre Hospital, Copenhagen, Denmark

Introduction and Objectives: Developmental coordination disorder (DCD) affects approx. 6% of children at primary school age and is characterized by motor coordination difficulties. A recent meta-analysis on performance deficits in children with DCD suggests impaired control of postural sway as well as predictive control of action [1]. Previously reported impaired postural control in bipedal standing in children with DCD [eg.2], may interfere with activities of daily living and participation in sport. However, little is known about the underlying mechanisms. Furthermore, there are contradicting results concerning the effect of disturbance of sensory input in DCD.

The aim was (1) to study static postural control and the effect of manipulating sensory input in children with DCD compared to typically developing children (TD), and (2) to investigate if both central and peripheral mechanisms are involved in impaired static postural control in DCD.

Methods: Nine children with DCD (age: 9.0±0.5 years, body mass: 33.1±2.3 kg, height: 139.9±2.5 cm, gender: 7 boys and 2 girls) and 10 TD (age: 9.1±0.4 years, body mass: 33.7±1.8 kg, height: 141.1±3.0 cm, gender: 7 boys and 3 girls) participated. Inclusion criteria for DCD were to meet the official criteria for DCD [3], and a score below the 15th percentile in the Movement Assessment Battery for Children-2 (MABC-2), which is classified as a motor skill deficit. The MABC-2 percentile was 3±1 in the included DCD group and 73±5 in the TD group.

Static balance was performed in barefoot bipedal standing on a force plate. The child was exposed to six different combinations of visual and support surface conditions (table 1) and was instructed to stand as still as possible for 3×30 s in each condition. Visual conditions included eyes open, eyes closed and a visual-conflict dome for producing inaccurate visual input. Support surface conditions consisted of a hard and a compliant (45×45×7cm foam) surface.

Data from an AMTI force plate was sampled at 1000Hz, down sampled to 100Hz and used to calculate sway length based on centre of pressure (CoP) motion. CoP displacement was decomposed into two components, rambling and trembling in anterior-posterior (AP) and medio-lateral (ML) direction. Sway length was used to quantify static postural control. Rambling quantified the migration of a moving reference point in relation to the body's equilibrium, and represents the supraspinal component of the CoP trajectory. Trembling quantified the oscillations around the reference point, and represents the spinal and peripheral component of the CoP trajectory [4].

Results: Children with DCD showed impaired postural control expressed as 46.4±5.4% larger sway length (mean of all conditions, p=0.004). In the condition with no sensory disturbance, the DCD group had 46.8% larger sway length than TD (0.62m/30s vs. 0.42m/30s, p=0.026). Sensory disturbance did not affect DCD more than TD (p=0.942) across conditions. These results confirmed a deficit in static postural control in children with DCD. Furthermore, this impairment was present

regardless sensory conditions, which suggested a deficit in sensory organisation rather than a deficit in specific sensory systems.

Rambling in DCD was 41.4±14.5% and 30.2±15.7% larger (mean of all conditions) in AP and ML direction, respectively (p=0.002, p=0.006). Trembling in AP direction was 77.5±7.3% larger (mean of all conditions) and 81.7±24.1% in ML direction compared to TD (p=0.015, p=0.000). These results demonstrated that the larger sway length in children with DCD could be explained by impaired central as well as peripheral control mechanisms, indicating contribution of less effective automated spinal adjustments to postural control, along with a deficit in supraspinal control of the body's equilibrium in DCD.

Conclusion: Static postural control was impaired in DCD. The results indicated that the reduced postural control in children with DCD could be explained by a deficit in peripheral mechanisms as well as a deficit in central control. The spinal involvement in balance impairments could have implications for future research in static balance and treatment of DCD.

Table:

Condition	Description	Accurate sensory signals available
1	Eyes open + hard surface	Somatosensory, visual, vestibular
2	Eyes closed + hard surface	Somatosensory, vestibular
3	Eyes open + compliant surface	Visual, vestibular
4	Eyes closed + compliant surface	Vestibular
5	Eyes open in dome + hard surface	Somatosensory, vestibular
6	Eyes open in dome + compliant surface	Vestibular

A MODEL FOR ROBUSTNESS OF STANDING POSTURE BASED ON JOINT COORDINATION, JOINT VISCOELASTICITY AND INTERMITTENT CONTROL STRATEGY

Hiroko Tanabe [1,*] Keisuke Fujii [2] Yasuyuki Suzuki [3] Motoki Kouzaki [1]

[1]Graduate School of Human and Environmental Studies, Kyoto University, Kyoto, [2]Research Center of Health Physical Fitness and Sports, Nagoya University, Nagoya, [3]Graduate School of Engineering Science, Osaka University, Osaka, Japan

Introduction and Objectives: The individual differences in joint coordination during standing tasks have been reported in recent studies. The functions of these different kinematic coordinative structures and their generation mechanisms cannot be understood through experiments, and instead require computer simulations using mechanical models. Human bipedal standing is often modeled as an inverted pendulum. Intermittent control has been demonstrated to be valid for human quiet standing in recent studies using inverted pendulum models. Thus, this study has two objectives. The first is to investigate the relationships between joint coordination, passive joint viscoelasticity, and neural joint control strategies. The second is to examine whether robustness varies depending on viscoelasticity or control strategies.

Methods: The quadruple inverted pendulum model was constructed as a model of human tiptoe standing using anthropometric parameters. The PD (proportional-derivative) intermittent feedback control model was used to simulate the fluctuations of the pendulum. We used fixed P and D gains for the first objective in this study. Three pairs of joint viscoelastic parameters, 81 pairs of joint control strategies (intermittent, continuous, or no active control for each four joints; 3^4 pairs), and two values which determine the intermittent switching boundary were used for the simulations to investigate the difference in joint coordination patterns between these variables. For the second objective, we calculated the stability region of gain P for each joint, which represents the feedback gain that CNS can select to stabilize the multi-link human body, that is, the robustness of the model. We also compared joint coordination (phase distribution) with experimental data to verify the model (in this case, the Gaussian white noise was added to each joint's torque) used in this study.

Results: We found that the model could be stabilized (we defined the temporary stabilization of the model as standing for 60 seconds converging towards zero joint angles) 30 pairs of simulation variables among 246 pairs. The hip joint was intermittently controlled for all of the 30 conditions and the MP joint was under intermittent control or no active control for the stability. The joint coordination patterns shown by phase distribution varied depending on both joint viscoelasticity and joint control strategies, suggesting that the difference in joint coordination reported experimentally in previous studies might be derived from such passive or active parameters. Stability region of gain P was also dependent on viscoelasticity or joint control strategies.

Conclusion: Our study suggests that not only active joint control strategy but also passive viscoelasticity result in the difference in joint coordination patterns and the robustness of standing posture. The methodology used in this study possessed high generality to examine the robustness or stability of standing posture. This study was able to provide

specific joint control strategy that achieves more robust posture for tiptoe standing, which will afford pedagogical knowledge about balance control training to us.

TEST-RETEST RELIABILITY OF POSTURAL CONTROL EVALUATED IN THE AQUATIC ENVIRONMENT USING A FORCE PLATFORM

João Pedro Batista Junior [1,*] Renata Campos [2] Maria Simone Barreto [2] Bruno Mazuquin [3] Jéssyca Nogueira [2] Josilainne Dias [2] Rodrigo Carvalho [4] Marcelo Taglietti [2] Felipe Moura [5] Ligia Facci [2] Jefferson R. Cardoso [2]

[1]PAIFIT Research Group, Instituto Federal do Paraná, [2]PAIFIT Research Group, Laboratory of Biomechanics and Clinical Epidemiology, Universidade Estadual de Londrina, Londrina, Brazil, [3]PAIFIT Research Group, University of Central Lancashire, Preston, United Kingdom, [4]Univervidade Federal do Vale do São Francisco, Petrolina, [5]Physical Education and Sports Centre, Universidade Estadual de Londrina, Londrina, Brazil

Introduction and Objectives: Postural control can be affected by external and internal perturbations that continually act on the body through several sensory systems such as visual, somatosensory and vestibular [1]. Immersion affect body biomechanics since water has specific properties such as hydrostatic pressure, buoyancy and density that may influence the postural control system. Force platforms are widely used to measure center of pressure variations, however, no study has demonstrated the reliability of an aquatic force plate to provide repeatable and consistent data. The aim of this study was to test the intra-subject reliability (test-retest) of postural control in the aquatic environment.

Methods: Fifty young subjects participated in the study, 32 female and 18 male, median of age Md=21 years (20-22/1°-3°), mass Md=58 kg (54-73), height Md=1.67 m (1.61-1.72) and mass in water Md=15 kg (10-23). Tests were performed in four conditions: two leg stand-eyes open (TEO), two leg stand-eyes closed (TEC), one leg stand-eyes open (OEO) and one leg stand-eyes closed (OEC) with a 48-hour interval between test and retest. The center of pressure (COP) data were collected with a 60x60x10 cm aquatic force plate (Bertec Corporation®, model FP4060-08-2000), set in a pool (15x13x1.30m) with water depth of 1.21m and water temperature of 32.5°C. The platform was connected to a computer through a 16-bit analogue to digital converter and the acquisition rate was 1000 Hz. The following variables were used: total mean velocity (TMV)(cm/s), mediolateral mean velocity (MMV)(cm/s), anteroposterior mean velocity (APMV)(cm/s), mediolateral amplitude (MLA)(cm), anteroposterior amplitude (APA)(cm) and area (cm^2). Intraclass correlation coefficient (ICC), Bland-Altman plots (and the standard error of measurement (SEM) were used to assess the reliability of data. All the procedures were approved by the local Ethical Committee (#217/2012).

Results: The test-retest results showed reliability from low to high. The MMV presented high-reliability ICC (0.75 CI 95% 0.56;0.86) with SEM of 2.58 (SD 5.16) and mean difference (of 1.44 cm/s; followed by TMV (ICC=0.73 CI 95% 0.53;0.84); SEM=3.08 (5.92) and (= 1.73 cm/s. The amplitude variable demonstrated lower reliability (ICC=0.33 CI 95% 0.16; 0.62); SEM=1.45 (SD 1.78) and = 0.18 cm.

Conclusion: Despite the large variability in the measurements derived from the COP, the aquatic environment has important physical properties such as buoyancy, which reduce body weight and change the forces acting on the joints, offering an alternative in the treatment of injuries. However, care must be taken when postural control is evaluated in the aquatic environment due to the low reliability of some measurements.

THE RELATIONSHIP BETWEEN MUSCLE QUALITY AND POSTURAL CONTROL IN OLDER ADULTS.

Gregory S. Walsh [1,*] Marco Arkesteijn [1] Daniel Low [1]

[1]Sport and Exercise Science, Institute of Biological, Environmental and Rural Sciences, Aberystwyth University, Aberystwyth, United Kingdom

Introduction and Objectives: Muscle strength decreases with age at a faster rate than muscle mass resulting in decreased muscle quality (MQ), the ratio of strength to muscle mass. The strength loss unexplained by reductions in muscle mass, result from neuromuscular and architectural degeneration in older adults [1]. Postural control (PC) requires visual, vestibular and somatosensory input and efferent neuromuscular output [2]. The neuromuscular alterations associated with declining MQ could impede somatosensory input and the output muscle activity required to maintain PC. The aim of this study was to determine if MQ and PC are correlated in older adults during quiet standing in eyes open (EO) and closed (EC) conditions. It was hypothesised that MQ would be significantly correlated with PC performance.

Methods: Twenty-five older adults participated in this study (10 males, 15 females, 66±9 years, 69.9±12.5 kg, 1.68±0.10 m). Dominant leg muscle mass was measured by dual energy X-ray absorptiometry and concentric and eccentric strength using an isokinetic dynamometer. Muscle quality was calculated as the ratio of muscle strength (summed flexor and extensor peak torques) to lean mass of the upper leg. A force plate, sampling at 48Hz, recorded quiet standing centre of pressure (COP) with EO and EC, with 5 60s trials for each condition. Traditional measures including sway length (SL), velocity (SV) and elliptical area (EA), and non-linear measures including anterior-posterior (AP) and medio-lateral (ML) fractal dimension (D_f) [3] quantified PC. The COP D_f is a measure of its complexity; a D_f of 1 is a rigidly controlled system and close to 2 as a system with little control. Pearson's correlation coefficients determined the relationship between MQ and PC and paired samples *t*-tests compared EO and EC PC, with a significance level of $\alpha=0.05$.

Results: None of the traditional variables were significantly correlated with concentric or eccentric MQ (table 1). Significant correlations were found for concentric and eccentric MQ and ML D_f with EO ($r=0.53$ and 0.63, $p<0.001$ respectively) and EC ($r=0.41$ and 0.61, $p<0.001$ respectively). Sway length ($t(24)=-4.69$ $p<0.001$), EA ($t(24)=-3.36$ $p=0.003$) and ML D_f ($t(24)=-2.1$ $p=0.04$) were significantly greater in EC conditions compared with EO conditions; AP D_f remained unchanged. There was no relationship between MQ and traditional measures of PC, suggesting these methods provide descriptive understanding of COP, however stability is not reliant on constraining postural sway but on controlling it. The D_f provides an insight into the underlying mechanisms of PC [4]. The significant correlations between ML D_f and MQ demonstrates that higher MQ leads to a more complex system in the ML direction. Higher MQ allows greater freedom in postural movements whilst maintaining PC, without needing to freeze the degrees of freedom of postural adjustments creating a rigid, less complex system. The greater range of movement in the AP than ML direction means the AP direction is less stable. It is likely that control in the AP direction requires greater sensory input, whereas, ML control requires less input so neuromuscular function predominates. The changes in D_f in the present study conflict with previous findings where AP D_f increases in EC compared with EO and no change in ML [4]. This is possibly explained by differences in trial length, 2 minute trials used in previous literature [4] may lead to increased fatigue compared to 1 minute trials, resulting in altered

fractal dynamics. This highlights that further study is required to develop a greater understanding of the relationship between MQ and PC dynamics.

Conclusion: This study demonstrated a significant relationship between MQ and PC measured using ML D_f but not with SL, SV or EA. Thus, although overall sway is not affected there is an alteration in the mechanisms of PC associated with MQ. Clinically these findings suggest that high ML PC complexity, represented by D_f, should not necessarily be interpreted as a reduction in PC, merely the presence of sufficient neuromuscular control to allow greater freedom in postural adjustments.

Table: Mean(SD) and correlation coefficients MQ and PC variables.

Condition	Variable	Concentric MQ ($Nm.kg^{-1}$)	Eccentric MQ ($Nm.kg^{-1}$)	Mean (SD)
EO	SL (cm)	-0.12	0.02	93.78(31.11)
	SV (cm/s)	-0.12	0.02	1.56(0.52)

BALLET DANCERS X PHYSICAL EDUCATION STUDENTS CENTER OF PRESSURE SWAYS: EFFECTS OF VISION AND FOOT POSITION

Marcus F. Vieira [1,*] Maiara Ferreira [1] Paula Lobo da Costa [2] Fernanda Nora [1]

[1]Bioengineering and Biomechanics Laboratory, Universidade Federal de Goiás, Goiânia, [2]Physical Education Department, Universidade Federal de São Carlos, São Carlos, Brazil

Introduction and Objectives: Ballet dancers practice demanding equilibrium tasks for many years and are sometimes considered experts in postural control [1,2], but this fact is controversial [3]. The aim of this study was to test the vision dependence for postural control in ballet dancers during bipedal (B) and tandem (T) standing (foot position) by analyzing the center of pressure (COP) sway.

Methods: Nine semi-professional ballet dancers (BD) and 10 physical education students (PES) gave written consent to participate in this study. COP sways for both positions were collected during 60 s by an AMTI forceplate at 100 HZ in opened (OE) and closed (CE) eyes conditions. The data was filtered by a 4th order, low pass, zero-lag Butterworth filter with a 12.5 Hz cutoff frequency. After a detrend operation, global variables (area, mean velocity-Vel, 80% power frequency-F80) were calculated to analyze COP sway in anterior-posterior (AP) and medial-lateral (ML) directions. COP power spectrum was estimated using the Welch method with 2000 samples per periodogram, resulting in a spectral resolution of 0.05 Hz. Thus, F80 power frequency, which encompass 80% of the area under the COP power spectrum, was estimated. A custom MatLab code was written to calculate the variables. Significant differences between groups, vision condition, foot position and interactions were analyzed by mixed repeated measures ANOVA (GLM 5), with $p<0.05$.

Results: Vison condition: BD group did not show significant differences between OE x CE, except in T position, whereas PES group showed significant differences in both positions (Table 1). Position condition: there were significant differences between B x T positions for both groups, for all variables. Interaction: there was only significant difference between BD x PES groups for F80 AP in T position and CE condition. In general, all variables were larger for PES group.

Conclusion: The T position was more challenging for both groups. Despite Area was larger for BD group in T position, the other variables were larger for PES group, indicating PES group is more instable in the T position. PES group showed larger F80 AP in CE in T position and larger velocity in both positions, indicating lower sway amplitudes, increased ankle stiffness due to changes in ankle torque pattern [4,5]. The opposite observations can be done for BD group.

Conclusion BD seems to be less dependent of vision. Although not significant, BD seems to be more stable than PES in the conditions tested.

IMPORTANCE OF BIARTICULAR LEG MUSCLES FOR BALANCE DURING UPRIGHT HUMAN STANDING.

Dario Tokur [1,*] Christian Rode [1] Fabian Hoitz [1] André Seyfarth [1]

[1] Sport Science, Lauflabor, TU Darmstadt, Darmstadt, Germany

Introduction and Objectives: Human bipedalism is characterized by an upright trunk posture and straight knee configuration during stance phases. The trunk must be balanced during movements like walking and running. This is an ongoing task also in standing as the body sways and has to be balanced. In order to keep an upright posture, humans can employ different control strategies such as the ankle or the hip strategy [2, 6, 7, 8]. Alternatively, they can also use the stepping strategy [4].

Ground reaction forces (GRF) during human walking intersect in a virtual pivot point (VPP) above the centre of mass. Here, simulations with a simple gait model tuning the GRFs to intersect a body-fixed VPP lead to postural stability [3]. Through activation of biarticular leg muscles humans are able to manipulate leg forces perpendicular to the leg axis with appropriate leg segment lenghts and muscle moment arms [5]. In this study we assess the relevance of this concept for humans by perturbed standing experiments.

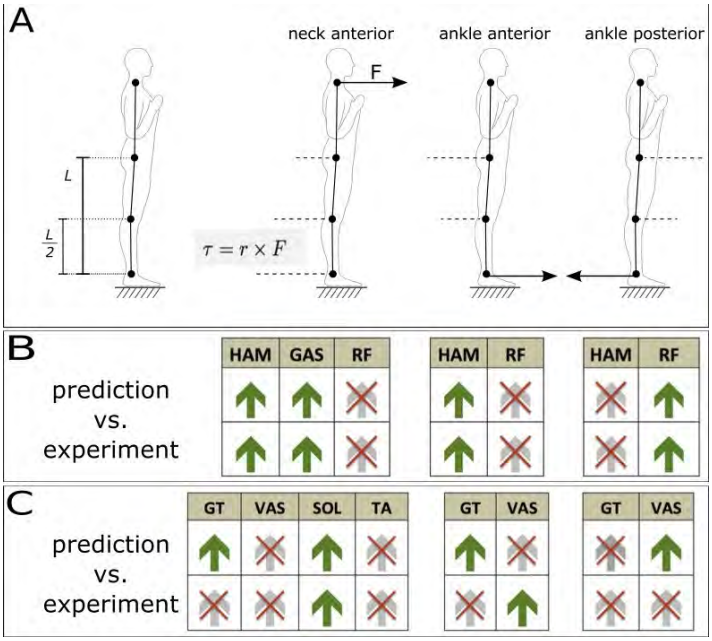
Methods: Nine healthy male subjects (24.3 ± 1.82 years, 77.6 ± 7.5 kg and 182.1 ± 7.5 cm) took part in this study. Human upright standing was perturbed by introducing constant external pulling forces (Fig. 1A – arrows; 10, 20 and 30N) at different body locations (ankle and neck) that created external torques (Fig. 1A – dashed lines) according to the pulling direction (anterior or posterior). Subjects were instructed to maintain their upright posture resulting in re-orientation of leg forces via muscles to compensate for the external perturbation. Kinematic, kinetic and electromyographical (EMG) parameters of selected mono- and biarticular leg muscles were recorded.

EMG signals were demeaned, filtered and normalized to MVC-signal (maximal voluntary contraction) as suggested by Konrad [1]. One-second means of unperturbed and perturbed standing were calculated in order to compare EMG differences under these circumstances.

Results: Figure 1 presents the results of the data analysis for selected bi- (Fig. 1B) and monoarticular (Fig. 1C) muscles. Upper rows show predicted change (green arrow up – increase; grey, crossed out arrow – no increase) in muscle activation, lower rows show the measured muscle activation. Muscle abreviations can be found in Table 1.

In contrast to monoarticular muscles, predicted changes in EMG for biarticular muscles largely comply with measured EMG changes. Moreover, seven out of ten biarticular muscles with predicted EMG increase revealed a significant positive linear relation between pulling force and EMG increase. For monoarticular muscles, this was only the case for two out of eight muscles.

Figure:



Caption: Figure1: Experimental design and results. A: experimental design with introduced external forces (black arrows), lever arm ratios (L and L/2) and resulting external torques (dashed lines) according to the perturbation location and direction (anterior or posterior). B+C: predicted (upper row) and measured (lower row) muscle activation (green arrow up – increase; grey, crossed out arrow – no increase) of biarticular (B) and monoarticular (C) muscles.

Conclusion:

Our static perturbation experiments (Fig. 1A) suggest, that upright posture can be maintained by manipulating GRF via perpendicular leg forces that are created by biarticular leg muscles. This indicates the relevance of the presented concept from Rode and Seyfarth [5] for humans.

Further data analysis comprising more sophisticated comparisons such as assessing the influence of knee angles during perturbation or a comparison with axial perturbation experiments will be done. Moreover, investigating the dynamic changes of leg force and muscle activation in response to a sudden release of the quasi static pulling force is scheduled.

RADIAL DISPLACEMENT ASSESSMENT OF BILATERAL SKELETAL MUSCLE ASYMMETRY

Lewis J. Macgregor [1,*] Angus Hunter [1]

[1]Health & Exercise Science Research Group, University of Stirling, Stirling, United Kingdom

Introduction and Objectives: Bilateral muscular asymmetry has been investigated in association with injuries [3] and athletic performance [1]. Muscle asymmetry has usually been quantified through differences in strength between contralateral limbs. Bilateral strength asymmetry of the knee extensors has been used in Sports Medicine to assess knee injury and inform rehabilitation programmes [8]. Asymmetry is commonly assessed by measures of peak isokinetic force [3], or through dynamic vertical jump tests [6]. Isokinetic or dynamic strength tests, provide information on isolated or multiple muscle groups, but cannot specifically identify issues in single muscles.

Assessment of muscle belly radial displacement is a sensitive [4] and reliable [7] measure of muscle contractile properties. This technique uses a portable displacement sensor to record muscle twitch response to a single submaximal electrical stimulus. The technique is passive and non-invasive and as such will not aggravate any existing skeletal musculotendinous injuries or impede recovery. Furthermore, the measure is unaffected by covariates such as volitional motivation. It is important to establish whether there is a direct relationship between asymmetry at the level of individual muscle twitch response and in the functional capability of the muscle group/ limb. Accordingly the aim of this study was to assess the relationship between bilateral asymmetry at the level of individual muscle twitch (radial displacement) and contractile function of the muscle group/ entire limb. This enabled us to establish the efficacy of a model for predicting functional asymmetry based on a passive, non-invasive and field based measurement.

Methods: Twenty volunteers (aged 17-45) reported to the laboratory following an overnight fast and rested in a supine position for 30 minutes. Then, muscle displacement, isometric and ballistic contractions were measured.

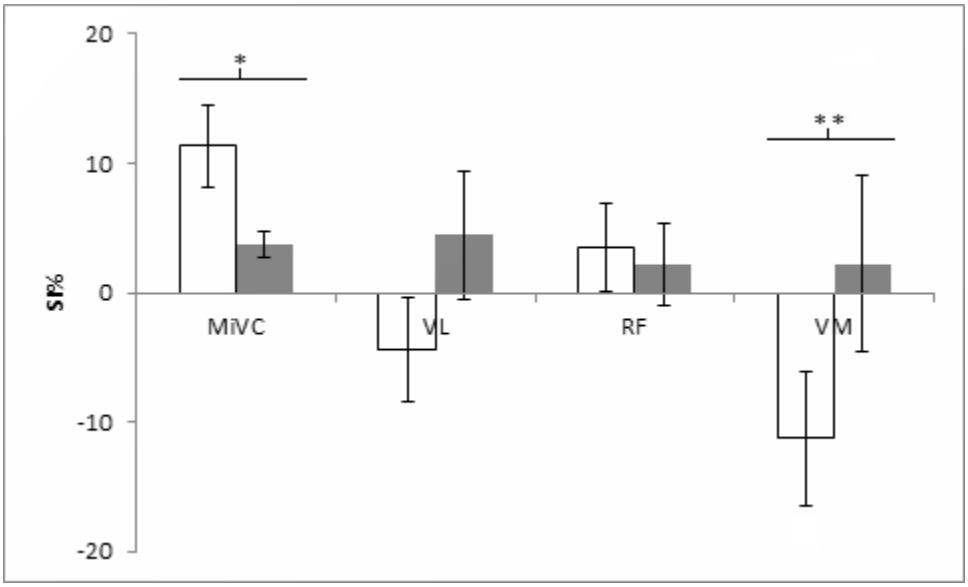
Muscle displacement responded to a 1ms electrical pulse to the muscle, through a pair of electrodes affixed to the skin directly above the muscle belly. Electrodes were located 10cm apart, with a displacement sensor (Digital-optical comparator, RLS Ltd, Slovenia) positioned perpendicular and equidistant between the two. Stimulation was progressively increased until peak muscle displacement (Dm) was achieved. This was recorded from the vastus lateralis (VL), rectus femoris (RF) andvastus medialis (VM) of both legs.

Maximal isometric voluntary contraction (MVC) of the knee extensors was assessed using an isokinetic dynamometer (Kin-Com Chattanooga Group Inc, Chattanooga, Tennessee, USA) at a knee angle of 60o (0o = full extension). Following a standardised warm up [2], three 5s MVCs were performed with 60s rest between efforts. Ballistic assessments were performed using a force platform (400 Series Force platform, Fitness Technology, Australia). Three single leg CMJs were performed on each limb. Participants performed a squat on the test leg, until a knee angle of 70o was reached, immediately a maximal vertical jump was executed, participants landed on the same single leg. For both MVC and CMJ the highest peak from the 3 repetitions was recorded for analysis. For each measurement parameter symmetry index (SI%) was calculated [4].

Using a threshold of >+10% [4] participants were categorised as asymmetric (AS) or symmetrical (SY), based on MVC and CMJ. One-way RM ANOVA with Tukey post hoc analysis was performed to explore differences in the SI% of MVC and Dm (VL, RF and VM) between SY and AS.

Results: The SI% of the SY group for MVC was significantly (p=0.032) lower than AS (3.71% compared to 11.31%). Dm in the VM was 11.27% higher in the weaker limb in AS. SI% for VM was significantly (p=0.027) different between AS and SY, as shown in figure 1.

Figure:



Caption: Symmetry index (%) of peak force and radial displacement, in the asymmetric (white) and symmetrical (shaded) groups. (VL: vastus lateralis, RF: rectus femoris, VM: vastus medialis). *: p = 0.032. **: p = 0.027

Conclusion: These findings suggest that asymmetries in VM twitch can predict functional asymmetries between lower limbs. Higher Dm in the VM of the weaker limb indicates decreased muscle tone in that muscle, compared to the VM in the stronger limb. Differences in muscle tone between contralateral muscles could be a primary predictor of functional asymmetry. This finding could pave the way for interventions, targeted at specific individual muscles, to manage injury and improve sporting performance.

LEARNING TO BALANCE ON ONE LEG

Jaap Van Dieen [1,*] Marloes van Leeuwen [1] Gert Faber [1]

[1]Human Movement Sciences, VU University Amsterdam, Amsterdam, Netherlands

Introduction and Objectives: We investigated changes in motor strategy in learning a novel balancing task. Balance control can be conceptualized as the control of the center of mass (CoM) in relation to the base of support. Three strategies are available to this end [1]: A) creating ankle moments to shift the centre of pressure (CoP), B) changing angular momentum of body segments around the CoM and C) creating a new base of support (e.g. by grabbing a handrail). Strategy C was considered task failure. We hypothesized that a shift in the use of strategies A and B would occur with training.

Methods: Fourteen young adults learned to balance on their preferred leg on a board mounted on a half cylinder with a 30 cm radius, which could rotate in the frontal plane. Subjects performed six 16-seconds trials standing on the board before training and six trials after 30 min training. LED markers on the board and on anatomical landmarks were tracked to determine CoM position and angular momentum time series. EMG of the adductor longus (AL) and gluteus medius (GM) muscles was measured. The sets of six trials consisted of two trials without manipulation, four trials with vestibular and visual manipulations. Motor strategies were investigated in the unperturbed trials only.

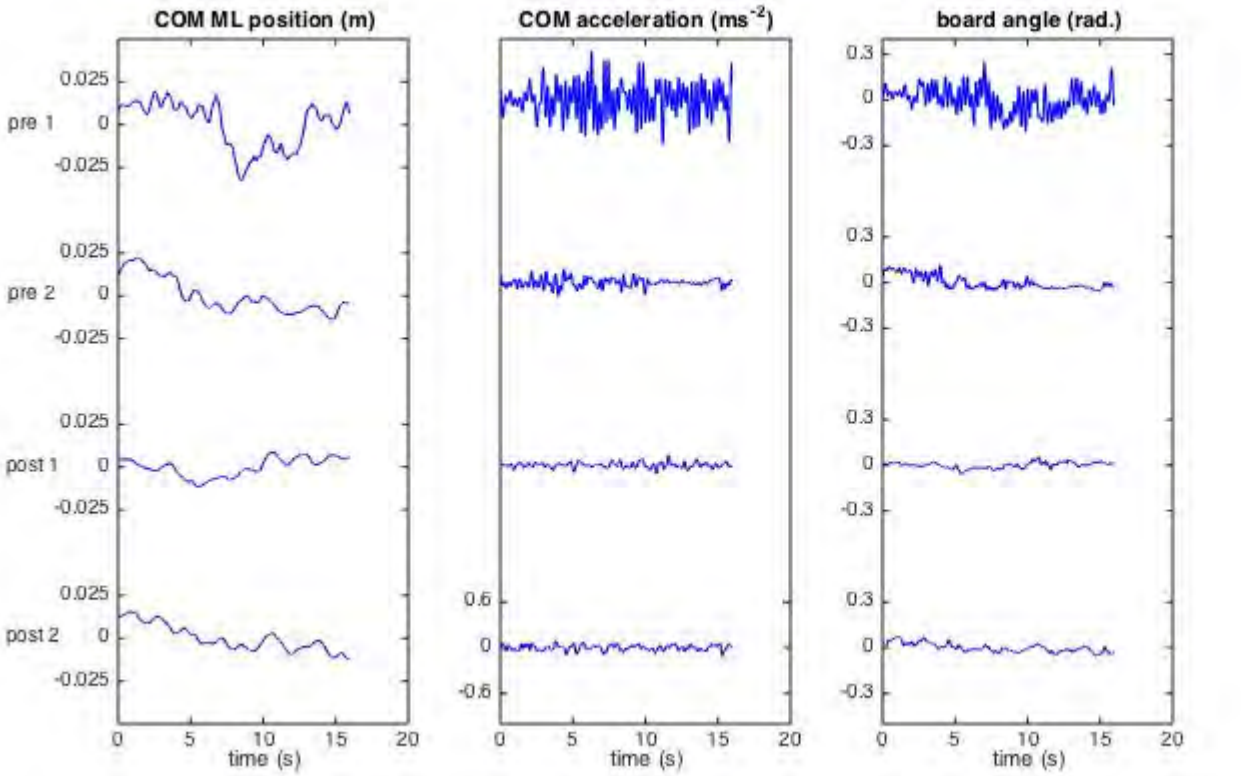
To quantify performance, the mediolateral path travelled by the CoM was determined. To assess motor strategies, we quantified the contribution of strategy B (changes in angular momentum) to CoM acceleration. In addition, we determined the means and coefficients of variation (CoV) of the EMG amplitudes. Finally, we determined the relative power of oscillations between 2.5-4.5 Hz observed in the CoM acceleration, the orientation of the board and the EMG amplitudes. Training effects were evaluated with repeated measures ANOVAs testing for effects of trial, to assess fast learning over repeated trials and for effects of 30-min training, to assess more gradual learning. In view of their distribution, EMG data were tested non-parametrically for differences between adjacent trials.

Results: Substantial postural sway and occasional loss of balance (touching the handrail) illustrated the difficulty of the balancing task. Overall angular momentum changes accounted for 70% of CoM acceleration. In most subjects angular momenta of the arms, trunk and head co-varied in-phase, apparently driven by motion around the hip of the stance leg. Substantial hip muscle activity was present in which phasic bursts were superimposed on tonic activity, sometimes reflecting reciprocal activation and sometimes reflecting co-activation. In the initial trials, strong oscillations of the CoM acceleration and the board orientation with a peak power between 2.5 and 4.5 Hz were observed in all subjects. Performance improved with training on short and long time scales as evidenced by a significant main effects of trial and training and a significant interaction effect on CoM path. The contribution of the derivative of the angular momentum to CoM acceleration decreased over trials from on average over 100%, indicating that strategy A and B counteracted each other, to about 50%, indicating that synergistic effects of both strategies. Significant main and interaction effects of trial and training on the contribution of angular momentum changes indicated a larger decrease between pre-training trials than between post-training trials. The relative power of CoM and balance board oscillations also decreased with training,

and a significant interaction reflected a substantial decrease between trials before training and a slight increase between trials after training.

Mean muscle activity of the AL and GM decreased significantly between the two pre-training trials by 36% and 26%, respectively, but did not change significantly between later trials. The CoV of the EMG amplitudes also decreased significantly between pre-training trials from about 40 to 25% for both muscles. Relative power decreased for GM only, from 50 to 34% between pre-training trials and from 34 to 26% between pre-training 2 and post-training 1.

Figure:



Caption: Typical example of the times series of the CoM position, its acceleration and the angle of the board with the horizontal.

Conclusion: Our results indicate that subjects rapidly improve performance in single leg balancing on an unstable object. Compared to standing on a rigid surface, standing on an unstable object changes the transfer function between ankle moment and CoM acceleration involved in strategy A. This apparently caused the oscillatory behavior, possibly due to too high feedback gains. In the initial trials, the ineffective use of strategy A had to be counteracted by means of strategy B. The oscillations were attenuated over subsequent trials, possibly by decreasing feedback gains, coinciding with a shorter sway path and less frequent balance loss, a reduced contribution of strategy B and reduced effort as reflected in decreased muscle activity.

MORPHOLOGICAL AND FLUID MECHANICS CHANGES TO THE CAROTID SIPHON OBSERVED IN MOYAMOYA DISEASE

Choon Hwai Yap [1,*] Muhammad Jamil [1] Mehnaz Haq [1] Heidi Kang Xue Han [2] Zhi Rui Lee [2] Phua Hwee Tang [3]

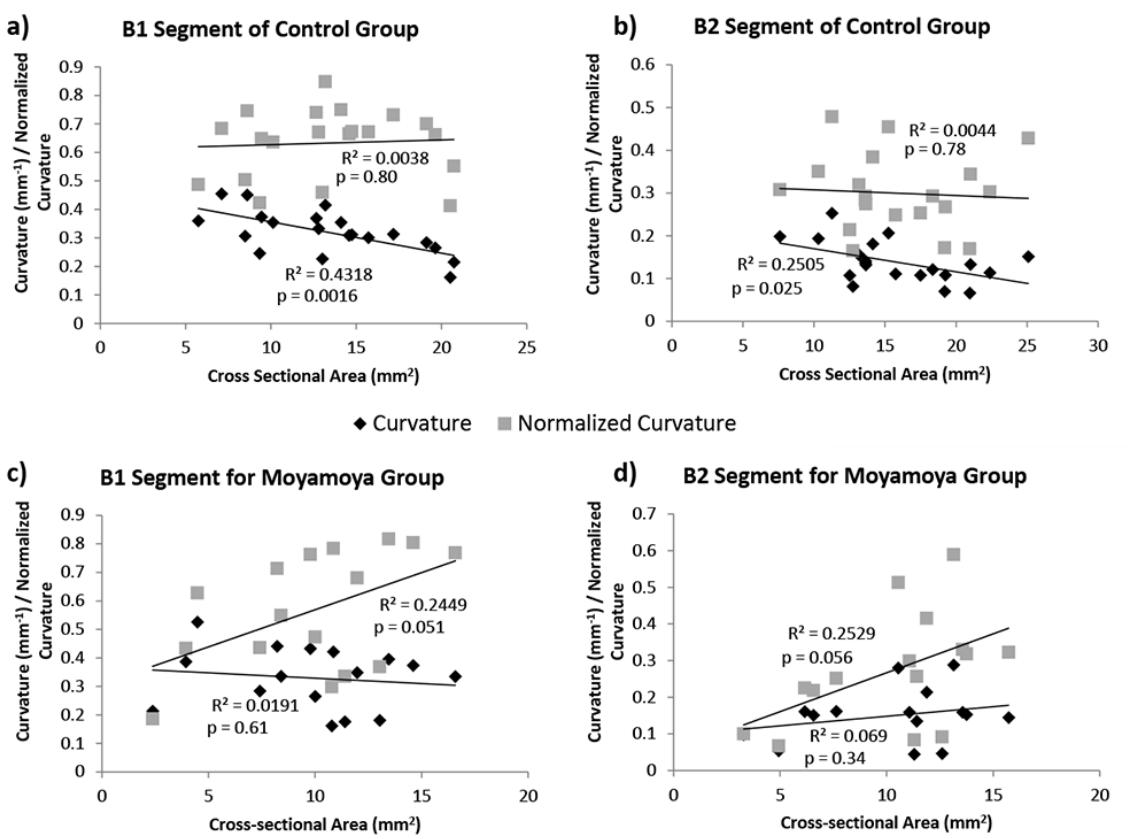
[1]Biomedical Engineering, National University of Singapore, [2]Hwa Chong Institution, [3]KKH Women's and Children's Hospital, Singapore, Singapore

Introduction and Objectives: Moyamoya is a cerebrovascular disease in which the distal end of the internal carotid artery is progressively occluded to cause deficiency of blood supply to the brain. Deficiency in blood supply then triggers angiogenesis and results in the formation of multiple small collateral arteries, which resembles a puff of smoke when viewed on CT scans. The disease was thus named: it was first reported in Japan in 1957, and was given the Japanese name of “Moyamoya” which translates to “a puff of smoke”. Moyamoya’s prevalence is 3 cases per 100,000 persons in Japan, affecting females almost twice as often than males [1], and about 0.57 per 100,000 individuals [2] in US. To date, the etiology of the Moyamoya disease is still unknown [1]. It has been hypothesized that hemodynamics plays a role in the pathogenesis of Moyamoya [3]. Canonical findings about the role of mechanical forces in vasculopathies such as atherosclerosis [4] and aneurysms [5, 6] have been presented previously. It has also been hypothesized that arteriogenesis and vascular remodeling via endothelium activation is triggered by the mechanical stimulus. Morphological aspects such as area constrictions [7], curvature [5] and torsion [8] play an important role in shaping the hemodynamics in the arteries. Study of these geometric and hemodynamic characteristics in the context of moyamoya may prove valuable in diagnosis and predicting the disease pathway.

Methods: A retrospective analysis of the Magnetic Resonance Angiography (MRA) image data from 5 Moyamoya and 10 control patients was performed. Moyamoya Data was available for both pre- and post-revascularization operations. The carotid siphon 3D geometry was segmented and analyzed for cross sectional area, curvature, tortuosity and torsion. Specific attention was paid to the proximal (B2) and distal (B1) bends of the carotid siphon. Computational Fluid Dynamics (CFD) analysis was performed to study pressure losses and secondary flows.

Results: Geometric analysis of the cross sectional area showed that Moyamoya patients had carotid siphons and internal carotid arteries which were significantly smaller in cross-sectional areas ($p<0.05$). Vessel sizes remained small even after revascularization operations. The disease also altered the relationship between the carotid siphon curvature and vascular size (Figure 1). For normal carotid siphons, the normalized curvature was found to be constant, indicating that non-dimensional shape of the siphon was retained despite growth. However, in Moyamoya disease, when the carotid siphon remodeled to change its cross-sectional area, the curvature of the siphon did not have a corresponding change, causing the vessel to deviate from having a constant normalized shape. Other geometric changes include : B2 torsion significantly increased in pre-op and post-op cases against controls, B2 tortuosity for post-op vs controls also increased significantly. Fluid mechanics analysis showed that in Moyamoya carotid siphons, the pressure drop increased and the secondary flow strength decreased as compared to the controls.

Figure:



Caption: Figure 1: Scatter plots of curvature and normalized curvature versus average cross sectional area of sections B1 & B2 respectively for Control (a-b) and Moyamoya (c-d) cases

Conclusion: Geometric and computational fluid dynamics analysis was performed on the control and diseased cases. The main findings observed are: (1) Internal carotid and carotid siphon are significantly smaller in diseased cases even after the revascularization surgery; (2) Control group growth progressed in such a way so as to keep the normalized curvature constant. In Moyamoya cases, the vascular curvature (un-normalized) remained constant and didn't keep pace with the vessel growth; (3) B2 segment of the carotid siphon had significantly higher torsion in Moyamoya patients; (4) hemodynamics changes such as higher pressure drop and lower secondary flows were observed in Moyamoya patients.

A NOVEL COMPUTATIONAL MODEL FOR THE HEMODYNAMICS OF BILEAFLET MECHANICAL VALVES IN THE OPENING PHASE

Mehdi Jahandardoost [1,*] Guy Fradet [2] Hadi Mohammadi [1]

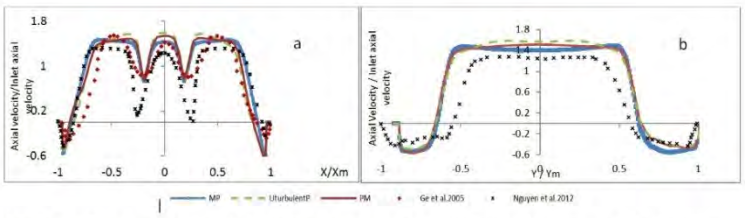
[1]Biomedical Engineering, [2]Department of Surgery , University of British Columbia, Kelowna, Canada

Introduction and Objectives: Bileaflet mechanical heart valves (MHVs) designs are known for providing a uniform flow profile and a lower incidence of structural complications. However, thrombus formation on the hinges, valve failure and leaflet escapement have been reported in certain designs. To date, in almost all of the modeling studies on the hemodynamics of bileaflet MHVs, a velocity (mass flow) based boundary condition and an axisymmetric geometry for the aortic root have been assigned which, to some extent, are erroneous. Also, the profile of velocity in downstream of leaflets has been reported contradictory. The reported values for the peak velocities range from 1 m/s to 3 m/s which highly depend on the model assumptions. The objective of this study is to demonstrate the importance of the exact anatomical model of the aortic root and realistic boundary conditions in the hemodynamics of the bileaflet MHVs. The model considered in this study is based on the St. Jude Medical (SJM) bileaflet mechanical valve in a novel modeling platform. Through a more realistic geometrical model for the aortic root and the SJM valve, we have developed a new set of boundary conditions in order to be used for the assessment of the hemodynamics of aortic bileaflet MHVs.

Methods: The present study examines both pressure- and velocity-based boundary conditions at the inlet and outlet to create the most realistic flow regime around the valve leaflets. The flow around the bileaflet MHV (SJM model) is pulsatile and encompasses the three regimes of laminar, transient, and turbulent. To predict the salient features of flow around the bileaflet MHV, the shear stress transport (SST) low-Re two-equation turbulence models were applied. There are three types of boundary conditions (BCs) considered in this study: (1) mass flow inlet and pressure outlet (MP), (2) turbulent fully developed velocity inlet and pressure outlet (UturbulentP), and (3) pressure inlet and mass flow outlet (PM).

Results: The velocity field around the valve leaflets, the vortex shedding after the leaflets, the secondary flow regions in the sinuses, etc., at three time phases of acceleration, maximum flow, and deceleration were extensively studied. In the following figure (“a” and “b”), the comparison between the velocity profiles of the current study and the study carried out by Ge et al. 2005, [1], and Nguyen et al. 2012, [2], are shown at the section downstream of the valve normal and parallel to the leaflets.

Figure:



Velocity profiles downstream of the valve normal to the leaflet and at maximum area location, (a) Re=7000 at t=0.5T (Max flow phase); (e) Re=7000 at t=0.5T (Max flow phase)

Conclusion: We have developed a new computational platform by which the hemodynamics of bileaflet mechanical heart valve can be assessed precisely. We quantitatively showed the importance of realistic aortic root geometry and boundary conditions on the hemodynamics of bileaflet mechanical valves. The results of the current study are significant for the design improvement of conventional bileaflet MHVs and for the design of the next generation of prosthetic valves.

MODELLING TEAR PROPAGATION IN THE ARTERIAL WALL

Lei Wang [1,*] Steven Roper [1] Xiaoyu Luo [1] N.A. Hill [1]

[1]School of Mathematics and Statistics, University of Glasgow, Glasgow, United Kingdom

Introduction and Objectives: An arterial dissection is an axial tear within the wall, which may create a false lumen through which blood flows. Propagation of the tear can quickly lead to death as a result of decreased blood supply to other organs, damage to the aortic valve, and sometimes rupture of the artery. We aim to compute the potential for tear propagation, with the ultimate aim of providing a quantitative prediction on the outcome of an existing arterial dissection, so aiding its clinical management.

Methods: To consider the propagation of an arterial dissection, we use a computational model that includes nonlinear deformation and pressure-driven failure of the arterial wall.

For failure criterion, we employ an energy approach, extending the Griffith energy balance principle [1] in linear elasticity to fibrous soft tissues with finite deformation. The material model is the Holzapfel-Gasser-Ogden constitutive law [2]. The geometry is simplified to that of an axisymmetric thick-walled cylinder and the small communicating tear is also ignored. An axisymmetric axial tear of length a is included in the centre of wall subject to a constant pressure p, assumed to be equal to the mean pressure in the lumen. Employing the finite element method through FEAP [3], we calculate the difference in the potential energy $E(a)$, before and after extending the tear from length a to $a+da$. If $E(a)-E(a+da)>G_c da$ where G_c is the minimum energy required for breaking the bonds of the tissue per unit length, the tear propagation is deemed to be energetically favourable.

Results: We report the effect of collagen fibre orientation and identify the regions with high risk of propagation in (a,p). Similar to our early result for a two-dimensional arterial wall strip [4], the result reveals that increasing either the tear length or the pressure enhances the energetically favourable propagation. Changing the orientation of fibres can slow down the tear propagation, and a tear arrest can occur when the surrounding connective tissues with sufficient stiffness are included.

Conclusion: We have developed a computational model for predicting the tear propagation in an axisymmetric thick-walled cylinder. The results provide some insights into the behaviour of the pressure-driven tear propagation in the arterial wall and other fibrous soft tissues.

ANEURYSM FORMATION: THE ROLE OF SAMPLE THICKNESS IN THE EXPERIMENTAL DATA COLLECTION

Serena de Gelidi [1,*] Gianluca Tozzi [1] Andrea Bucchi [1]

[1]School of Engineering, University of Portsmouth, Portsmouth, United Kingdom

Introduction and Objectives: Despite several experimental methodologies are available to characterize mechanical properties of soft biological tissues, a standard protocol is still missing.

In order to determine the stress achieved in the stretched materials, measurement of sample thickness represents a crucial step. Typically, the thickness is measured for each specimen by laser micrometer [1] or assumed constant for all samples tested [2]. This study aims at investigating the formation of aneurysm, using uniaxial tensile tests performed on healthy porcine descending aortas. The impact of current practice in thickness estimation is assessed by means of finite element predictions.

Methods: Porcine aortas were collected from a local farm house about one hour after sacrifice. The tissue was stored in isotonic saline solution at -20°C within 4 hours [3]. Dumb-bells shapes were cut out by means of a custom made die, ISO 37:2005(E), type 4, from thoracic aortas. Thickness and initial length were optically determined using a customised Matlab® script (Mathworks, Massachusetts, US) for each sample. In order to enhance the contrast of the region of interest (ROI), a black background was applied for the estimation of the thickness. Similarly, a white background was used for the initial length. In both cases, Sobel edge detection method is applied on the ROI, which was manually selected (Figure 1). Pixel conversion in mm is based on the grip dimensions, previously measured by an electronic calliper.

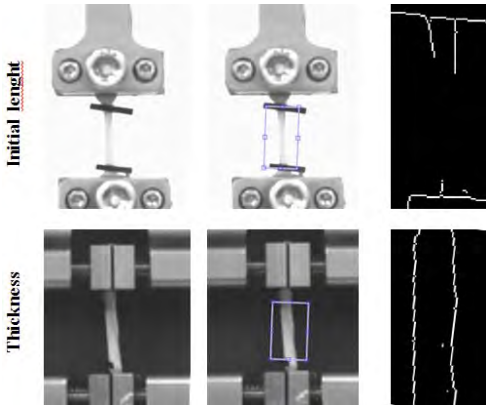
Six samples were pre-conditioned by 5 cycles performed at $1.2 Hz$. Uniaxial tensile tests were carried out at $0.2 mm/s$ speed rate onto a BOSE® Electroforce (Model, Bose Corporation, USA) equipped with a 250N load cell.

Three values of thickness were considered for the stress evaluation: sample specific (through MatLab script), $1.5 mm$ and $3.5 mm$ constant. For each of them, the stiffest and the softest stress-strain responses were selected.

Filtered stress-strain data were fitted by 1st order Ogden, Neo-Hookean and Yeoh strain-energy functions and imported in a simplified artery, modelled as a tube in Abaqus® (Dassault Systèmes S.A., France). Four node shell elements with reduced integration (S4R) were adopted to mesh the tube, being the radius equal to $9.5 mm$, thickness $1 mm$ and length $200 mm$ [4]. As boundary conditions, both ends were fully constrained and an internal inflating pressure with magnitude of $1 kPa$ was applied. Elastic instability, representing aneurysm formation, was investigated by modified Riks method [5].

Results: No critical pressure was obtained for the Yeoh strain-energy function, although this fits all the experimental data. Critical pressure values for the other two strain-energy functions are reported in Table 1.

Figure:



Caption: Figure 1 - Steps of Matlab script: ROI selection and application of Sobel edge detection method.

Conclusion: A novel method to estimate the sample specific thickness is presented. Differently from other works [1], the thickness value is computed as the average of all points included in the ROI (Figure 1).

Critical pressure values appear to be considerably scattered when a constant value of thickness is assumed in the stress calculation (Table 1). Comparing results related to the stiffest and the softest data for each thickness, the minimum scatter (~1kPa) is obtained for the sample specific thickness. Therefore, the most accurate prediction seems to be related to a precise thickness determination (Matlab script) as proposed in this work.

Extension of this work will include biaxial tensile tests combined with FE simulations on a model of descending aorta, as a refinement of the presented tube.

Table:

Strain-energy function	sample specific		1.5 mm		3.5 mm	
	stiffest	*softest*	*stiffest*	*softest*	*stiffest*	*softest*
1st order Ogden	8.678	no CP	2.072	no CP	6.609	no CP
Neo-Hookean	8.376	7.754	5.730	6.298	7.668	11.888

Caption: Table 1 - Critical pressure values [kPa] obtained for the stiffest and softest stress-strain behaviour calculated for three different thickness values: sample specific, 1.5mm and 3.5mm. When no critical pressure is reached, "no CP" is reported.

ELLIPTIC ST. JUDE BILEAFLET MECHANICAL HEART VALVES

Hadi Mohammadi [1,*] Mehdi Jahandardoost [1] Guy Fradet [2]

[1]Biomedical Engineering, [2]Department of Surgery , University of British Columbia, Kelowna, Canada

Introduction and Objectives: St. Jude Medical (SJM) bileaflet mechanical valves were approved by the Food and Drug Administration in 1977. The SJM valve design consists of two semicircular leaflets which pivot on hinges. It provides good central flow, the leaflets open completely, and the pressure drop across the valve is trivial. However, non-physiological hemodynamics around these valves may lead to red blood cells lysis and therombigenic complications. Also, the regurgitation-flow in SJM valves is almost twice that of the native valves in the aortic position. In this study, we suggest a new design for the stent (housing) of SJM valves in which 15% ovality is applied to the stent whereas its perimeter remains constant.

Methods: In a pilot study, the hemodynamic performance of the proposed design is analyzed in the closing phase and compared to that of conventional SJM models. The fluid analysis (Blood) is based on the control volume with moving boundaries in the vicinity of the leaflets. To solve governing equations in order to calculate the pressure and the related force, finite strip method has been implemented. Only 32 strips is enough to calculate the force due to pressure applied on the leaflets. To solve equations of motion Runge-Kutta in forth order has been implemented [1].

Results: Results show that while the elliptic SJM model offers a shorter closing phase (9.7% shorter), the regurgitation flow remains almost unchanged. In other words, even though the dynamic response of the valve is improved, the regurgitation flow is not decreased. Thus, a more efficient effective orifice area (EOA) is shown to be provided by the proposed model. The proposed model is shown in the following figure.

Figure:

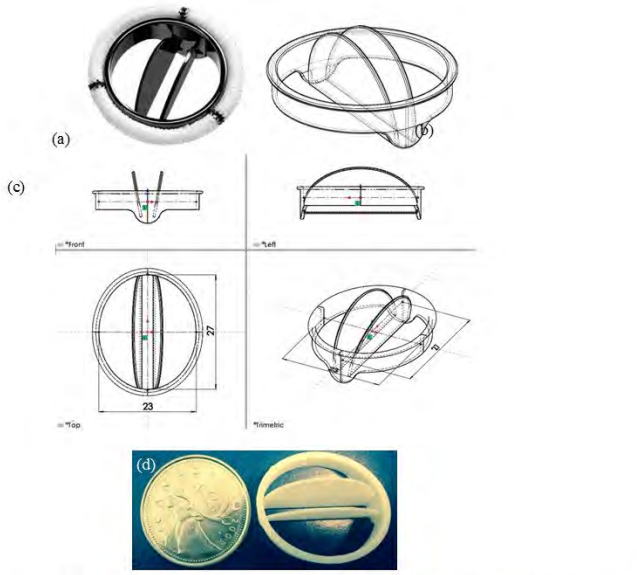

Figure: The conventional SJM valve (a); our design of conventional SJM model (b); the engineering drawing the proposed elliptic SJM valve (c); and the fabrication of the proposed elliptic SJM model (d)

Conclusion: The preliminary calculations presented in this study justify an improved hemodynamics of elliptic SJM valves compared to conventional models; the proposed design shows promise and merits further development.

ANATOMY OF A 2.40 METER HIGH JUMP

James Becker [1,*]

[1]Kinesiology, California State University, Long Beach, Long Beach, United States

Introduction and Objectives: As an event, the high jump has been heavily researched. Many of these studies have been performed in practice settings or controlled research environments. For competition specific jumps, there have been detailed biomechanical studies on the men's high jump conducted at the IAAF Junior and Senior World Championships. Additionally, there have been numerous competition reports from Jesus Dapena and colleagues based on data collected at the USATF National Championships in the United States. However, in all these reports, no jumps over 2.40 have been reported. In fact, there currently is no data in the literature documenting a jump over 2.40 meters. This is not totally surprising since this feat has only been accomplished by 12 individuals. The purpose of this study is to report a detailed biomechanical analysis of three of the twelve 2.40 meter jumps which occurred during the 2014 track & field season. These jumps include Derek Drouin's (DD) 2.40 clearance at the Drake Relays in April 2014, and clearances of 2.42 by both Bohdan Bondarenko (BB) and Mutaz Essa Barshim (MEB) at the Adidas Grand Prix in June 2014.

Methods: Jumps were recorded using four HD video cameras (JVC GC-PX10, JVC Corp.), with two cameras filming jumpers approaching from the left side and two cameras filming jumpers approaching from the right side. A frame rate of 60 Hz and a shutter speed of 1/1000 was used for all recordings. A 68 point calibration frame with dimensions of 2m x 2m x 2m was used to calibrate the area encompassing the athlete's approach from approximately 6 steps out from plant through to the takeoff and flight phases. The calibration frame was placed in multiple positions and a multiphase DLT calibration was used to calibrate the full volume. Twenty body landmarks were manually digitized from five steps out from the plant through until the jumper landed on the pit. The two cameras were synchronized using the timing of foot contact and toe off for the last four steps of the approach and three dimensional coordinates were reconstructed using the direct linear transformation. Coordinates were smoothed using an interpolating quintic spline function. The whole body center of mass (COM) was calculated as the weighted sum of the individual segment center of mass locations based on Dempster's data. Finally, custom software was used to calculate commonly reported descriptors of high jump performance.

Results: COM Heights: The height of the COM when the takeoff foot touched down was 49.8%, 52.0%, and 52.6% standing height for MEB, BB, and DD, respectively. All three athletes raised their COM to over 70% of their standing height by the time their takeoff foot left the ground. In terms of overall COM trajectory, both BB and DD demonstrated their lowest point during mid-support on their penultimate step while MEB's lowest point was immediately after the takeoff foot touched down. As a result, MEB had a large negative vertical COM velocity (-0.4 m/s) when the takeoff foot touched down while BB and DD had values of -0.2 and 0.1 m/s, respectively. However, at the time the takeoff foot left ground, MEB had a vertical COM velocity of 4.8 m/s compared to 4.5 m/s for both BB and DD. This resulted in MEB's peak COM height being 2.52 m. while BB and DD only raised their COM to 2.47 and 2.42 m., respectively.

Approach Velocities: The horizontal velocities of the COM at touchdown of the takeoff foot were remarkably fast at 8.1 m/s, 8.0 m/s, and 7.9 m/s for MEB, BB, and DD, respectively. Pooling data from numerous sources in the literature suggest these velocities are in the 95th percentile for MEB and BB, and the 85th percentile for DD. All three jumpers achieved at least 70% of their approach velocity prior to entering the curved portion of the approach. During the curve, all three athletes increased their step frequencies as they got closer to the takeoff step while maintaining relatively consistent step lengths. Layout of the Approach: All three athletes showed smooth, gradual reductions in orientation relative to the bar during the curved portion of the approach. This resulted in inward leans of the torso of 14.7°, 20.4°, and 15.9° away from the bar at the time of touchdown of the takeoff foot for MEB, BB, and DD, respectively. During the takeoff the athletes rotated so they were leaning 3.2°, 6.0°, and 4.8° towards the bar, respectively.

Conclusion: These data show several common factors for elite level high jumping including using a high approach velocity, generating momentum early in the approach, and laying out the width of the curve so that it results in a smooth curve. If done correctly, the resulting postures allow for the generation of appropriate amounts of angular momentum during the takeoff which leads to an effective bar clearance. Despite these similarities, differences were observed in the way the athletes lowered their COM during the penultimate step. Functional consequences of these differences are not yet clearly understood.

AS-0447

OPTIMUM TECHNIQUE FOR MAXIMISING HEIGHT IN A STRAIGHT HANDSPRING SOMERSAULT VAULT

Michael Hiley [1,*] Maurice Yeadon [1]

[1]SSEHS, Loughborough University, Loughborough, United Kingdom

Introduction and Objectives: The mechanics of the table contact phase of gymnastics vaulting is dependent on the initial contact conditions and the technique used during the contact phase. Although there are numerous coaching publications on vaulting, there is no general consensus about the importance of table contact technique. The aims of this study were to investigate the effect on peak post-flight height of the straight handspring somersault vault (Figure 1) arising from (a) initial conditions at touchdown and (b) joint torques during the contact phase (technique).

Methods: In order to investigate the effects of initial conditions and table contact technique on vaulting performance a torque-driven computer simulation model was developed. The model simulated the interaction between a seven-segment gymnast and a single-segment vaulting table during the table contact phase of the vault. The torque generators were defined based on the measured torque / angle / angular velocity relations and represented the maximum voluntary torques that the gymnast could produce (Forrester et al., 2011). An evaluation of the model was conducted by assessing how accurately simulations matched the recorded performances of three recorded vaults.

Three optimisations were carried out in order to maximise the post-flight height under different conditions. In the first optimisation the table touchdown configuration and orientation were varied whilst while torque activations from the matched simulation were maintained. The second optimisation used the touchdown configuration and orientation from the recorded performance and the torque activation parameters were varied in order to determine the potential improvement arising from contact phase technique changes. In the third optimisation the configuration, orientation and torque generator activation parameters were allowed to vary in order to maximise post-flight height. The model was constrained to stay on the parabola defined by the gymnast's horizontal and vertical velocity at springboard take-off in all optimisations.

Results: The peak post-flight height of the recorded vault was 2.72 m. When the configuration and orientation at touchdown were varied (optimisation 1) the peak post-flight height increased to 2.83 m (Table 1). When only the torque activation parameters were varied (optimisation 2), the peak post-flight height increased to 2.82 m. In the third optimisation where the touchdown configuration and orientation along with the table contact activations were allowed to vary the peak post-flight height increased to 3.12 m.

Figure:

Caption: Figure 1. The straight handspring somersault vault.

Conclusion: The aim of this study was to investigate the extent to which the conditions at vaulting table touchdown and the technique during table contact affected peak post-flight height during a straight handspring somersault vault. When only the initial configuration and orientation of the model were allowed to vary, an increase in peak post-flight height of 0.11 m was achieved compared to the recorded performance. When only the technique during table contact was allowed to vary, the increase in peak post-flight height was 0.10 m. These results suggest that changes in initial conditions and contact technique have a similar influence on post-flight height.

The increase in height of 0.41 m between performance (2.72 m) and optimum simulation (3.13 m) when both configuration and technique were allowed to vary may seem rather high but it is consistent with the heights reached in elite performances of handspring double front somersault vaults (3.0 ± 0.1 m) which have a similar angular momentum requirement (Takei, 2007). This suggests that the improvement is feasible.

The straight handspring somersault vault has previously been optimised for both post-flight height and distance using a passive two-segment simulation model (King et al., 1999). The optimal configuration during the instantaneous table contact was found to be with 178° between arms and torso. In the recorded performance and optimisations the configuration exhibited an angle at the shoulder and varying amounts of hip hyperextension (Table 1). Opening the shoulder angle during table contact allows the gymnast to do work and increase the post-flight height.

Table:

Simulation	Gymnast	Opt1	Opt2	Opt3
Touchdown angles				
torso [°]	5°	-21°	5°	-33°
shoulder [°]	134°	102°	134°	97°
hip [°]	187°	204°	187°	202°
Post-flight				
peak height [m]	2.72	2.83	2.82	3.13
rot. potential [ss]	1.37	1.34	1.34	1.35
time [s]	0.92	0.97	0.95	1.08

AS-0448

NOVEL EVIDENCE OF SOCCER BALL KICKING TO PRACTICAL COACHING INSTRUCTIONS

Hiroyuki Nunome [1,*] Hironari Shinkai [2] Yasuo Ikegami [3]

[1]Fukuoka University, Fukuoka, [2]Tokyo Gakugei University, Tokyo, [3]Aichi Shukutoku University, Nagoya, Japan

Introduction and Objectives: In soccer kicking, ball impact is the most crucial component of the skill for determining both the quality of ball impact and the resultant ball velocity. Much practical advice exists on how to impact on the ball and handle the ball impact phase. For example, coaches often advise players to 'kick through the ball' or 'push the ball as long as possible'. However there has been limited evidence to support these types of instruction from a biomechanical perspective. The present study aimed to better develop our understanding of soccer ball impact phase, and to shed some light on the veracity of some practical coaching instructions currently used.

Methods: To illustrate representative ball impact phase kinematics, the instep kicking motion through ball impact was captured at 1000 Hz and a new time-frequency filtering algorithm which allowed changing the cut-off frequency along the time was applied to the coordinates (Study 1). Also, to clarify detailed foot--ball interaction during ball impact, a mathematical model was developed to compute the centre of gravity of the deforming ball using high-speed video records (Study 2, see Figure 1). Additionally, the relationship between the ball velocity and contact time was detected through an experiment, in which a regular soccer ball was directly fired by a soccer ball launching machine at a force platform fixed vertically on a pedestal with five different velocities (Study 3).

Results: Angular and linear velocity changes observed in Study 1 were very different from those reported previously. In fact, the shank was still angularly accelerating and the foot was still linearly accelerating up until the moment of ball impact, with both reaching their peak angular and linear velocity at, or up to 2 ms, after this moment. In Study 2, the change of the foot CG velocity, the ball CG velocity and the ball deformation during ball impact suggested interesting aspects of ball impact dynamics during kicking. First, the foot acts to deform the ball (phase I), followed by ball acceleration until foot and ball speeds are similar (phase II). The ball then begins to reform while still accelerating (phase III). The last phase shows little interaction between foot and ball suggesting no influence on ball speed. Moreover, Study 3 confirmed a strong, negative relationship between the ball velocity and contact time.

Conclusion: Our research group succeeded in providing kinematic evidence that strongly supports the practical advice of kicking like 'kick through the ball' focusing on the motion after the foot contacts with ball. On the other hand, the nature of ball impact dynamics have highlighted a gap between what players try to do and phenomena actually happening on the foot during ball impact. Study 2 revealed that it is impossible for players to intentionally lengthen ball contact time and there is a negative relationship between ball contact time and resultant ball velocity. Some coaching cues seem to be inaccurate, in particular for ball impact time, but some of them like 'kick through the ball' have recently been supported scientifically and likely work to fine tune the kicking technique.

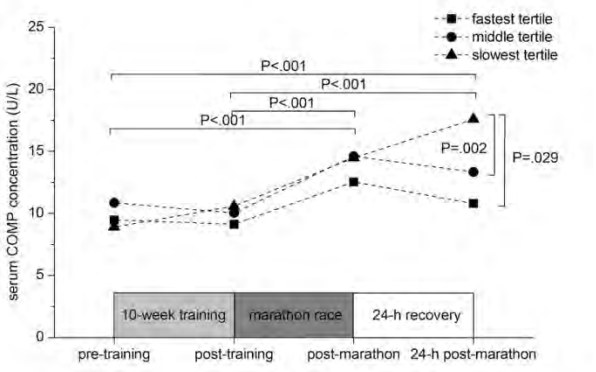
EFFECT OF REGULAR RUNNING TRAINING AND MARATHON RUNNING ON SERUM COMP CONCENTRATIONS IN NORMAL-WEIGHT AND OBESE RUNNERS

Annegret Muendermann [1 2,*] Jeroen Geurts [1] Thomas Nickel [3] Arno Schmidt-Trucksäss [4] Martin Halle [5] Henner Hanssen [4]

[1]Orthopaedics, University Hospital Basel, Basel, Switzerland, [2]Sport Science, University Konstanz, Konstanz, [3]Medizinische Klinik und Poliklinik 1, Ludwig-Maximilians-Universität München, Munich, Germany, [4]Institute of Exercise and Health Sciences, University Basel, Basel, Switzerland, [5]Department of Prevention and Sports Medicine, Technische Universität München, Munich, Germany

Introduction and Objectives: Healthy cartilage undergoes constant turnover of cartilage constituents, including collagen, proteoglycans, and cartilage oligomeric matrix protein (COMP), although at different rates. While there are a number of markers for cartilage turnover, COMP may be involved in the pathomechanics of osteoarthritis [1]. Several studies have shown that serum COMP concentration decreases in response to unloading [2] and increases in response to exercise where it returns to baseline within 30 min to 1 hour after mild to moderate exercise [3] and within 24 to 48 hours after a marathon race [4]. However, the effects of regular exercise training and acute bouts of prolonged exhaustive exercise on serum COMP concentration in obese persons—who are at a higher risk of developing osteoarthritis [5]—have not been investigated. The objective of this study was to test if changes in serum COMP concentration in response to regular running training and acute marathon running differ between normal-weight and obese runners with different fitness levels.
Methods: Forty-five subjects participated in this study (IRB approved) after providing informed consent (Table 1). Subjects were divided into three groups, obese recreational (BMI ≥ 30 kg/m^2), lean recreational and competitive runners [6]. All subjects completed a 10-week running training prior to participating in a marathon race. Blood samples were taken at the beginning of the training, and immediately before, immediately after and 24-hours after the marathon race, and serum COMP concentrations were determined using ELISA kits. Repeated measures ANOVA was used to determine the effect of running on COMP with between subject factor group and covariates BMI, age, 10-week running distance and finishing time. Because of the non-significant group effect and a significant time*finish time effect, the analysis was repeated with factor finishing time tertiles and Fisher's LSD posthoc tests ($P<.05$).
Results: Only small change in COMP were observed during the regular training program. COMP increased by 44% during the marathon race ($P<.001$). COMP did not differ between groups defined by running level, age, 10-week running distance or BMI at any time point. However, finishing time significantly influenced changes in COMP over time. COMP in subjects in the fastest (-12.8%) and middle tertile (-2.8%) decreased while COMP in subjects in the slowest tertile increased (+22.4%) within 24 hours after the marathon race ($P<.001$). Although BMI did not significantly influence changes in COMP levels, BMI was significantly greater in the slowest tertile than in the middle and fastest tertile ($P<.001$).

Figure:



Caption: Fig 1. Serum COMP concentration before and after regular running training and marathon running in the fastest, middle and slowest runners.

Conclusion: Interestingly, finishing time appeared to be a stronger predictor of changes in COMP during the 24 post-marathon recovery than the subjects' body weight or running level. Although the running distance was the same for all subjects, those with slower finishing times presumably took more steps during the marathon. A previous study [4] has shown that COMP takes up to several days to recover after longer running races including ultramarathons. Similarly, it is possible that in the slowest runners in our study, the marathon may represent a relatively greater exercise stress compared to their regular running training than in the middle and fastest runners. These finishing time related post-marathon changes in COMP may represent differences in post-stress tissue metabolism between groups. Such differential metabolic responses in different groups of runners may explain the low prevalence of OA in former elite marathon runners [7] and warrants further investigation to understand the effect of and the recovery after acute bouts of prolonged exhaustive exercise especially in slower runners. In general, not only the response to but also the recovery from a bout of exercise may contain critical information on the health status of cartilage.

Table:

	Slowest tertile	*Middle tertile*	*Fastest tertile*	*P-value*
N	15	16	14	
Age (years)	40.1 (7.4)	40.9 (6.3)	38.9 (4.8)	.691
Height (cm)	182 (7)	179 (8)	181 (4)	.467
Body weight (kg)	94.6 (14.7)*	78.4 (12.6)	76.4 (4.9)	<.001
BMI (kg/m^2)	28.4 (3.3)*	24.3 (3.0)	23.3 (1.0)	<.001
Finishing time (min)	291.3 (16.5)*	244.6 (12.2)*	201.3 (14.7)	<.001

* significantly different from the faster groups (P<.05)

ABILITY TO MODULATE MUSCLE SYNERGY IS THE KEY ASPECT THAT DISTINGUISHED COMPETITIVE ROWERS FROM NOVICE

Shazlin Shaharudin [1,*] Sunil Agrawal [2]

[1]Sports Science Unit, Universiti Sains Malaysia, Kota Bharu, Malaysia, [2]Mechanical Engineering, Columbia University, New York, United States

Introduction and Objectives: The robustness of muscle synergies have been extensively studied across different variables. However, no study has been done to determine the robustness of muscle synergies across different physiological demands which is particularly important during rowing because huge muscle mass are being recruited following the high intensity exercise. It was shown previously that muscle synergies are highly associated to rowing economy [1]. The objective of the study is to evalute the key strategy for competitive rowers to remain efficient during intense rowing events.

Methods: Ten collegiate rowers and ten physically active males were recruited. Muscle synergies were extracted from 16 rowing specific muscles using Principal Component Analysis with varimax rotation. Three specific physiological tests were conducted to examine the robustness of muscle synergies across different energy demands. Rowing performance, movement economy, kinematic and physiological variables were analyzed.

Results: Three functional muscle synergies with high indices of similarity were extracted in both groups, across three specific physiological tests. Synergy #1 which comprised of leg and back muscles and Synergy #2 which consisted of upper limb muscles were activated during drive phase, while Synergy #3 engaged during the transition of strokes. Despite equivalent level of fitness (e.g. $VO_{2\,max}$ and maximal heart rate values), the rowers performed better than novices in terms of rowing performance variables (e.g. distance covered, economy of movement, energy expenditure and power output), which ruled out physiological fitness as a bias in this study. Significant association was found between muscle synergies and rowing economy. Rowers utilized different rowing strategy with longer and slower strokes compared to the untrained subjects. The temporal adjustment of muscle synergies by rowers group enhanced their economy of movement.

Conclusion: The rowers were able to achieve better rowing economy due to their longer-slower rowing strokes which is a characteristic of practice-related adaptation that decreases energy expenditure [2]. Developing economical rowing strokes should be the focus of beginners, while the experienced rowers could achieve better rowing performance by enhancing muscles coordination. The findings of this study could be applied by fine-tuning the temporal aspect of muscle coordination in order to enhance the economy of movement which will lead to better performance in sports.

GUSIMBUKA URUKIRAMENDE: WERE AFRICAN HIGH JUMPERS THE REAL WORLD CHAMPIONS?

Ine Van Caekenberghe [1,*]Peter Aerts [1 2]Wim Derave [1]Matthieu Lenoir [1]Veerle Segers [1]Dirk De Clercq [1]

[1]Department of Movement and Sports Sciences, Ghent University, Ghent, [2]Department of Biology (Functional Morphology), University of Antwerp, Antwerp, Belgium

Introduction and Objectives: Extraordinary high jumping performances of 2.30 m to 2.50 m are documented in reports, photos and films of European colonists visiting ceremonials in Rwanda during the interbellum. Some even speak of world records [cited in 1]. However, no objective height measurements were made. The reported heights are astonishing because athletes performed a typical “Gusimbuka urukiramende” technique, resembling Western roll, on bare feet. However, they pushed off on a rock, which assisted in reaching a higher bar clearance [2]. We have digitized and analyzed historical recordings (photos and films) of Gusimbuka jumps to compare them to contemporary international performances. As such, performance level of Gusimbuka athletes could be evaluated objectively.

Methods: Belgian colonial archives were searched for recordings of high jumping sequences. Of the 5 films and 85 photos retrieved, 2 films (Terres Brulées – 1938, and L’Afrique au Jeu – 1952) and 3 photos, showing bar clearance, were used for biomechanical analyses (in total of 18 jumps of 10 athletes).

After calculating a 15-segment kinematic model (mass distribution by Dempster [3]) the apex of the body centre of mass during bar clearance ($h_{BCOM\ MAX}$), the lowest point of the body in the plane of the bar ($h_{BODY\ LOW}$), take-off height on the stone ($h_{TAKE\text{-}OFF}$) and bar height (h_{BAR}) were calculated relative to ground level (Fig.). Perspective in the images was accounted for by applying scaling factors based on perspective-induced segment length changes.

For the photos in which we can scale heights to an absolute dimension (known body height, BH, of people on the photos/films), we report the absolute performance in meter. For the film images (no spatial or temporal calibration), performance is expressed relative to BH of the athlete.

Results: For results see table.

The athlete clears the bar if $h_{BODY\ LOW}$ is higher than h_{BAR}. For maximal performances at contemporary international competitions $h_{BODY\ LOW}$ could be considered equal to the reported h_{BAR} (since athletes mostly pass just above h_{BAR}). In Gusimbuka performances, $h_{BODY\ LOW}$ mostly still is a lot higher than h_{BAR}. Therefore we will compare $h_{BODY\ LOW}$ of Gusimbuka athletes to h_{BAR} of contestants in Olympic finals in the same time period. However, two corrections still need to be made:

(1) Since non-Gusimbuka athletes take off from h_{GROUND}, $h_{TAKE\text{-}OFF}$ has to be subtracted from $h_{BODY\ LOW}$ for Gusimbuka athletes (Fig.).

(2) Furthermore, pushing off from an elevated surface elicits an added beneficial effect on jumping performance (h_{GAIN}), which also has to be subtracted from $h_{BODY\ LOW}$ to obtain the net performance. Own previous research on Fosbury jumps from an elevated surface [2] enabled to quantify h_{GAIN} for the Gusimbuka technique. In contrast to the inherent downward BCOM velocity at the onset of a push-off at ground level, a Gusimbuka athlete already has an upward velocity when

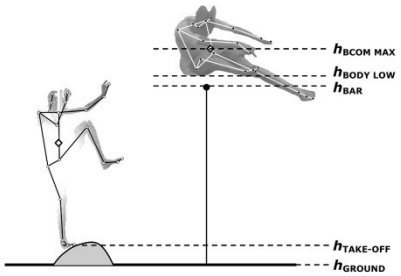
initiating his push-off from the stone. This results in a larger final vertical take-off velocity and a h_{GAIN} of 0.04 m (or about 2% of BH).

To date, only jump 1 could be dated exactly. Its net performance (1.92 m) can be compared to those of the 1928 Amsterdam Olympics, in which this height would have resulted in a silver medal.

Comparison of Gusimbuka performances in the films (in BHs) to performances at Olympic finals (in meters) can be done in two ways: (1) BH of the Gusimbuka jumpers can be estimated and used to rescale the performance to meter. (2) BH of the Olympic athletes could be determined and used to rescale their performances to BH. Both pathways are being further investigated to obtain the most appropriate comparison. Nevertheless, Gusimbuka athletes are Watutsi, which are tall people. Estimating their body height at 1.90 m, we simulated the net performances, which showed that at the Olympics in between 1936 and 1952, Gusimbuka athletes could have competed in Olympic finals. Even more, the best athletes could have won a medal.

It is currently unknown whether the analyzed Gusimbuka jumps represent the maximal performances of the Gusimbuka athletes. Further analyses of (historical and present-day) Gusimbuka performances could lead to insights for sports today. Given that Gusimbuka athletes should use the present-day jumping technique (Fosbury Flop), could they perhaps still compete at international level?

Figure:



Caption: Gusimbuka urukiramende

Conclusion: During the interbellum Gusimbuka athletes could have (successfully) competed in Olympic finals.

Table:

	PHOTOS (n=3) (meter)			MOVIES (n=15) (*BH)		
	Jump 1	**Jump 2**	**Jump 3**	**M**	**±**	**SD**
$h_{BCOM\ MAX}$	2.38	2.33	2.31	1.25	±	0.08
$h_{BODY\ LOW}$	2.16	2.13	2.12	1.11	±	0.07
h_{BAR}	1.94	2.07	2.04	1.06	±	0.07
$h_{TAKE\text{-}OFF}$	0.20	0.20	0.20	0.12	±	0.02

BIOMECHANICAL COMPARISON OF TIBIOTALOCALCANEAL AND TIBIOTALAR FUSION

Swati Chopra [1,*] Rayan Baalbaki [1] Maria Josina Pichonnaz [1] Julien Favre [1] Xavier Crevoisier [1]

[1]Site Hôpital Orthopédique, Centre Hospitalier Universitaire Vaudois (CHUV), University of Lausanne, Lausanne, Switzerland

Introduction and Objectives: Tibiotalar fusion/ ankle arthrodesis (AA) is an established surgical procedure to address end stage ankle osteoarthrosis (AOA). Tibiotalocalcaneal fusion (TTC) is a salvage procedure for diverse ankle-hindfoot pathologies which can also be used in combined osteoarthrosis of the ankle and subtalar joints. Biomechanical studies have already shown several drawbacks of AA due to altered gait mechanics [1],[2]. Furthermore, increased compensatory motion of the neighboring joints have been demonstrated in case of AA. Therefore, fusing not only the tibiotalar but also the subtalar joint would result in even greater biomechanical alteration. The study aims to investigate whether or not the fusion of the tibiotalar along with the subtalar joint is biomechanically detrimental.

Methods: 42 participants (14 in each group), including controls, 2-5 years TTC using retrograde intramedullary nailing, and AA patients were assessed using foot-worn inertial sensors (Physilog®) and pressure insoles (Pedar®) along with clinical questionnaires including: EQ 5D, AOFAS-hindfoot and FAAM. Each subject performed 4 walking trials of 50m, 2 trials per foot. Plantar pressure parameters (PPP) assessed included total contact duration (Tc), Max Force (Max F), Max Pressure (Max P) in 10 foot regions. Kinematics analysis included assessment of the sagittal range of motion (ROM) at MPJ1, midtarsal and tibio-calcaneal segments. Spatiotemporal parameters (STP) included cadence, stance, double support, stride, speed, peak swing speed, toe-off and heel-strike pitch angles and inner stance duration- loading, foot-flat and push-off. All together 30 PPP (3 in each of the 10 foot region), 3 ROM and 11 STP parameters were assessed. Statistical analysis included the use of Wilcoxon signed-rank and Wilcoxon rank sum tests for intra-individual and inter-individual comparison, respectively ($p<0.05$).

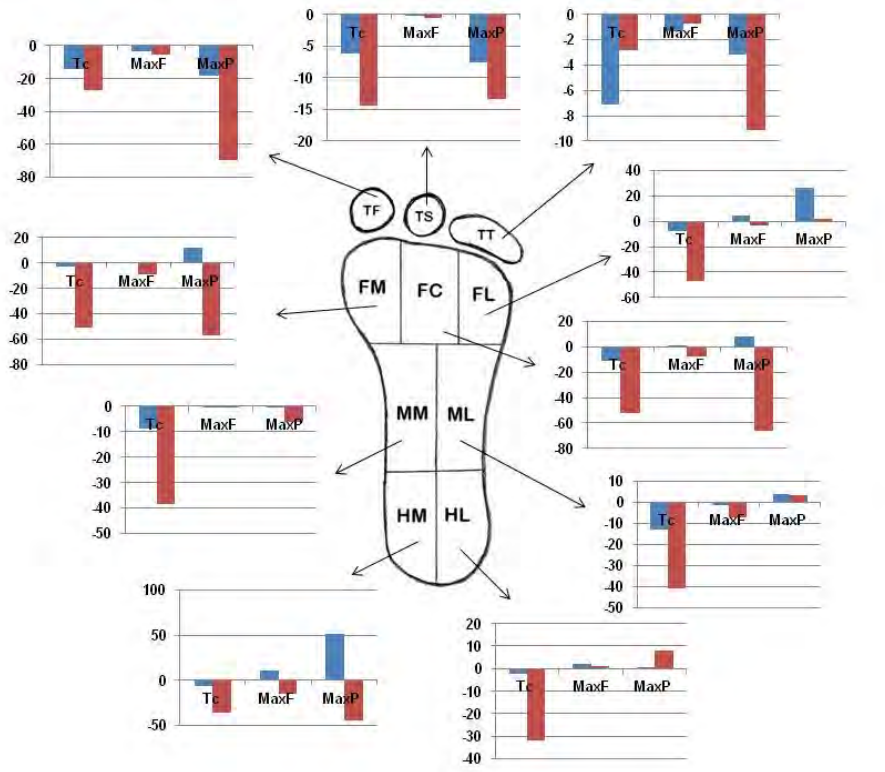
Results: All three subjective scores showed no significant difference between the outcomes of the two surgical groups. Gait results with significant difference ($p<0.05$):•

AA operated (op) foot vs TTC op foot comparison- PPP: 4 out of 30 parameters; ROM: Sagittal- all 3 joints.

- TTC op vs unop side comparison- PPP: 5 out of 30; ROM: Sagittal- MPJ1, ankle; STP 3 out of 11 parameters.
- TTC op vs control comparison - PPP: 11 out of 30; ROM: Sagittal- all 3 joints, STP 9 out of 11 parameters.
- TTC unop side vs control comparison - PPP: 11 out of 30; ROM: Sagittal: MPJ1; STP: 10 out of 11 parameters.

Figure 1 shows the difference of the median of PPP between the two sides for TTC and AA groups.

Figure:



Caption: Figure 1: Plot of plantar pressure parameters, showing the difference of the median between TTC op to TTC unop side (Blue) and AA op to AA unop side (red). Results close to zero represents bilateral symmetry and negative results represent higher values on the unop sides.

Conclusion: The study reported similar gait results on the op sides of TTC and AA, however, unlike AA, TTC patients showed good bilateral symmetry with the unop side loading as much as the op side. In comparison to controls, both op and unop sides in TTC group showed a significant difference in similar gait parameters, representing an altered but near symmetrical gait pattern. Based on the results, the fusion of the hindfoot between 5-10° of valgus, along with tibiotalar, appears to result in better loading of the ankle as well as the whole foot in comparison to leaving the calcaneum free. Thus, this study concludes that the fusion of the calcaneum along with the tibiotalar joint is *not* biomechanically detrimental, and is likely an improvement.

LOWER LIMB MUSCLE ACTIVITY STRATEGY AND POSTURAL SWAY IS CHANGED DURING BALANCE TASKS IN GIRLS WITH GENERALIZED JOINT HYPERMOBILITY

Birgit Juul-Kristensen [1,*] Pia Melcher [2] Jesper Sandfeld [2] Katrine Lyders [3] Peter Hendriksen [2] Bente Rona Jensen [2]

[1]Institute of Sports Science and Clinical Biomechanics, University of Copenhagen,, Odense M, [2]Integrated Physiology, Department of Nutrition, Exercise and Sport, University of Copenhagen,, Copenhagen, [3]Institute of Sports Science and Clinical Biomechanics, University of Southern Denmark, Odense M, Denmark

Introduction and Objectives: Generalized Joint Hypermobility (GJH) in children, is defined by a Beighton score ≥ 6 positive joint tests out of 9, and the prevalence varies from 5-57% depending on tests and criteria used, in addition to the population. GJH and joint pain are major criteria for the connective tissue disorder of Hypermobility syndrome (HMS), where reduced balance has been reported in children with HMS [1]. The objective was to study knee muscle activation and postural sway during balance tasks in girls with GJH.

Methods: A total of 16 girls with GJH and 11 girls with no GJH (NGJH), aged 14 years were recruited randomly from a Danish cohort of school children. Additional inclusion criteria for GJH were at least one hypermobile knee, while for NGJH it was at least one knee without hypermobility. Postural sway, as two-legged with eyes open and closed (2EO, 2EC), and one-legged stance with eyes open (1EO), was measured on a force plate (60 s), and Rambling and Trembling of the directions medial-lateral (ML), anterior-posterior (AP), and Center of Pressure Path Length (COPL) were calculated. Surface EMG was recorded (dominant leg) on the following muscles: quadriceps (Q, mean of vastus medialis and lateralis), hamstrings (H, mean of biceps femoris and semitendinosus), and gastrocnemius (G, mean of gastrocnemius medialis and lateralis), during all balance tasks. EMG was normalized to isometric Maximum Voluntary EMG, expressed as %MVE. Co-contraction index (CCI) was calculated as the ratio of co-contracting muscle activation multiplied by the summed muscle activity (CCI = (%MVEmin/%MVEmax) * (%MVEmin+%MVEmax)), minimum and maximum muscle activity were based on mean Q-activity, mean H-activity and mean G-activity, and the final CCI was calculated (mean, medial and lateral CCI of H/Q and G/Q) over the number of balance tasks. Ratio of the medial/lateral HQ and medial/lateral GQ were further calculated. Self-reported knee related physical function was assessed with the Knee Injury and Osteoarthritis Outcome score for children (KOOS-Child). A general linear regression (mixed model) analysis was used to study between group differences.

Results: GJH did not report lower knee function than NGJH in the separate dimensions, but GJH had significantly larger sway length in 2EC (COPL 1.64 vs. 1.37 m/min, $p<0.001$). Furthermore, a tendency to larger values in 2EO in the anterior-posterior direction of Rambling (7.92 vs 6.05 mm, p=0.073) and Trembling (5.17 vs 3.88 mm, p=0.093) was found in GJH. There were no group differences in completion of the balance tasks.

During 2EO GJH had significantly lower muscle activity, seen in mean Q (1.29 vs 2.30%MVE, $p=0.053$), with a tendency also to lower activity in VM (1.15 vs 2.11%MVE, $p=0.072$). During 2EC and 1EO GJH had significantly lower GL activity (2EC: 2.45 vs. 3.55%MVE, $p=0.005$; 1EO: 9.40 vs. 13.45%MVE, $p=0.010$), with a tendency also to lower activity in mean

G in 1EO (12.95 vs 15.71%MVE, p=0.068). CCI of the lateral HQ was significantly lower, and the ratio of medial/lateral HQ significantly higher in GJH, during all three balance tasks.

Conclusion: During static balance girls with GJH and at least one hypermobile knee performed with larger postural sway than NGJH, and maintained the standing position with a lower muscle activity in knee extensors and plantar flexors. Furthermore, GJH had a higher medial knee muscle activity relative to the lateral activity compared to NGJH. This may contribute to the increased risk of knee injuries[2], and development of osteoarthritis in the medial knee compartment. The clinical application calls for taking this into account in prevention management strategies.

INSIGHTS INTO THE BIOMECHANICAL MECHANISMS FOR THE DEVELOPMENT OF CHRONIC EXERTIONAL COMPARTMENT SYNDROME

Andrew Roberts [1 2,*] David Roscoe [1 3] David Hulse [1]

[1]Academic Department of Military Rehabilitation, Defence Medical Rehabilitation Centre, Epsom, [2]Department of Sport and Health Sciences, University of Exeter, Exeter, [3]Centre for Biomedical Engineering, University of Surrey, Guildford, United Kingdom

Introduction and Objectives: Chronic exertional compartment syndrome (CECS) presents as exertional pain in the lower limb as a result of elevation of intramuscular compartment pressure. Conservative treatment through biomechanical changes has recently been promoted as a viable option for CECS. Forefoot running was first described as a possible treatment in a case report by Cunningham [1] This has since been followed up by further case reports and a study of ten US military patients [2-4]. However, to date, there have been no studies examining the biomechanical differences between patients and controls in order to better define the pathophysiology and accurately inform such treatments. This study aimed to compare the kinematic and kinetic differences in cases with CECS and asymptomatic controls.

Methods: 20 men with symptoms of CECS of the anterior compartment and 20 asymptomatic controls agreed to participate. Diagnoses other than CECS were excluded with rigorous inclusion criteria and magnetic resonance imaging. Kinematic and kinetic data were collected during walking and marching. Participants were provided with military issue silver shadow training shoes for collection of shod trials. Barefoot trials were also collected.

A biomechanical model was then created in Visual3D with segments definitions based on recommendations in the literature [5-8].

Temporal-spatial variables, joint angles, moments and ground reaction forces were compared between groups. Bootstrapped t-tests and ANCOVA tests were used to investigate these differences (Matlab/SPSS). The methods described by Hof [9], and recommended by Pierrynowski [10], to normalise gait data to body size were used. Angles of the foot and the shank segments in relation to the lab were also analysed.

Results: Cases were significantly shorter ($p=0.002$) and took a relatively longer stride (in relation to leg length) than controls when shod. There were no differences in normalised step time, stance time and swing time. There were also no clear differences between cases and controls in any of the angles above the ankle at any point during the gait cycle. Consistent differences were identified in ankle inversion, ankle dorsiflexion and in the corresponding X and Z axes of the foot-lab angle (Table 1). The most consistent differences in joint moments were also at the ankle joint. This suggests that CECS is predominately caused by and/or affects the ankle joint system.

Cases demonstrated less ankle inversion at the end of stance and the beginning of swing. This coincided with the generation of lower ankle inversion moments. Cases also had more ankle plantarflexion from mid-stance to toe-off.

Conclusion: The differences demonstrated in the biomechanics and stature of patients provide potential mechanisms for the development of CECS in this population. The reduced stature in combination with an increased stride length may result in an excessive load on Tibialis anterior (TA), when walking/marching at high speeds. The transition from walking to

running is dependent on leg length and transfers the work from the dorsiflexor muscles to the larger proximal muscles [11]. Discomfort in the muscles of the anterior compartment can occur in healthy individuals during fast walking [12]. It follows that within the military training environment, if the anterior compartment muscles are consistently required to generate high loads, this could trigger the pathological changes seen in CECS.

The lower ankle inversion moments suggest that the TA of cases either can not generate the normal load or can not transfer the force generated as efficiently as controls. Reduced force transmission through the tendon and linked fascia would then lead to the differences observed in the ankle angles. The reasons for this are unknown although this could be a result of the reduced strength typically seen in these patients [13, 14]; or due to a mechanical disadvantage resulting in inefficient force transmission. The differences in joint angles and moments therefore indicate an impairment of the function of TA. It is unclear whether this is a cause of, or result of the condition.

Table:

Joint	Movement	Bootstrapped t-test (%)	ANCOVA (%)	Direction of effect
Ankle	Inversion (x-axis)	63-70	62-69	CON>PT
	Plantarflexion (z-axis)	55-57	NONE	PT>CON
Foot-lab	Inversion (x-axis)	83-89	87-88	CON>PT
	Plantarflexion (z-axis)	34-58	NONE	PT>CON

VALIDITY AND RELIABILITY OF HIP PARAMETERS WITH PELVIC AXIAL ROTATION DURING X-RAY ACQUISITION

Ayman Assi [1,*] Ziad Bakouny [1] Elie Saghbini [1] Fares Yared [1] Aren Joe Bizdikian [1] Sabine Esber [1] Gerard Elie Bakhos [1] Nour Khalil [1] Christophe Sauret [2] Wafa Skalli [2] Ismat Ghanem [1]

[1]Laboratory of Biomechanics and Medical Imaging, School of Medicine, University of Saint-Joseph, Beirut, Lebanon, [2]Laboratoire de Biomécanique, Arts et Métiers ParisTech, Paris, France

Introduction and Objectives: In order to assess hip disorders in children and adults, clinical parameters are measured on frontal X-rays of the pelvis [1,2]. These radiographs require standard positioning of the patient during acquisition. To our knowledge, there are no studies that have investigated the effect of axial rotation of the pelvis on the clinical parameters of adults' and children's radiographs. The aim of this study was to estimate the effect of erroneous positioning of patients, during pelvis frontal X-ray acquisition, on the reliability and validity of hip parameters.

Methods: Helical pelvis CT scans (slice thickness: 0.6mm) of 8 children (3 F and 5 M, age: mean 12 - SD 2.2) and 9 adults (5 F and 4 M, age: mean 51 - SD 26) were considered. Frontal Digitally Reconstructed Radiographs (FDRRs) were reconstructed from CTs. Then, for each patient, axial rotation of the pelvis was simulated and the corresponding FDRRs were reconstructed at 5°, 10°, 15° and 20° of axial rotation (Figure 1). Clinical parameters were measured digitally on each radiograph, for both the left and right sides of each patient: Vertical Center Edge (VCE) angle, HTE angle, Sharp's angle, Lateral Subluxation (LatSub) angle, Acetabular Fossa relative to the ilioischial line (AcetFossa), Acetabular Depth (AcetD) distance, Acetabular Width (AcetW) distance and Migration Percentage of the Femoral Head (MPFH). Three trained operators repeated the measurements 3 times each, in each axial rotation position. Intraclass Correlation Coefficient (ICC) was evaluated for intra and inter-observer agreement. The 95% confidence interval (95%CI) was calculated as 2SDs of inter-observer reliability. The bias of each clinical parameter, in each axial rotation position, was calculated as the absolute mean difference relatively to the 0° position.

Results: Intra and inter-observer agreement was shown to be very high (ICC>0.9) for all parameters and all axial rotation positions except for the AcetFossa (ICC= 0.5) in adults. In the absence of axial rotation of the pelvises (0°), the 95% CI of HTE, VCE, Sharp's angle and MPFH were lower than 5 measurement units (m.u.) and lower than 1 cm for the AcetabD, AcetW, AcetFossa and LatSub. The 95% CI increased with pelvic axial rotation: it exceeded 5 m.u. for VCE, MPFH and reached 7° for HTE at 20° of axial rotation. However, it remained constant for the remaining parameters. All the parameters showed an increase in bias during axial rotation of the pelvis , where MPFH and VCE showed greatest bias (7.5% and 6° respectively in children and 5.5% and 4.6° in adults) at 20° position. AcetabD, AcetW, AcetFossa and LatSub exhibited a bias <1cm.

Figure:

Caption: Figure 1- Frontal digitally reconstructed radiographs of the pelvis at the different degrees of axial rotation

Conclusion: Hip parameters measured on frontal radiographs were shown to be less accurate and less reliable when pelvic axial rotation increased. The AcetFossa showed a smaller ICC in adults because the location of the ilioischial line differed from the anatomical situation with increased pelvic rotation and thus led the operators to confusion. The bias was systematically higher for all parameters in all axial rotation positions in children compared to adults. It exceeded 10% of normative values for most of the clinical parameters in both children and adults, when axial rotation exceeded 10°. This bias could significantly affect hip disorders' assessment.

PREDICTORS OF MIDFOOT DEFORMITY AND FUNCTION IN INDIVIDUALS WITH DIABETES AND PERIPHERAL NEUROPATHY

Mary Hastings [1,*] Michael Mueller [1] James Woodburn [2] Michael Strube [3] Paul Commean [4] Jeffrey Johnson [5] Victor Cheuy [1] David Sinacore [1]

[1]Physical Therapy, Washington University School of Medicine, St. Louis, United States, [2]Institute for Applied Health Research, Glasgow Caledonian University, Glasgow City, United Kingdom, [3]Psychology, [4]Electronic Radiology Laboratory, [5]Orthopaedic Surgery, Washington University School of Medicine, St. Louis, United States

Introduction and Objectives: Diabetes mellitus (DM) related medial column foot deformity is a major contributor to high plantar pressure that often leads to midfoot ulceration and major lower extremity amputation.[1] However, very little is known about the quality and function of the structures that support the medial column of the foot, a critical step in halting or preventing amputation. The purpose of this study was to examine the relationship of medial column alignment and midfoot function to: intrinsic foot muscle and fat volumes, posterior tibialis and flexor digitorum tendon volumes, plantar fascia volumes, and plantarflexor peak torque in individuals with DM, peripheral neuropathy (DMPN) and controls.
Methods: Twenty-three participants with DMPN were compared to 12 age and weight-matched participants without DM, PN, or medial column deformity (control). Radiographs, kinematics, magnetic resonance imaging, and biodex were used to measure: 1) medial column standing alignment (Meary's angle- the angle formed by the line that bisects the talar head and neck and the line through the longitudinal axis of the 1st metatarsal), 2) midfoot function (forefoot relative to hindfoot plantarflexion during the heel rise task), 3) intrinsic foot muscle and fat, posterior tibialis and flexor digitorum tendon, and plantar fascia volumes, and 4) plantarflexor peak torque at 60 deg/sec, respectively. A ratio of posterior tibialis tendon (PT) volume to flexor digitorum longus (FDL) tendon volume was calculated for each participant in order to mimic standard clinical radiologist practice. Groups were compared on key variables using a two-tailed independent T-test. Simultaneous entry multiple regression was used to determine predictors of midfoot deformity (Meary's angle) and midfoot function (forefoot relative to hindfoot plantarflexion excursion during the heel rise task) in the DMPN participants.
Results: Meary's angle was not different between groups ($p=.48$) although the DMPN group had much higher range of measures than the control group (DMPN range= -36° to 7°, Control range=-21° to -3°). (Table 1) Compared to controls, the DMPN group had: 1) reduced plantarflexion of their forefoot relative to their hindfoot during the heel rise task ($p<.01$); 2) decreased intrinsic foot muscle volumes ($p<.05$); 3) increased intrinsic foot fat volume ($p=.01$); and 4) decreased plantarflexor peak torque ($p<.01$). The PT/FDL tendon volume ratio and intrinsic foot muscle volume were significant predictors of Meary's angle ($p<.05$) and accounted for 43% of the variance in Meary's angle. Intrinsic foot fat volume and plantarflexor peak torque were significant predictors of plantarflexion excursion of the forefoot relative to hindfoot during the heel rise task ($p<.05$) and accounted for 37% of the variance in forefoot relative to hindfoot excursion.
Conclusion: Individuals with DMPN have marked deterioration in leg function and foot muscle quality. The deterioration of the supporting structures of the medial column (intrinsic foot muscles/fat volume, PT/FDL tendon volume, plantarflexor peak torque) predicts midfoot alignment and foot function. Additional prospective research is required to monitor

alignment, structure, and function over time to inform early intervention strategies with the goal to prevent deformity, ulceration, and amputation.

Table:

	DMPN (n=23)	Control (n=12)	P value
Lateral Radiograph (degrees)			
Meary's Angle	-13 (11)	-11 (5)	.48
Muscle Volume (cm^3)

A CANINE GAIT ANALYSIS PROTOCOL FOR THE ANALYSIS OF THE BACK MOVEMENT: ASSESSMENT OF KINEMATIC AND KINETIC VARIABLES IN GERMAN SHEPHERD DOGS

Andrea Cereatti [1 2,*] Elif Surer [1] Maria Antonietta Evangelisti [3] Lucia Manunta [3] Gabriele Paolini [1] Ugo Della Croce [1 2]

[1]POLCOMING, University of Sassari, Sassari, [2]Interuniversity Centre of Bioengineering of the Human Neuromusculoskeletal System, Rome, [3]Pathology and Veterinary Clinic, University of Sassari, Sassari, Italy

Introduction and Objectives: Degenerative lumbosacral stenosis (DLSS) is a common disorder affecting large breed dogs and in particular German Shepherd (GS) dogs. Currently, the most common treatment is surgery, however surgical timing and techniques are still controversial [1]. In this regard, instrumented movement analysis is a powerful tool for improving the clinical intervention efficacy [2]. The majority of the gait analysis protocols proposed were devised to analyze hind limbs kinematics [3]. To authors' knowledge, only few studies focused on the movements of the back [4] and, a complete description throughout the entire gait cycle of the kinematic data variability is still lacking. Aim of the present study is two-fold: (i) to present and validate a gait analysis protocol specifically designed for the evaluation of the back motion in both sagittal and horizontal planes; and (ii) to provide normative data of the spatio-temporal parameters, kinematics and kinetics quantities during quadrupedal stance posture and level gait in healthy GS dogs.

Methods: Eight healthy GS dogs (ages: 5.6 ± 2 yrs) were enrolled in the study.

A set of 17 markers was placed as shown in Fig. 1. A virtual marker defined as the midpoint between the two iliac crests, was also defined. A multi-segmental model including ten 2D segments was used (Fig. 1).

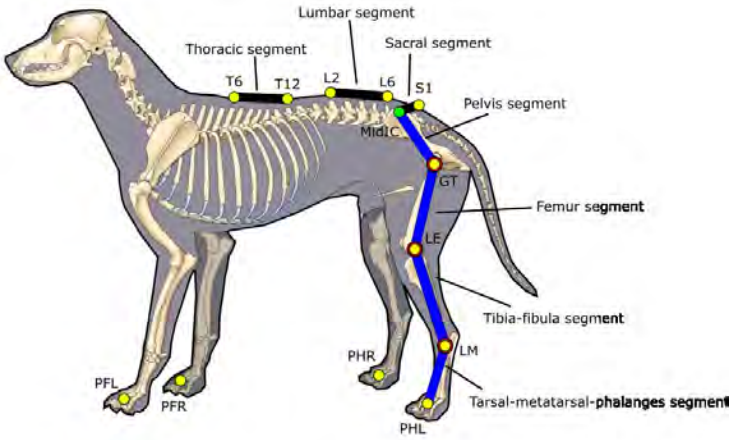
Spatio-temporal parameters were determined from the trajectories of the markers on the paws. The joint angular kinematics were defined by projecting the markers positions on the sagittal (*S*) and horizontal (*H*) planes and then by computing the relevant angles. Sagittal angular kinematics were estimated for the tarsal, the stifle and the hip joint; the pelvis motion was described in the *S* plane (pelvic tilt) and the *H* plane (pelvic rot). The movement of the vertebral column was described by the relative angular motion in the *S* and *H* plane between the sacral and thoracic segment and the lumbar and thoracic segments.

The instantaneous positions of the markers were reconstructed using a 6-camera optoelectronic system (Vicon) acquiring at 100 Hz (6 Hz cut-off frequency). Two force platforms (AMTI) were used to record ground reaction forces (GRF) at 100 Hz. The experimental acquisition sessions consisted in a) static trials with the dog in quadrupedal stance posture; b) six gait trials during which only stereo-photogrammetric data were acquired.

Grand mean and standard deviation (*std*) values of the posturographic angles and of the GRF were computed. For each kinematics variable, grand mean, grand *std* values were computed over the subjects for each gait cycle percentage.

Results: The average cadence and *std* were 154.5 ± 18.5 step/min, stride duration and length were 0.8 ± 0.1 s and 1.0 ± 0.2 m. From the grand mean curves of the angular kinematic variables, *ROM* and the *std* values, averaged over the gait cycle, were extracted. For sake of brevity, kinetic data are not reported.

Figure:



Caption: Anatomical landmarks identified by the skin markers and multi-segmental model.

Conclusion: The reliability of a novel canine gait analysis protocol was assessed on healthy GS dogs. The greater angular excursions were found, in descending order, for the hip, stifle and hock joints. Whereas the amplitude of the thoraco-lumbar movements in the *H* and *S* planes were comparable, the lumbo-sacral movement in the *H* plane was 3.5 times greater than in the *S* plane. The inter-subject joint angular variability ranged, for all segment and joints between 0.27 to 0.36. The largest variability were observed for the pelvis motion. The proposed protocol produced high repeatable kinematic data thus suggesting its effectiveness in assessing gait deviations from normality. The present protocol was specifically designed to assess functional limitations and motor impairments associated to the presence of pathologies affecting the vertebral column and in particular DLSS disease in dogs. As opposed to previous studies in which the spinal column was modeled as a single segment, the movement of the spinal column was modeled as a three segment linkage. The additional information provided by the model can improve the procedure and outcome of spinal column surgery.

Table:

Segmental and joint kinematics	ROM [°]	std/ROM
Thoraco-lumbar angle (*S* plane)	3.9	0.27
Thoraco-lumbar angle (*H* plane)	4.5	0.31
Lumbo-sacral angle (*S* plane)	3.2	0.29
Lumbo-sacral angle (*H* plane)	11.2	0.32
Pelvic tilt	8.5	0.33
Pelvic rotation	7.2	0.36
Hip flex/ex	31.0	0.30
Stifle flex/ex	27.1	0.31
Hock flex/ex	23.8	0.27

THE USE OF FEEDBACK TO REDUCE THE ERRORS ASSOCIATED WITH PLACEMENT OF ANATOMICAL MARKERS FOR KINEMATIC GAIT ANALYSIS.

Reed Ferber [1 2,*] Sean Osis [1 2] Blayne Hettinga [1 2] Ricky Watari [1] Ryan Leigh [1]

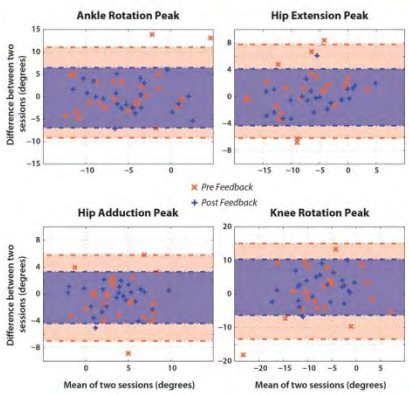
[1]Kinesiology, University of Calgary, [2]Running Injury Clinic, Calgary, Canada

Introduction and Objectives: Anatomical marker placement is the single largest source of error in gait analyses [1,2]. Previously, we developed a method that 'scores' marker placement by comparing marker coordinates to a morphometric "norm" to address this problem [2]. The outcome is an inter-quartile range ratio (IQRR), a non-parametric description of the location of a given marker placement within the distribution of normalized marker-coordinate reference data. The purpose of this study was to evaluate the use of this marker placement location feedback method, based on the IQRR, and to measure concomitant changes in peak ankle, knee, and hip joint angles during treadmill walking.

Methods: Twelve subjects (6 males; 60.0 +/- 4.5 yrs; 1.70 +/- 0.10 m; 75.3 +/- 16.4 kg) participated, as part of a larger clinical study. A single experienced examiner placed retro-reflective 9mm markers over specific anatomical landmarks of bilateral ankle, knee, and hip joints [2,3]. After the first placement and collection of a 1 second standing trial, visual feedback was given using the IQRR score for each marker with a threshold of 0.8 chosen as a cutoff. The examiner had the opportunity to correct their placement and a second standing trial was taken. Data for a single walking trial was then collected by an 8-camera Vicon system at 200Hz. Walking data were analyzed (3D GAIT software) using both standing trials (Pre Feedback vs. Post Feedback) to calculate discrete kinematic variables. Collections with these subjects were repeated again 2-7 days later, and changes in the limits of agreement (LOA) were evaluated between Pre and Post conditions, across both sessions.

Results: All but one joint angle LOA measurement was reduced after using feedback. The greatest changes were observed in ankle rotation, knee rotation, and hip adduction/extension peak angles, all with decreases greater than 5 degrees, representing more than 30% reductions in LOA (Figure 1). There were slight decreases for ankle eversion and hip rotation peak angle LOA, and a slight increase for knee flexion peak angle; however, all of these changes were less than 2 degrees, or 7%.

Figure:



Conclusion: We quantified the use of marker placement location feedback, based on the IQRR score, and subsequently measured greater than 5-degree reductions (> 30%) in inter-session limits of agreement.

Caption: Figure 1 - Bland-Altman plots of joint angles, across two sessions of data collection, which displayed the greatest differences between Pre and Post. The limits of agreement Post Feedback (dark shade) have narrower ranges than Pre Feedback (light shade).

POWER OUTPUT OF OAR BLADE IN CONTEXT OF ROWER LEG, KNEE AND TRUNK COORDINATION IN ON WATER SKULL ROWING

Chris T.M. T. Baten [1,*] Mats Baten [2] Fred Vuijk [1]

[1]Ambulatory 3D Analysis of Movement, Roessingh Research and Development, [2]Kottenpark College, Enschede, Netherlands

Introduction and Objectives: In varsity rowing results are obtained by skillfully delivering power to the water through the oar blades, optimally in amplitude and pattern.

This paper describes a method estimating blade power output and its application to actual on water rowing in 6 rowers in repeated sessions of multiple bouts at competition speed. The power profiles are discussed in the context of the 3D kinematics of the oar, boat and rower knee joint, trunk and elbow joint of the rower.

Methods: 6 rowers performed two 4 hour measurement sessions of 3 sets of 400m rowing on 2k competition speed and tempo, followed by 600m of light rowing before starting the next set. Experiments were conducted on the Twente Canal under mostly clear weather conditions with a slight downwind. Sessions were divided in part A and part B with 1.5 hour resting period in between.

Before, in between and after each session body segment calibrations were performed to estimate and test and/or confirm the relative orientation between the IMMU coordinate frames and the body segment coordinate frames. This was also done for the sensors on oars and boat.

17 wireless IMMUs were placed on boat, oars (2 each), upper and lower leg, pelvis, thorax, upper and lower arms and feet. Also a bow and stern camera was mounted (GoPro) and a recording tablet and wireless IMMU receiver/commander dongle were mounted in a box on the boat just behind the rower.

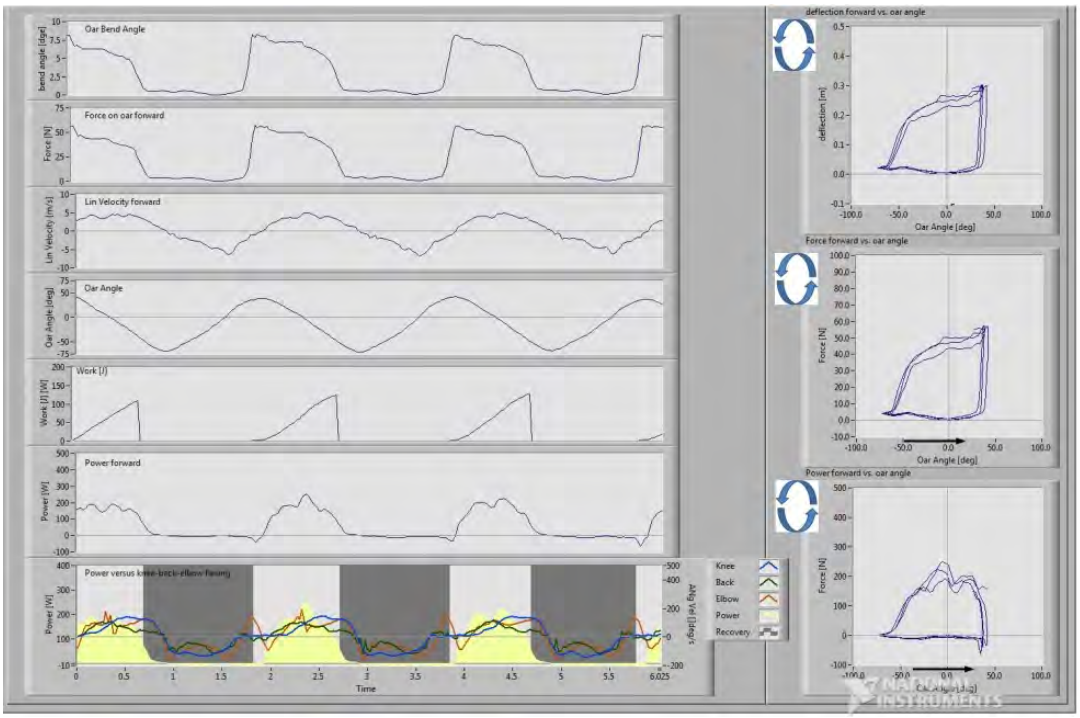
Power was estimated from data from 2 IMMUs on each oar. The relative angle between both IMMUs was then related to the force to the oar on the section where the blade attaches to the oar. For this a relationship is used determined by data from a separate calibration session. In this session the oar was horizontally fixated at 2 points representing hands and rig contact and different weights were applied at a point just before the of the blade attachment. Oar absolute inclination and angle around the vertical axis of the boat were taking into account. the power was split in a component in 'forward' direction and one in lateral direction.

Results: The force to bending angle α calibration procedure yielded linear relationships (R^2 = 0.99, no significance in second order term).

Figure 1 shows an example data of one piece of rowing data. Shown are from top to bottom: oar bend angle, oar forward force, forward velocity, oar angle, work, forward power and power versus knee, trunk and elbow flexion. This example illustrates clearly the consistency of amplitude and detail in the estimated entities on a similar level in power estimates as in knee, trunk and elbow kinematics estimates. This was observed throughout all experiments. Groupwise (statistical) evaluation of the rower 3D kinematics data revealed consistent high repeatability within subjects over sessions, consistent rower knee, trunk elbow coordination styles characteristics and consistent fatigue induced effects. This data behavior,

together with the consistency observed in the power data details as described above, suggests that similar observations can be made for the power data on a group level. This information is however not yet available at the moment of submission of this abstract.

Figure:



Caption: Figure 1: Example of data obtained during actual on water rowing. Top to bottom: oar bend angle, oar forward force, forward velocity, oar angle, work, forward power and power versus knee, trunk and elbow flexion.

Conclusion: It appeared feasible to synchronously record 3D kinematics of 13 body segment, boat and 2 oars with wireless IMMUs, 2 video streams. Recording of oar bending from data of 2 IMMUs on each oar and calibration of oar bending to oar force seemed possible in such a detail and consistency that oar output power could be estimated consistent in amplitude and in detail in a consistent way with the knee, trunk and elbow flexion details.
Although no absolute validation of power data is perfomed yet, studying these output power profiles in the context of the coordination details promises already to be of use for studying rower skill efficiency and effectiveness.

ADAPTATION AND VALIDATION OF AN EXISTING FOREARM MODEL FOR CORRECTING SOFT TISSUE ARTEFACT THROUGH MULTIBODY OPTIMISATION

Alexandre Naaim [1 2 3 4,*] Florent Moissenet [4] Raphael Dumas [1 2 3] Thierry Haumont [5] Laurence Chèze [1 2 3]

[1]Université de Lyon, [2]Université Claude Bernard Lyon 1, Lyon, [3]Laboratoire de Biomécanique et Mécanique des Chocs, IFSTTAR, Bron, France, [4]Laboratoire d'Analyse du Mouvement et de la Posture, CNFR - REHAZENTER, Luxembourg, Luxembourg, [5]Chirurgie Infantile, CHU CAEN Hôpital Femme Enfant, Caen, France

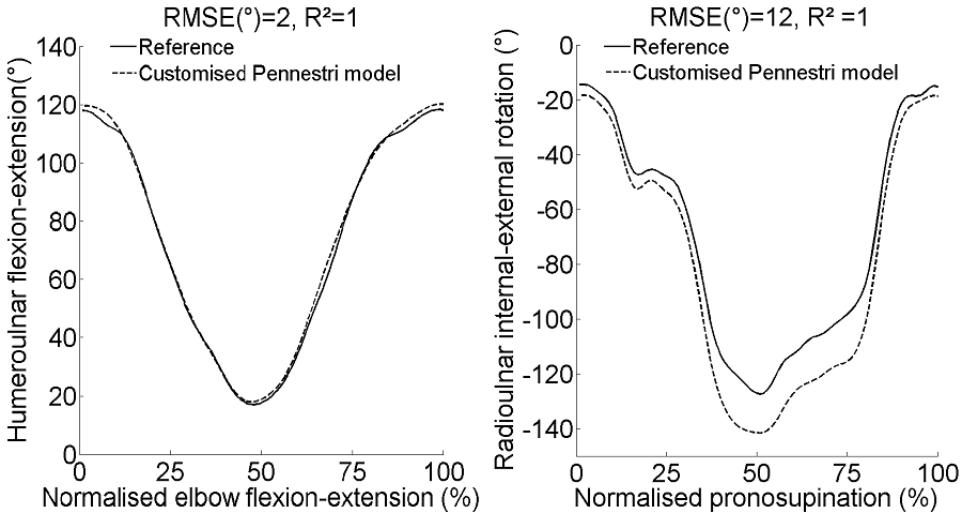
Introduction and Objectives: Motion capture can be limited by Soft tissue artefact (STA) especially for upper limb motions. However, using multibody optimisation (MBO) methods can allow reducing STA. In MBO, a kinematic chain composed of rigid segments linked by joint models allows studying the limb movements. The segments positions are then optimised through the minimisation of the squared distance between model-determined (MDM) and measured (MM) markers trajectories. However, MBO is highly sensitive to the joint models. Duprey et al. [1] showed that the use of anatomy-based models allows for a better correction of STA in the lower limb. In the same idea, the model proposed by Pennestri et al. [2] was used in the present study to model forearm. This model is composed of 3 segments (humerus, radius and ulna) linked in a closed loop chain by 3 joints (humeroulnar (HU): hinge, humeroradial (HR): spherical, radioulnar (RU): sphere-in-cylinder). It presents the advantage to be simple and to require only geometrical parameters for its construction that can be easily obtained through functional methods or imaging technics. However, the joint centre positions defined by Pennestri et al. [2] remain arbitrary. The aim of the study was then to customise the geometry and to evaluate the resulting model for MBO. The general objective was to evaluate if the upper limb model can replicate a bone kinematics measured ex vivo.

Methods: A study was performed on a cadaver (man, 99 yrs) at the Laboratory of Anatomy of the CHU of Caen. Clusters of markers were rigidly fixed on hand, radius, ulna, humerus, scapula, clavicle and thorax. All anatomical landmarks recommended by ISB [3] were pointed during a static recording. Joint centres and axes were obtained with functional methods by mobilising the cadaver. Glenohumeral centre was defined using a method based on a SCoRE methods [4,5]. The SCoRE method was also used to define the RU and HR centres through respectively a pronosupination (PS) movement and a PS with elbow flexion-extension (FE) movement. Elbow FE axis was defined using the SARA method [6]. Data were recorded using a 100Hz optoelectronic tracking system (Qualysis AB, Sweden) and transferred to Matlab R2011b using the Biomechanical Toolkit [7] for all computations. Original model geometry was replaced by the geometry determined by the functional methods. Spherical joints were used to model all the shoulder joints without considering the scapulothoracic joint. Mean and standard deviation between the position of MDM and MM were calculated as indicators of goodness-of-fit. The kinematics obtained from MDM and MM for the HU FE during an elbow FE and the RU internal-external rotation (IER) during PS, following ISB recommendations [3], were compared using RMSE and R^2.

Results: The MBO was unable to converge when using the original Pennestri model and consequently no results are available in that case. The customised Pennestri model seems to fit closely to the markers (Table). Except for one marker, the difference was always less than 3.6mm. Figure shows that the model fit very well the data for HU FE during elbow FE.

However, for RU IER, the model fit well the data but not above 100° pronation where a maximum 15° difference can be found.

Figure:



Caption: Reference and model based kinematics for humeroulnar (HU) flexion-extension (FE) during an elbow flexion–extension (FE) and radioulnar (RU) internal-external rotation (IER) during pronosupination (PS).

Conclusion: As it was impossible to obtain any result with the original Pennestri [2] model it can be concluded that it is incompatible with the bone kinematics studied and that it should be avoided to be used directly. The proposed customised Pennestri model [2] based on functional methods, seems fitting well the movements of the forearm except for high pronation. It would have been possible to obtain a better fitting by eventually adding degrees of freedom(DOF) in the model. Moreover, a more complex model including ulna translation and swaying did not show significant differences with the Pennestri model when using skin markers [8]. As a result, the proposed model could be considered as a valuable model of the forearm for MBO.

Table:

Markers		PS		Elbow FE	
		Mean(mm)	Std(mm)	Mean(mm)	Std(mm)

COMPARISON OF TIBIAL AND FEMORAL ACCELERATIONS USING MOTION CAPTURE AND INERTIAL MEASUREMENT UNITS

Sara S. P. Marreiros [1,*] Jody Riskowski [1] Martijn Steultjens [1]

[1]School of Health and Life Sciences, Glasgow Caledonian University, Glasgow, United Kingdom

Introduction and Objectives: Measurements of joints kinematics are important for the development and validation of musculoskeletal computer models, which are often used to assess normal and pathological gait patterns [1]. Commonly, these measures are collected using a laboratory-based motion capture (MoCap) system with cameras and reflective markers. However, recent technology advances have introduced wearable measurement systems, also known as inertial measurement units (IMUs) that use accelerometers, magnetometers, and gyroscopes to measure movement and orientations [2].

Soft-tissue artefact (STA) is the main source of errors associated MoCap systems. IMUs may be better suited to addressing STA as well as provide a means for addressing joint action in everyday activities performed outside the laboratory. However, the validity and reproducibility of the joint local accelerations measured by the IMUs relative to motion capture is unknown. Therefore, the purpose of this study is to compare tibial and femoral accelerations near the knee joint obtained between a MoCap system and IMUs.

Methods: Kinematic, kinetic and accelerometer data from 8 participants were collected in 7 self-selected walking trials. Kinematic data was collected using a 14-camera MoCap system (Qualisys, Sweden) synchronized with 4 tri-axial IMUs (Opal™, APDM, USA), with both systems sampling at 128 Hz. Ground reaction forces (Kistler, USA) were collected at 2560 Hz.

IMUs were placed in an anterior and lateral position on the right thigh and shank (Femur Front and Lateral and Tibia Front and Lateral) near the knee joint, with three reflective markers on each sensor to track the IMU spatial location and orientation. A full body marker set protocol was used to collect participants' kinematic data. Markers trajectories were filtered using a 4th order low pass Butterworth filter with 20 Hz cut-off frequency; IMUs signal was not filtered.

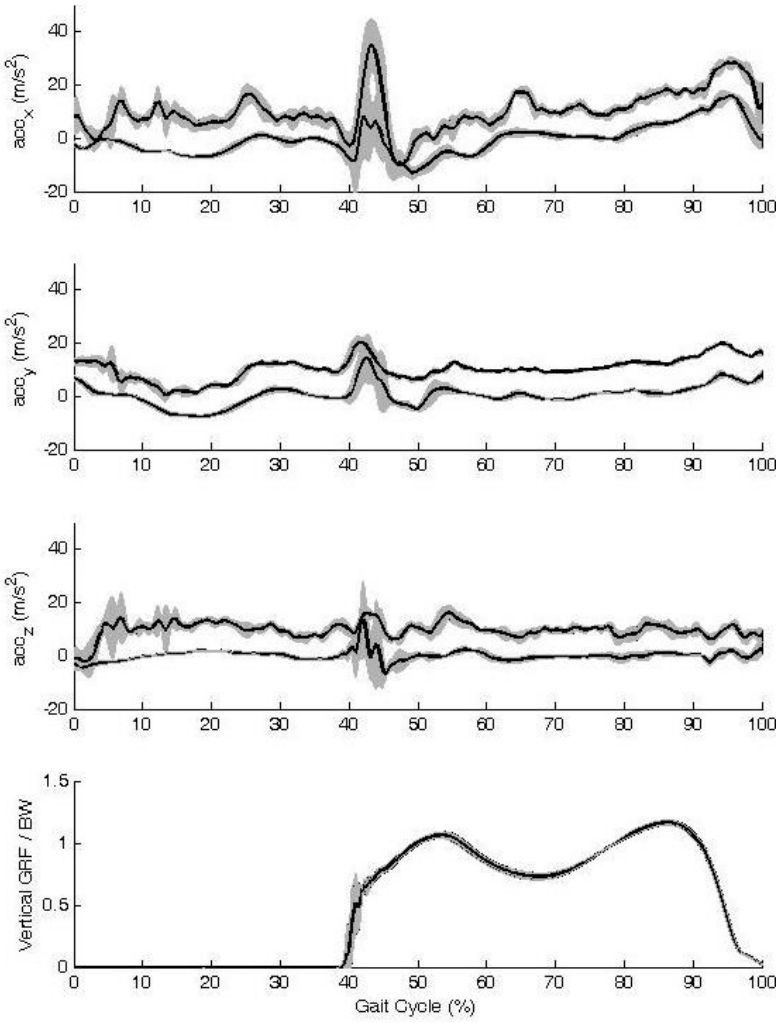
A scaled musculoskeletal model [3], modified to allow 5 DoF (2 translations and 3 rotations) in the knee, was used to measure femoral and tibial accelerations through inverse kinematics (IK) using OpenSim v3.2 [4]. Accelerations measured by the IMUs were compensated for gravity using the IMUs self-reported spatial orientation. Acceleration in OpenSim were measured for fixed points correspondent to the IMUs origins fixed for the correspondent limb, with the assumption the IMUs' location and orientation as measured in a static trial was maintained through all gait trials. Both signals are represented in OpenSim default coordinate system (x: posterior anterior, y: vertical, z: medial lateral) and in bone local coordinate system.

Correlations between IMUs and MoCap accelerations were measured for each IMU position and axis, with means determined at both the participant- and group-level.

Results: Mean accelerations through the gait cycle were more stable when obtained through the unfiltered IMU relative to the filtered IK measure as the IMUs signal had a lower SD relative IK signal.

Mean correlations in x-axis and for the y-axis for the tibia IMUs and femur lateral IMU were high (Table; range: 0.781 - 0.836). Femur front (FFront) IMU had a moderate correlation (0.619). In the z-axis, correlations were low to moderate (range: 0.355 - 0.615).

Figure:



Caption: Accelerations from IMUs and IK for participant 4, TLateral point and GRF. Means and SD are represented. The acceleration from IK is off-set vertically 10 m/s2.

Conclusion: The high correlation in acceleration obtained between the IMUs and MoCap suggest that the IMUs can accurately measure accelerations and, has a portable device has the advantage of not being restricted to a laboratory. However, the lower correlations in z-axis can be related with errors in the estimation of gravity orientation suggesting that using only the hardware reported orientation may not be sufficient for this compensation.

HIP JOINT BIOMECHANICS DURING GAIT IN PEOPLE WITH AND WITHOUT SYMPTOMATIC FEMOROACETABULAR IMPINGEMENT

Laura Diamond [1,*] Tim Wrigley [1] Rana Hinman [1] Paul Hodges [2] John O'Donnell [3] Kim Bennell [1]

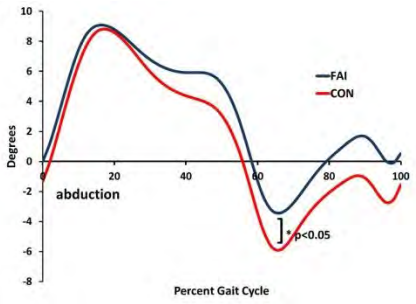
[1]Centre for Health, Exercise and Sports Medicine, The University of Melbourne, Melbourne, [2]Centre of Clinical Research Excellence in Spinal Pain, Injury & Health, The University of Queensland, Brisbane, [3]St Vincent's Hospital, East Melbourne, Australia

Introduction and Objectives: Femoroacetabular impingement (FAI) is a morphological hip condition that can cause hip/groin pain and impaired performance in younger active adults, plus lead to stiffness, muscle weakness, structural damage, and possibly hip osteoarthritis [1,2]. FAI results when the proximal femur abuts against the acetabular rim [1,3]. Understanding the impairments associated with FAI is crucial to guide treatment and rehabilitation strategies. Gait is the most common repetitive voluntary movement performed [4] and there is limited and conflicting evidence to suggest that hip ROM during walking is reduced in people with symptomatic FAI, despite the fact that motion in this task is generally pain free, and does not reach the end of available range [5] where painful impingement might occur. The study objective was to compare three-dimensional (3D) hip joint gait biomechanics between a symptomatic FAI and an asymptomatic control group.

Methods: Thirteen patients with FAI diagnosed clinically and with imaging features, and 15 age, gender, BMI, and activity level matched asymptomatic controls underwent a 3D gait analysis (Vicon, Oxford, UK). All patients were scheduled for hip arthroscopy surgery; patients with bilateral FAI were tested on the more symptomatic side. Subjects were required to walk along a 10-meter walkway in the laboratory six times at a self- selected speed. 3D lower limb kinematics and inverse dynamics were calculated from marker triads and the ground reaction force [6]. Joint moment data was normalised to bodyweight times body height. Peak hip angles and ROM in each plane, and peak hip moments were compared between the two groups using multivariate ANOVA. Walking speed and demographic variables were examined for between-group differences using independent t-tests ($\alpha = 0.05$).

Results: Results are shown in Table 1. There were no significant between-group differences in demographics or walking speed. The max abduction angle was significantly reduced in the FAI group compared to controls (Figure 1). There were no other significant differences between groups for hip angles or moments.

Figure:



Caption: Mean hip adduction/abduction angle gait waveforms for FAI and control groups.

Conclusion: A significantly decreased peak hip abduction angle was found during gait in people with symptomatic FAI. No other variables differed between the groups. This study is limited by a small sample size and a control group that was not imaged to ensure absence of asymptomatic FAI bony changes. The clinical significance of these hip ROM differences for symptoms are unclear and requires further consideration, but might relate to an overall strategy to limit motion of the painful hip. More demanding tasks designed to target positions of impingement, such as squatting and stair climbing, might reveal greater insight into the nature of the biomechanical impairments in this population. Examination of these tasks and the function of the surrounding deep hip muscles with intramuscular electromyography is the aim of current work to better understand the neuromuscular changes in FAI as potentially modifiable targets for treatment.

Table:

Group	**Age** (yrs)	**Males**	**BMI** (kg/m^2)	**FAI type** (cam:combined)	**Tegner Physical Activity Level** (/10)	**Walking Speed** (m/s)	**Max abduction** (swing) (°)	**Max adduction** (stance) (°)	**Frontal plane ROM** (cycle) (°)

AS-0464

THE EFFECT OF UPPER ARM MASS ON THE THROWING VELOCITY

Patrick Fasbender [1,*] Nicholas P Linthorne [1] Thomas Korff [1] Vasilios Baltzopoulos [1]

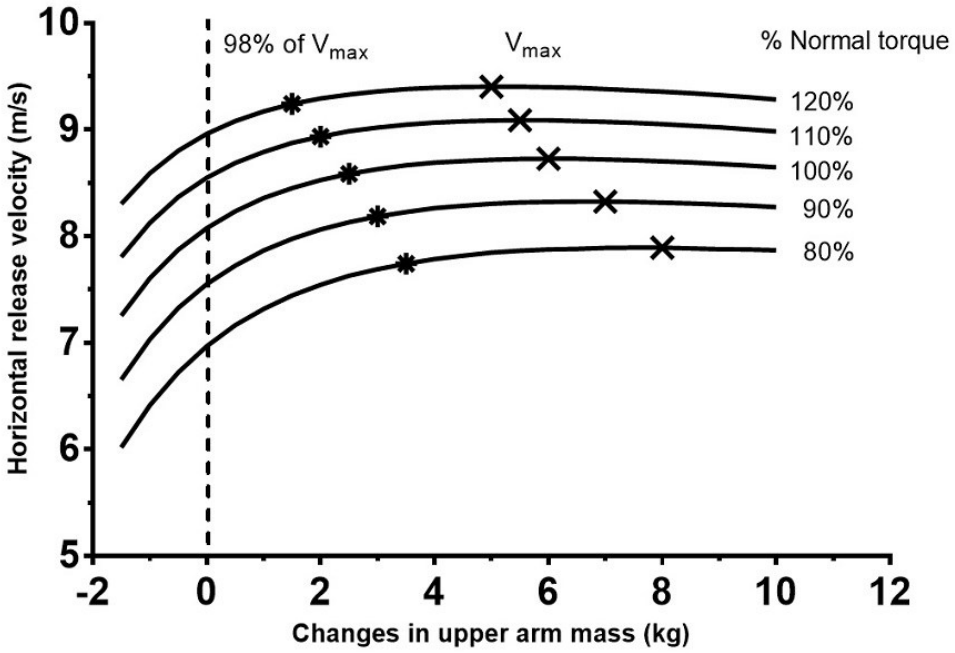
[1]Department of Life Sciences, Brunel University, Uxbridge, United Kingdom

Introduction and Objectives: Throwing performance is important in many sports where the goal is to throw a projectile as fast or as far as possible. The most important determinant of throwing performance is release velocity, which is determined by muscular strength, inter-muscular coordination, inertial properties and transfer of angular momentum. Results from previous studies suggest that throwing performance might be improved through deliberate manipulation of the mass of the athletes' arm segments. Southard[1] found that with an additional 1.4 kg strapped on the upper arm the peak velocity of the hand when throwing a 114 g ball increased by about 5%. Similarly, Kim and colleagues[2] found that arm swing speed was slightly increased when the mass of the upper arm was increased by 25% and 50%. An interesting question arising from these results is whether there is an optimal upper arm mass that maximises release velocity. Apart from a sports performance perspective, a greater understanding of the interaction between upper arm mass and throwing performance could also be beneficial in child development, and might help to explain the gender gap in throwing performance. The aim of this study was to investigate the relationship between upper arm mass and release velocity using computer simulation.

Methods: A 2D computer simulation (Working Model 2D), consisting of two rigid bodies (upper and lower arm) and two torque generators (shoulder and elbow), was used in this study. The torques used to drive the model were obtained from experimental data. For this purpose, one subject with an upper arm mass of about 2.0 kg[3] performed a maximal throw while sitting on a chair and throwing a tennis ball at a target 3 m away. The participant was instructed to use his dominant arm in the sagittal plane without using his trunk. Kinematics were obtained using motion analysis, and joint torques at the shoulder and elbow were obtained using inverse dynamics in an OpenSim model[4]. The torque profiles were approximated by a 3rd order polynomial, which was used as the torque generator for the 2D computer simulation. In the simulations, the upper arm mass was varied between 0.5 and 12.5 kg, and the shoulder torque was varied between 80 and 120% of the experimentally determined value to investigate if the mass-dependence of throwing performance could be dependent on the capacity for muscular torque production at the shoulder.

Results: The optimal upper arm mass that produced the greatest release velocity was between 7 and 10 kg (Figure 1), with the optimal upper arm mass decreasing with increasing shoulder torque. The gain in horizontal release velocity obtained when using the optimum upper arm mass ranged from +5.0% in the highest shoulder torque condition to +13.3% in the lowest shoulder torque condition. Increasing the upper arm mass by 2 kg, similar to the maximal values used by experimental studies[1][2], resulted in increases in horizontal release velocity of between 3.70% and 8.25%. Although the maximum release velocity occurred with an additional mass of between 5 and 8 kg on the upper arm, an additional mass of only 1.5 to 3.5 kg produced a release velocity that was within 2% of the maximum velocity (Figure 1).

Figure:



Caption: Effect of upper arm mass on horizontal release velocity for five torque conditions.

Conclusion: This study highlights the mechanical effect that upper arm mass has on throwing performance. It extends our knowledge about how the horizontal release velocity changes with upper arm mass increases that exceed the masses tested in previous studies. In sports, adding an extra 5 to 8 kg to the upper arm mass would help athletes to optimise throwing performance by maximising the release velocity. Although such a large upper arm mass is physiologically unrealistic, our results suggest that substantial improvements in release velocity can still be obtained with a more modest upper arm mass. Understanding the effect of mass distribution in the arm on throwing could have implications on child development and training. During growth, a child's forearm and hand segment reach adult proportions before the upper arm[5], and this hinders the learning of the "adult" throwing pattern. As this study used a 2D simulation, the recorded throwing movement had a number of limitations. This type of throw did not take the internal/external shoulder rotation into consideration, which is important in a maximal-effort throw. Future research should investigate if similar effects are observed in more complex simulations.

SINGLE LEG TRIPLE HOP TEST INVERSE KINEMATICS WITH DIFFERENT MARKERS WEIGHTS USING OPENSIM

Felipe Alvim [1,*] Paulo Lucareli [2] Luciano Menegaldo [1]

[1]Biomedical Engineering Program, Federal University of Rio de Janeiro, Rio de Janeiro, [2]UNINOVE, São Paulo, Brazil

Introduction and Objectives: Computer modeling in biomechanics is a widely used tool that helps understanding how neuromusculoskeletal system interact to generate movements. One of the widely used software for biomechanical analysis is OpenSim, which is an open-source platform [1]. For finding muscle activations history from kinematical data, one of the typical OpenSim applications, its workflow comprises a series of steps. Initally, a generic musculoskeletal model is used as basis, which is scaled to meet subject's anthropometry. In the sequence, inverse kinematics (IK) and inverse dynamic problems are solved. The resulting torques are then distributed among the muscles through a static optimization solution. The objective of solving an IK problem is to find a series of model positions that minimizes the distances between experimental and virtual markers placed on the model. OpenSim's User Guide recommendation is increasing the weights of markers placed at the bone landmarks for improving motion accuracy results delivered by IK tool. However, no further information is provided. The accuracy of IK results influences the subsequent steps further used in OpenSim workflow. Thus, the aim of this work is to evaluate the results of IK tool applying different groups of weights to markers placed at bone landmarks. Joint angles determined by usual rotation matrix approach [2] was used as a gold standard.

Methods: Ten female subjects were recruited to participate. They performed a single leg triple hop test (SLTHT) wile kinematic data were collected by an eight infrared camera system (SMART-D BTS®, Milan, Italy). Data were sampled at 100 Hz. Twenty five markers were attached to the skin based on Vicon Plug-in-Gait biomechanical model [3]. The markers trajectories were filtered using a Woltring filtering routine, with a 12 Hz low-pass cutoff frequency. For comparison, the joint angles were calculated by Euler angles-based rotation matrix approach [3]. The preparation phase of one attempt was selected to be analyzed for each subject. Model was scaled and the resulting scaled model was then used by a OpenSim run with IK tool. For each trial three inverse kinematic problems were solved. In the first (G1) all markers weights had the same unitary value. In second (G2) all markers placed on bone landmarks (7th cervical vertebra, anterosuperior and posterosuperior iliac spines, lateral femoral epicondyle, lateral malleolus, middle third of foot between the 2nd and 3rd metatarsals and calcaneus) have they weights defined as 10. Finally, in the third IK problem (G3), all markers placed on bone landmarks have they weights defined as 100. Hip flexion, hip adduction, hip rotation, knee flexion and ankle dorsiflexion, all corresponding to the jumping side were analyzed. Joint angles calculated by both approaches were interpolated to 101 samples and the root mean square error (RMSe) between them evaluated. Normality of dataset was verified and one way ANOVA to repeated measurements was applied to verify the existence of differences among RMS errors of the three groups of weights in the different joint angles. Tukey HSD post hoc test was applied to identify differences found in the ANOVA. Significance level of 5% was adopted.

Results: The means and standard deviations to RMSe values, of each joint angle and markers' weight group are shown in Table 1.

Statistical tests verified statistical differences only in hip flexion RMSe values between G1 and other groups. There was no difference between RMSe of G2 and G3 in hip flexion. All others RMSe values between G1, G2 and G3 weights groups in other joint angles showed no statistical differences.

Conclusion: This work have shown that increasing markers weights by one order of magnitude reduced the RMSe between hip flexion angle calculated by conventional rotation matrix approach and Opensim's IK tool. No effects were found with further increase of increasing weights of bone placed markers. In addition, no statistical differences were found in RMSe values with increased weights in other joint angles.

Table:

	G1	G2	G3

ASSESSMENT OF EFFECTS OF ENHANCED EXTRACELLULAR MATRIX STIFFNESS DUE TO BOTULINUM TOXIN ON MUSCULAR MECHANICS USING FINITE ELEMENT MODELING

Ahu N. Turkoglu [1,*] Can A Yucesoy [1]

[1] Biomedical Engineering Institute, Bogazici University, Istanbul, Turkey

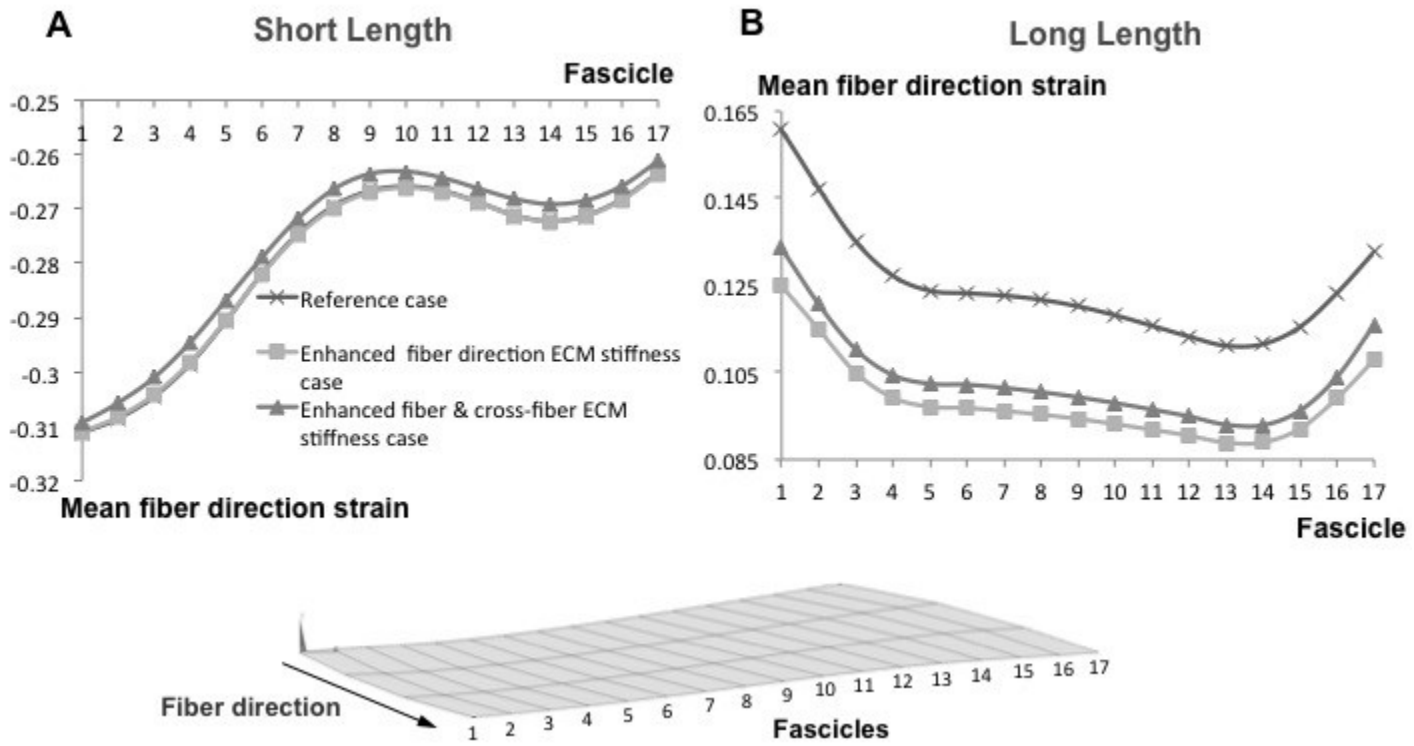
Introduction and Objectives: Botulinum toxin type A (BTX) injections are commonly used to treat cerebral palsy (CP) patients. Partial muscle paralysis allows limiting hyper-excitable stretch reflexes and reducing spasticity. However, BTX also affects muscular mechanics substantially, which is functionally very important. Recently in a limited number of experiments, force measurements of muscle exposed to BTX were done over a range of muscle lengths. These studies show that the force reduction effect is not constant but variable with muscle length [1-2], and BTX can decrease muscle length range of force exertion [1]. Our previous finite element modeling study on effects of BTX on muscular mechanics indicate that a vast majority of sarcomeres attain higher lengths than identical sarcomeres of the BTX-free muscle [3]. Such *"longer sarcomere effect"* (LSE), can be considered as the characteristic determinant of effects of BTX on muscular mechanics leading to variable force reduction and decreased length range. LSE is ascribed to muscle fiber-extracellular matrix (ECM) interactions [4] and hence should be directly dependent on the mechanical properties of the ECM. Remarkably, recent experiments also show that BTX injection causes increased passive muscle forces and collagen content of the ECM [1], suggesting an increased stiffness of muscular connective tissues. Taking these in to account and using finite element modeling we aimed at testing the hypothesis that ECM stiffness increase due to BTX causes LSE to be more pronounced.

Methods: Our long existing Linked Fiber-Matrix Mesh model was used by inactivating selected muscle elements to represent partial muscle paralysis effect of BTX. Muscle modeled earlier with the middle half of its volume paralyzed [3] was chosen as the reference case. Compared to that, two manipulated ECM stiffness cases were studied: enhanced ECM stiffness in (i) muscle fiber direction only and (ii) muscle fiber and cross-fiber directions together. ECM stiffness was manipulated by changing related material properties to achieve steeper stress-strain curves (up to two fold at high strain).

Results: Manipulated ECM stiffness cases did show higher muscle passive forces (e.g. by two fold at high length) compared to the reference case. A more pronounced LSE was also found however limited to shorter muscle lengths (for approx. 60% of the length range). In contrast, for intermediate and longer muscle lengths LSE was less pronounced. See the figure for mean strain values along muscle fascicles modeled at short and long muscle lengths exemplifying this finding. Therefore, our hypothesis was confirmed only in part. However, the effects of manipulated ECM stiffness on muscular mechanics were substantial. The optimum length for the manipulated ECM cases shifted to lower muscle lengths decreasing the active length range of force exertion (up to 13%). Notably, the active force production potential of the activated muscle parts increased (up to 7%). This is because enhanced LSE at shorter muscle lengths favor active force production of sarcomeres operating at the ascending limb of their force-length curves. Similarly, reduced LSE at longer muscle lengths cause sarcomeres operating at the descending limb of their force-length curves to produce more force. Narrowing of the length range of muscle force exertion does not agree with the intention of improving joint range of

motion of treated CP patients using BTX. Therefore, it represents an inferior effect. Enhanced active force production potential of the activated muscle parts of muscle exposed to BTX compromises the force reduction effect, which can be counter-indicated in case of agonist-antagonist force imbalance. However, muscles of CP patients are known to be weak. For such patients this can offer a balance between reduced spasticity (via paralyzed muscle volume) and availability of sufficient muscle force to coop with the demands of bodily motion.

Figure:



Caption: Effects of increased ECM stiffness on longer sarcomere effect (LSE). Partially paralyzed muscle model represents muscle exposed to BTX (activated muscle parts: fascicles 1–5 & 13–17; paralyzed muscle parts: fascicles 5–13). Compared to the reference case, fascicle mean fiber direction strains of manipulated ECM stiffness cases decreased at short (A) and long (B) lengths indicating more and less pronounced LSE, respectively.

Conclusion: Manipulated ECM stiffness mimicking experimental findings has complex effects on mechanics of partially paralyzed muscle representing muscle exposed to BTX. Varying LSE for different muscle lengths is the central determinant, implications of which should be further investigated also experimentally.

EFFECT OF METHOD FOR DETERMINING INITIAL MUSCLE ACTIVATIONS ON SIMULATIONS OF SQUAT JUMPING

Zachary J. Domire [1,*] John Challis [2]

[1]Department of Kinesiology, East Carolina University, Greenville, [2]Department of Kinesiology, Pennsylvania State University, State College , United States

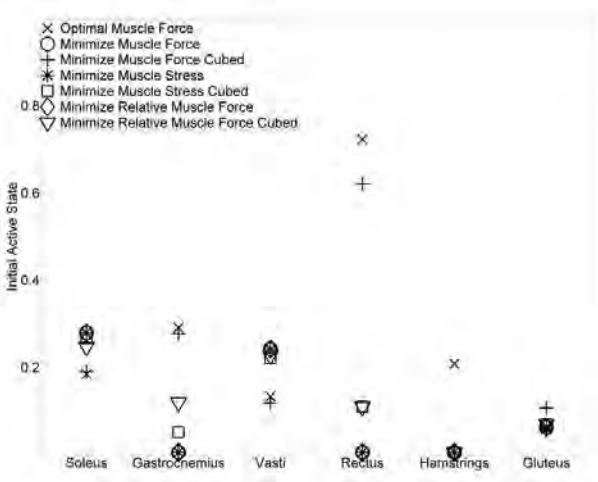
Introduction and Objectives: For most human movements there is more than one muscle that can complete the task. This redundancy has several biological advantages, but during submaximal movements this for allows infinite combinations of muscle forces that produce the same motion. A common approach for determining individual muscle forces is to perform inverse dynamics and optimize the relative contributions to the joint torque such that muscle force or muscle stress is minimized [1]. These approaches result in estimates for muscle force contributions with little or no co-contraction. If instead muscle force or stress cubed is minimized some co-contraction is typically present [2]. Performing computer simulations of movements is an alternative approach to identifying individual muscle forces. Simulations can solve for muscle forces that optimize the movement towards achieving an objective such as maximizing performance [3] or minimizing energy cost [4]. However, the initial muscle forces are still often calculated using a static optimization approach [5]. The goal of this study is to examine the effects of instead solving for the initial muscle forces such that the choice also minimizes the objective function during simulated jumping.

Methods: The model used is similar one validated previously [3]. The model is comprised of four rigid links connected by frictionless hinge joints. The initial posture of the squat was selected to be similar to what was used by experimental subjects from Challis and Domire [3]. The model is actuated by six muscle-like actuators representing the major muscle groups of the lower extremity. Each of these muscle-like actuators were Hill-type models consisting of a series elastic element and a contractile elements with nonlinear activation dynamics as well as force-length and force-velocity properties. The optimal control problem was converted to a static problem by representing the time histories of the neural excitations with discrete control nodes separated by 0.05s, with linear interpolation between nodes. The neural excitation control nodes were selected with a genetic search algorithm. The objective function for optimization was to maximize vertical energy at take-off with constraints to ensure the simulation was performed without a countermovement and the initial position was in static equilibrium. The initial muscle activations were solved for such that the choice either maximized the objective function or such that one of six static criteria was minimized: minimizing muscle force, muscle stress, relative muscle force, muscle force cubed, muscle stress cubed, or relative muscle force cubed. Jump heights and initial muscle activations were compared across the simulations.

Results: The optimal initial muscle activations included larger activations of the bi-articular muscles compared with the uni-articular muscles at each joint, and therefore, substantial co-contraction was present in the initial posture. The initial muscle activations for the linear approaches were identical. The linear approaches all included no initial contribution from bi-articular muscles, and therefore, had no co-contraction. The non-linear approaches included co-contraction to varying degrees (Figure 1). Minimizing muscle force cubed produced the largest activations in the bi-articular muscles of any of the static approaches. The activations of the gastrocnemius and rectus femoris were similar to the optimal solution. None

of the static approaches resulted in any hamstrings activity in the initial posture. The Jump heights were similar across approaches. However, jump height was largest when the initial activations were optimized for performance (Table 1). The jump height was smallest for the linear approaches and closest to optimal when minimizing muscle force cubed.

Figure:



Caption: Figure 1. Initial muscle activations selected using various approaches.

Conclusion: While the impact on jump height of using various approaches to determine initial muscle activations was small, there was considerable variation among the initial muscle activations selected. The optimal solution was the only one of the simulations to include hamstrings activation at the beginning of the jump. The results suggest that athletes due to subtle sub-maximal initial activation of their muscles can influence jump performance.

Table:

Objective Function	Jump Height (cm)
Optimal Force	24.3
Min Force	24.1
Min Force Cubed	24.3
Min Stress	24.1
Min Stress Cubed	24.1
Min Relative Force	24.1
Min Relative Force Cubed	24.1

AS-0468

OPTIMISATION OF GLENOHUMERAL STABILITY IN A MUSCULOSKELETAL MODEL

Edward K. Chadwick [1,*] Dimitra Blana [1] Ton van den Bogert [2]

[1]Institute for Science and Technology in Medicine, Keele University, Stoke-on-Trent, United Kingdom, [2]Department of Mechanical Engineering, Cleveland State University, Cleveland, United States

Introduction and Objectives: Many clinical problems in the shoulder involve loss of stability of the glenohumeral (GH) joint, leading to loss of function and pain. Understanding the role of different structures around the shoulder is therefore important to understanding the normal function of the joint. Musculoskeletal models can provide insight into the function of musculoskeletal systems by allowing examination of internal variables that are hard to measure in vivo. A number of shoulder models have been presented [1], with varying degrees of complexity. Two models with a complete description of the shoulder girdle are the Delft Shoulder and Elbow Model [2] and the Dynamic Arm Simulator [3]. GH stability in these models is described by the joint reaction force (JRF) vector. The joint is assumed to be stable when the direction of the JRF lies inside the rim of the glenoid, modelled as an ellipse, and instability is assumed to arise when the JRF falls outside the rim. In inverse-dynamics, instability is prevented using a non-linear constraint that ensures the JRF remains inside the rim. This leads to recruitment of the rotator cuff (RC) muscles to maintain GH stability, consistent with patterns seen in vivo.

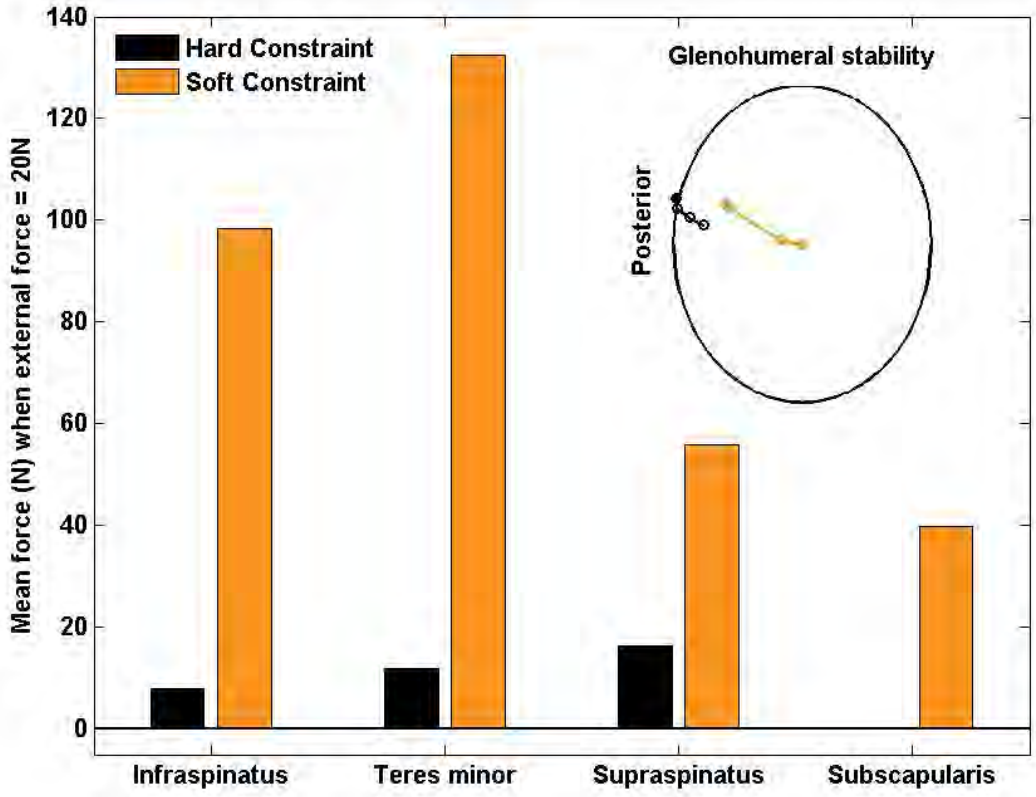
However, for movement patterns where the joint is naturally stabilised by external loads, there is no additional RC muscle force requirement, even if that results in a JRF that falls just inside the rim. If the loads suddenly change, the joint could become unstable; a hard constraint that becomes active only when the JRF reaches the rim might not best represent physiological control mechanisms. An alternative method is to include GH stability in the cost function, and minimise the deviation of the JRF from the centre of the ellipse. This may lead to a more natural and gradual increase in RC activation as GH stability is increasingly challenged. The objective of this study was to test such an approach.

Methods: The Dynamic Arm Simulator consists of seven segments, eleven degrees of freedom, and 138 muscle elements [3]. Inverse-dynamic simulations were implemented as optimisation problems and solved using Direct Collocation [4]. This method discretises both control and state variables on a temporal mesh, transforming a constrained optimal control problem into a set of algebraic constraints. The constraints are based on an implicit formulation of system dynamics, described in [3]. The optimization has an additional constraint per time node, which requires that the scapula stays on the surface of the thorax to avoid winging. The objective function consists of two terms, one that encourages the simulation to stay close to the measured kinematics, and one that minimizes muscle energy consumption, described in [5]. GH stability is included either as an additional constraint at each time node (hard constraint, HC) or as an additional term in the objective function (soft constraint, SC), weighted equally to energy consumption.

Results: As an example of a potentially destabilizing task, the model was set to 20° shoulder flexion with the arm straight, with an external force pushing the hand upwards at 0, 10 and 20N. This load does not significantly recruit the superior rotator cuff muscles (which participate in abduction) and therefore allows examination of their stabilising role in response to load magnitude changes. The direction of JRF was calculated at each force level, for HC or SC. These are shown as

empty circles in figure 1, pointing further from the center of the ellipse as the external force increases, with the HC JRF reaching the rim when the force is 20N. The muscle co-contraction required to centralize the SC JRF is evident by the higher mean force of the RC muscles (shown in the figure for the maximum force of 20N). Subsequently, the external force was removed suddenly and the instantaneous JRF direction was calculated (filled circles). In the case of the HC, this led to instability (the circle is outside the ellipse), while for the SC the joint remained stable.

Figure:



Caption: Comparison of rotator cuff forces and glenohumeral stability between hard and soft constraint methods

Conclusion: A novel approach to modelling GH stability in inverse dynamics that involves minimising instability, rather than including it as a constraint, has been presented. The method produces a pattern that maintains joint stability with a larger margin than the constraint method, and may represent a more physiological approach. Future work will involve in vivo measurements to validate the approach and identify optimal weight factors for the terms in the cost function.

TOWARDS THE GENERATION OF A PARAMETRIC FOOT MODEL USING PRINCIPAL COMPONENT ANALYSIS

Alessandra Scarton [1,*] Zimi Sawacha [1] Claudio Cobelli [1] Xinshan Li [2 3]

[1]Department of Engineering Information, University of Padova, Padova, Italy, [2]Department of Mechanical Engineering, [3]The Insigneo Institute for in silico Medicine, University of Sheffield, Sheffield, United Kingdom

Introduction and Objectives: The diabetic foot is one of the most serious complications of diabetes mellitus, which causes alterations in foot structure and leads to the development of plantar ulcers [1]. Several 3-dimensional (3D) finite element models (FEMs) have been proposed to study the behaviour of the foot own to their ability to characterise and quantify the loads developed in the different anatomical structures, and how these affect foot tissues under different loading conditions [2-3]. Current methods for the development of foot FEMs are based on individual specific MRI or CT data, which in addition of being either expensive or time consuming, requires high levels of user intervention due to the complexity of foot anatomy. The purpose of this study was to develop a method for generating a parametric foot model based on Principal Component Analysis (PCA). The procedure was first applied to the first metatarsal bone (FMTB), by taking into account that the area underneath the FMTB is one of the most subjected to plantar foot ulcers in diabetic subjects [1]. PCA has already been used for the characterisation of other bones such as the adult femur [4].

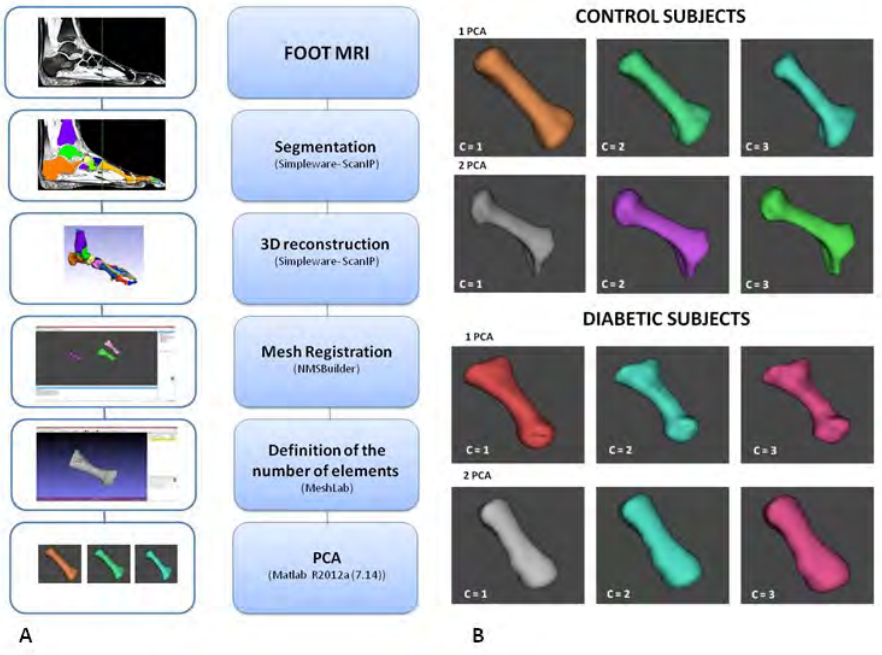
Methods: MRI scans of 6 subjects, 3 healthy (HS) (mean age 32.3 ± 10.1 years, mean BMI 21 ± 1.6 kg/m^2) and 3 diabetics (DB) (mean age 65.6 ± 5 years, mean BMI 29.4 ± 6.5 kg/m^2) feet were acquired as in [3]. The grey scale images were segmented with Simpleware-ScanIP software (v.5.0) into 30 bones and the foot skin as contour of the homogenous mass of foot soft tissues. Each foot mesh was generated as in [3] and the FMTB mesh of every subject was extracted. Then PCA was applied in order to identify the main features that characterise the anatomical variations of FMTB. Before PCA was performed, the bone FEMs were aligned to eliminate spatial variations, and the same number of elements was applied to each mesh. Two software were used to achieve these tasks: NMSBuilder for mesh co-registration and MeshLab for controlling the number of elements. The elements of the meshes were reordered using k-nearest neighbour algorithm so that the nodal numbers were consistent across all FEMs. Nodal coordinates of the meshes were extracted to form a matrix **M** where each row corresponded to one individual. The mean nodal coordinates M_{mean} across the population were then calculated and subtracted from **M** to obtain M_{adjust}= **M**- M_{mean}. The covariance matrix of M_{adjust} was evaluated and an eigenvalue analysis was performed using Matlab 2012a (7.14) (an example of the workflow is reported in Figure A) [5]. The procedure was applied first to the controls and the diabetic subjects separately (considering two distinct groups including 3 subjects each), and then by considering a whole group of 6 undifferentiated subjects.

Results: The PCA analysis resulted in a set of eigenvalues and associated eigenvectors, which represented the principle variations in the different FMTB meshes. This shape change was visualised by generating hypothesised models that contains features of the principal components by applying the following equation:

$$M_{new}=M_{mean}+U_i c\sqrt{\lambda_i}$$

Where M_{new} represents the new mesh and c is the scale factor that controls the amount of variation captured by the eigenvalues and eigenvectors (λ_i, U_i) in both positive and negative directions (see Figure B).

Figure:



Caption: In A the workflow to run the PCA. In B the differences between the bones of the 2 groups after PCA.

Conclusion: In this study, PCA has been successfully applied to the database of 6 meshes and it has shown some preliminary results in anatomical variations within the dataset.Results showed that the most significant shape variations were located in the proximal aspects of the bones, followed by the distal ends of the bones, as shown in Figure B. When the procedure was applied to two distinct groups each containing 3 subjects, only the first two eigenvalues were significant. However, by considering a whole group of 6 undifferentiated subjects 5 eigenvalues were significant. This suggested a limited number of subjects available in the dataset. In the future, we plan to improve PCA predictions by including additional subjects into the study. Interestingly, the shape variations between healthy and diabetic patients were considerably different (see Figure B), which may provide insights into structural changes for diabetic patients in the future. Another limitation of the present study is the high computational cost considering only a single bone. However, it demonstrated that variations in FMTB morphology could be extracted using PCA. Further improvements can be made to improve computational efficiency and high performance computing resources could also be used in the future in order to apply PCA on all the foot.

AS-0470

THE ROLE OF SARCOMERE LENGTH NON-UNIFORMITIES IN RESIDUAL FORCE ENHANCEMENT

Kaleena R. Johnston [1,*] Azim Jinha [2] Walter Herzog [2]

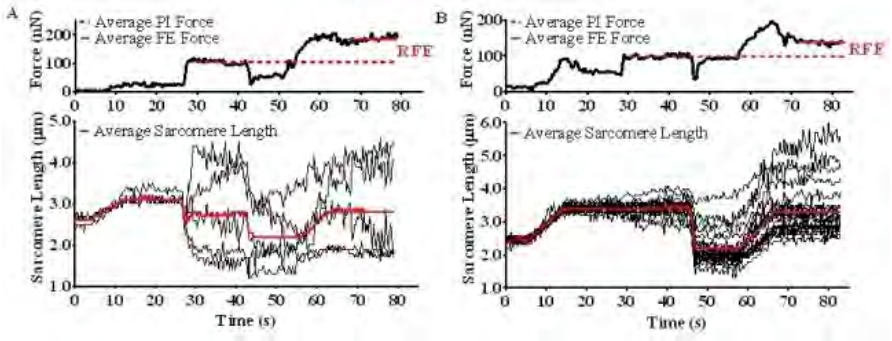
[1]Faculty of Kinesiology, [2]University of Calgary, Calgary, Canada

Introduction and Objectives: Residual force enhancement (RFE) is a characteristic of skeletal muscle describing the increase in isometric steady-state force following an active stretch (force-enhanced, FE), compared to the force of an isometric contraction at the final length (purely isometric, PI) [1]. It has been suggested that RFE is a result of the unstable nature of sarcomeres at lengths along the descending limb of the force-length relationship. This instability of sarcomere lengths is thought to cause long, weak sarcomeres to lengthen more than short, strong sarcomeres, when a myofibril is actively stretched. This mechanism is proposed by the Sarcomere Length Non-Uniformity Theory, and if it is the mechanism of RFE, then sarcomeres should become more non-uniform in length after an active stretch [2]. Previous research, however, has reported an inherent stability of sarcomeres following active stretching [3]. While this contradicts earlier hypotheses, it is still unclear whether sarcomere length non-uniformities play a role in the development of RFE. Therefore, the purpose of this study was to investigate the hypothesis that sarcomere length non-uniformities would increase from the PI state to the FE state.

Methods: Isolated rabbit psoas myofibrils (n = 12) were stretched passively to an average sarcomere length along the descending limb of the force length relationship [4]. Myofibrils were then activated. Five seconds after full activation, they were rapidly shortened, held for ten seconds, and then stretched back to the original length [5]. Individual sarcomere lengths and force were determined throughout the protocol and were used to identify steady state PI and FE conditions (Figure 1). Standard deviations (SDs) of the mean sarcomere lengths in each state were compared to analyze non-uniformity.

Results: Myofibril forces increased from the PI state (127 ± 44 nN) to the FE state (174 ± 52 nN), showing 39 ± 15 % RFE (p = 0.002). Mean sarcomere lengths were 2.8 ± 0.3 µm and 2.9 ± 0.3 µm for the PI and FE states, respectively. Mean sarcomere lengths in each state for each individual myofibril were compared to ensure that the force in the FE state could be compared to the force in the PI state. Mean sarcomere length SDs significantly increased from the PI state (0.7 ± 0.4 µm) to the FE state (0.9 ± 0.5 µm), (p = 0.008).

Figure:



Caption: Results from two of the myofibrils indicating the force (top) and the lengths (bottom) of each individual sarcomere along the myofibril throughout each experiment. Red lines on each graph indicate average values. Myofibril A demonstrated 78 % RFE with no increase in sarcomere (n = 5) length non-uniformity (SD = 1.1 μm). Myofibril B demonstrated 40% RFE and an increase in sarcomere (n = 23) length non-uniformity from 0.2 μm to 0.8 μm.

Conclusion: While statistical analyses of the current results suggest that sarcomere length non-uniformity may play a role in the phenomenon of RFE, three of the twelve myofibrils did not show an increase in sarcomere length non-uniformity. Despite this, all of these myofibrils demonstrated RFE. Interestingly, one of these three myofibrils exhibited the greatest amount of RFE (78 %) out of all of those tested (Figure 1A). In addition, one myofibril exhibited four times more non-uniformity in the FE state (SD = 0.8 μm) compared to the PI state (SD = 0.2 μm) (Figure 1B). These results suggest that, on average, there is an increase in sarcomere length non-uniformity following active stretching of single myofibrils; however, an increase in sarcomere length non-uniformity is not essential to produce RFE following active stretching. Therefore, the development of sarcomere length non-uniformities during active muscle stretching is neither a necessary nor a sufficient condition for RFE and in order to fully understand this phenomenon, it is necessary to investigate other possible mechanisms contributing to RFE.

SIMULATING SHORTEST MUSCULOTENDON PATHS ACROSS MULTIPLE BIOLOGICALLY ACCURATE WRAPPING SURFACES IN REAL TIME

Andreas Scholz [1,*] Michael Sherman [2] Ian Stavness [3] Scott Delp [4] Andrés Kecskeméthy [5]

[1]Department of Mechanics and Robotics, University of Duisburg-Essen, Duisburg, Germany, [2]Department of Bioengineering, Stanford University, Stanford, United States, [3]Department of Computer Science, University of Saskatchewan, Saskatoon, Canada, [4]Departments of Bioengineering and Mechanical Engineering, Stanford University, Stanford, United States, [5]Chair of Mechanics and Robotics, University of Duisburg-Essen, Duisburg, Germany

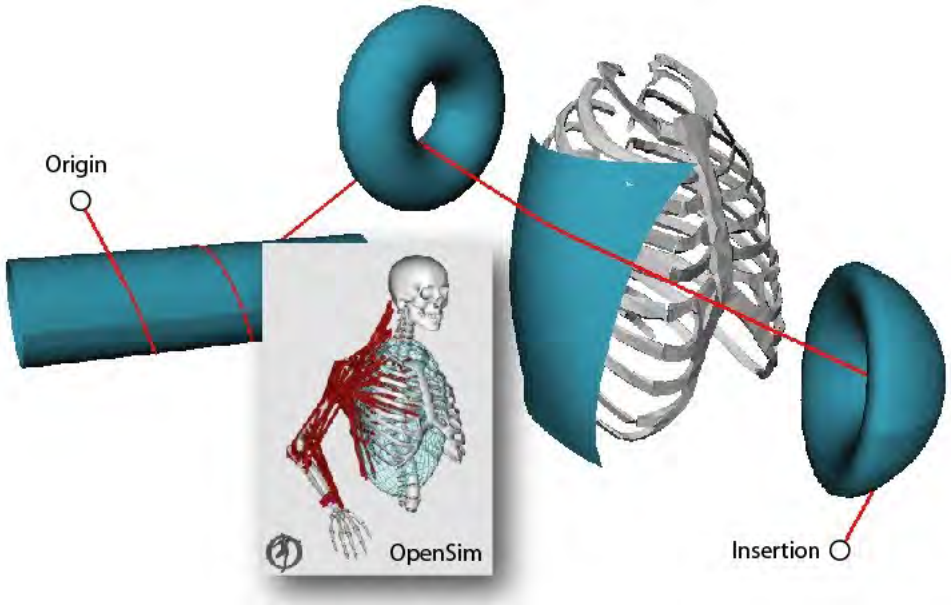
Introduction and Objectives: In musculoskeletal simulations, musculotendon paths are commonly modeled as locally length-minimizing strings which wrap around geometric obstacle surfaces representing bones and neighboring tissue. An accurate computation of these paths, their length and their rate of length change is essential to the correct prediction of muscle moment arms, muscle forces, and the resulting joint loads. Biological muscle typically wraps around multiple complex obstacles, yet state-of-the-art muscle wrapping methods are either limited to analytical results for a pair of simple surfaces [1], or they are computationally expensive [2]. This trade-off between accuracy and speed has limited the development of more accurate musculoskeletal models, particularly of the back and shoulder, the hip, or the hand. Here we present a method for the fast and accurate computation of a musculotendon's shortest path across an arbitrary number of general smooth wrapping surfaces, and an explicit formula for the path's exact rate of length change. We demonstrate by simulation benchmarks that the method computes high-precision solutions for path length and rate of length change, allows for wrapping over biologically accurate surfaces, and is capable of simulating muscle paths over hundreds of surfaces in real-time.

Methods: Our goal is to compute a muscle's locally shortest path between its origin point O and its insertion point I, while it wraps around a series of obstacle surfaces. Since the total path minimizes the length between O and I, it can be considered as a concatenation of length-minimizing curve segments, i.e., straight lines between the surfaces and geodesics on the surfaces. The solution approach for finding the total path consists in finding a set of geodesics on the surfaces such that all transitions between the straight lines and adjacent geodesics are collinear, i.e., the transitions have no 'kink'. The collinearity conditions at the transitions between geodesics and straight lines are used to formulate a set of nonlinear constraint equations for the shortest path. The shortest path in the neighborhood of a given configuration is computed by finding the root of the constraint equations via Newton's method using an explicit Jacobian. The Jacobian contains the partial derivatives of the path's constraints with respect to natural variations of the parameters that define each geodesic: the starting point, direction, and length. Since the constraints for each geodesic only depend on the parameters of the geodesic itself, and the parameters of the two neighboring geodesics, the Jacobian Matrix has band structure. Therefore, the computational costs of our method grow linearly with the number of wrapping surfaces which makes the method very efficient for simulating shortest wrapping paths over multiple obstacle surfaces. A muscle path's rate of length change, i.e., its contraction velocity, is an important input when computing muscle forces using Hill-type

muscle models. We have derived an explicit formula for the exact path's rate of length change to avoid nonsmooth approximations with finite differences.

Results: We demonstrate the method's ability to wrap over nonsimple, biologically accurate surfaces and its computational speed using two simulation benchmarks: (1) a force-driven simulation in which a single muscle path wraps around four (nonsimple) surfaces: a cylinder, a torus, a parametric surface patch fitted to a human ribcage, and an elliptic torus. In the literature, the geometry of the human ribcage is typically approximated by an ellipsoid (see OpenSim model in Fig.), which causes errors in muscle moment arms and muscle forces. For the shown simulation time-frame, the path length was 46.89 LU (length units) and its exact rate of length change was -3.02 LU/s; (2) we evaluated the computational costs by wrapping a single muscle path over a variable number of moving cylinders using a desktop computer with an Intel i7, 3.5GHz. For 500 cylinders, the real-time factor was 0.62 (faster than real-time) and for 1000 cylinders it was 1.34 (slower than real-time).

Figure:



Caption: Wrapping over multiple (nonsimple) obstacles including a surface patch fitted to a human ribcage.

Conclusion: In contrast to existing methods, the presented method is both general and fast. It does not rely on special-case solutions and can handle a large number of nonsimple wrapping surfaces in real time. It computes time-continuous, geometrically smooth, and high-precision solutions for the shortest path, its length, and its rate of length change. The theoretical derivations of the method are slightly more involved compared to existing methods, yet the final methods's implementation into biomechanics software packages is straight forward. Because of its speed and its generality, we believe the method will allow biomechanists to develop more accurate yet fast musculoskeletal models.

A THREE-DIMENSIONAL MUSCULOSKELETAL MODEL OF THE LABRADOR RETRIEVER (CANIS FAMILIARIS) PELVIS AND HIND LIMBS

Walter Dingemanse [1,*] Ilse Jonkers [2] Lode Bosmans [2] Magdalena Müller-Gerbl [3] Jos Vander Sloten [4] Ingrid Gielen [1]

[1]Department of Medical Imaging and Small Animal Orthopaedics, Faculty of Veterinary Medicine, Ghent University, Merelbeke, [2]Human Movement Biomechanics Research Group, Faculty of Kinesiology and Rehabilitation Sciences, KU Leuven, Leuven, Belgium, [3]Institute of Anatomy, Basel University, Basel, Switzerland, [4]Biomechanics Section, Faculty of Engineering Science, KU Leuven, Leuven, Belgium

Introduction and Objectives: In veterinary medicine, canine sports medicine is one of the most recent research areas. The use of musculoskeletal computer models provides a great opportunity to further enhance our understanding of joint biomechanics and limb function [1].

As a result of the extreme variation in body types between different dog breeds, there is a need for breed-specific biomechanical research. Kinematic and kinetic gait analysis have already been applied in veterinary medicine [2,3], but current multi-body simulation models consist of limited data from mixed-breed dogs [4]. The accuracy of canine gait analysis, can greatly be improved by using breed-specific musculoskeletal models.

The objective of this study was to develop a breed-specific musculoskeletal model of the hind legs of a Labrador Retriever. To facilitate collaboration with other specialists, it was important to use readily available modelling software.

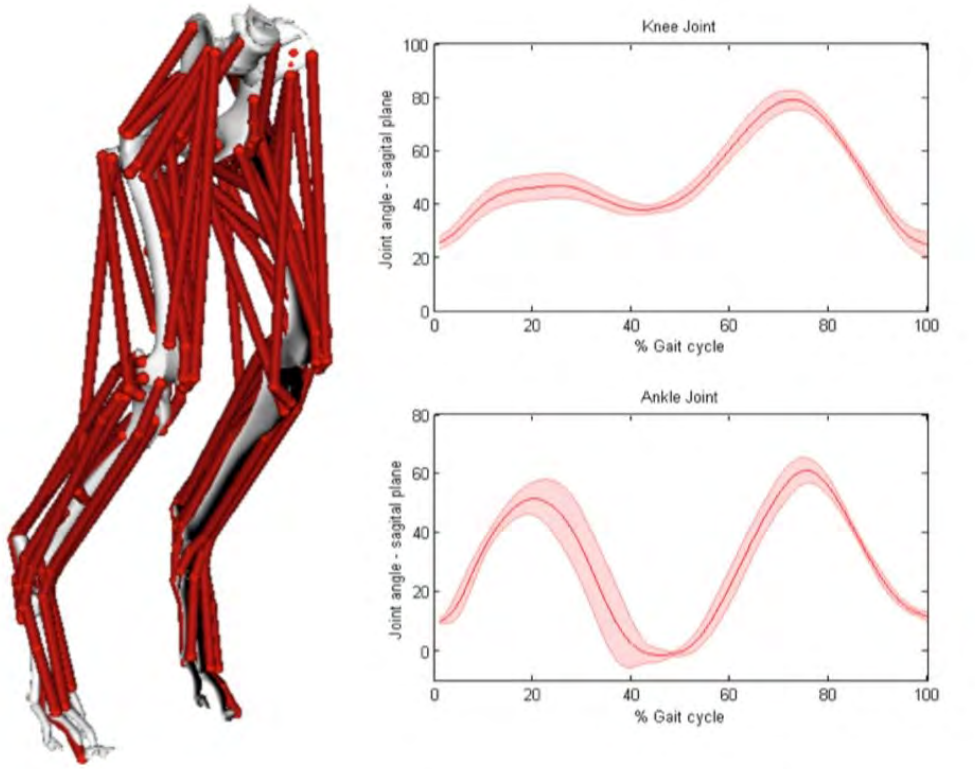
Methods: The musculoskeletal model was based on a computed tomographic (CT) scan of a healthy, adult Labrador Retriever. Bone geometry, was derived from the CT images using segmentation and three dimensional rendering (Mimics, Materialise, Leuven, Belgium).

Segment definitions were based on literature [5] and dynamical segmental parameters were determined non-invasively using CT and computer software (Abaqus, Dassault Systemes, Vélizy-Villacoublay, France).

The musculoskeletal model was based on the widely used, open-source software OpenSim [6] and included bone geometry from the last lumbar vertebra, sacrum, pelvis, femur, patella, tibia, tarsal bones, and phalanges. Left and right limb were assumed to be equal. Four different segments were defined pelvis, femur, tibia and foot. The hip joint was modeled as a spherical joint with three degrees of freedom (DOF) between the femur and the pelvis. The hip joint center (HJC) was identified by fitting a sphere to the femoral head. For the knee joint, flexion and extension was modeled by coupling rotation to translation of the tibia relative to the femoral condyles. The movement of the patella also included rotation and translation, in function of the knee angle. The ankle joint was modeled as a one DOF hinge joint between the tibia/fibula and the talus with the joint axis between the distal aspect of the medial and lateral malleolus. The tarsal bones and phalanges were assumed to be rigidly connected for simplification purposes. For each leg, 39 musculotendon units were represented. Muscle geometry was based on CT images and insertion points were checked with available literature [7] (Figure). The kinematic markers were placed on anatomical landmarks and included at least 3 markers per segment.

Results: Using the canine OpenSim model, kinematic and kinetic data was used to execute inverse kinematics and inverse dynamics, in five Labrador Retrievers, providing joint angles and moments (Figure). This model can be considered a generic model for Labrador Retrievers, a breed often studied in canine biomechanical research.

Figure:



Caption: Musculoskeletal model of the hind limbs and pelvis (left) and joint angles of the knee and ankle joint (right)

Conclusion: To the author's knowledge, this is the first description of a breed-specific musculoskeletal model of the hind limbs of a dog. Although inter-subject variation will exist, the breed-specific model conformation provides a significant improvement over current multi-body simulation models. Further development of the model will include refinement of the foot-segment, and the inclusion of muscle- and tendon-specific parameters. The open-source nature of this model allows further improvements and modifications through collaboration with the whole canine biomechanical research community.

BODY SEGMENT PARAMETERS AND INERTIAL PROPERTIES OF THE GERMAN SHEPHERD POLICE DOG

Yvette Jones [1 2,*] Silvia Raschke [1] David Kenyon [1] Philip Riches [2]

[1]Technology Centre, British Columbia Institute of Technology, Burnaby, Canada, [2]Biomedical Engineering, University of Strathclyde, Glasgow, United Kingdom

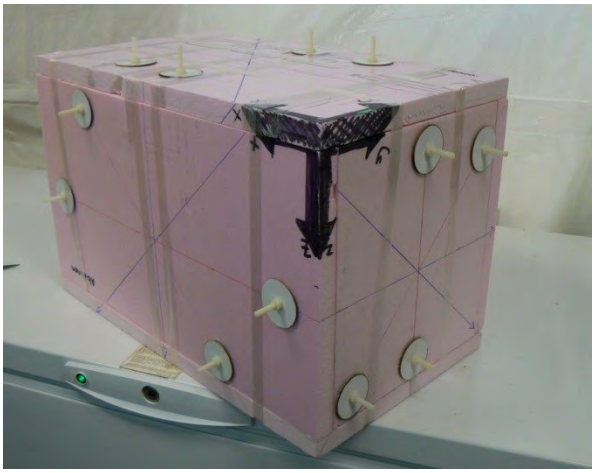
Introduction and Objectives: In Canada, the German Shepherd (Alsatian) is the breed of choice for the majority of police forces across the country. They must maintain top physical condition to obtain success in their job and do so through regular training over the course of an average eight-year career. An injury while training or on the job will sometimes put both dog and handler out of commission and it is up to the veterinarian to get the team back on the job. But while there has been great progress in attaining knowledge of veterinary musculoskeletal disease and surgical techniques, evaluation of functional outcome from these techniques have been primarily subjective and based on the experience and observational skills of the clinician. There is little consistent data available to assist veterinarians in making clinical decisions. In fact, differences of as much as five months have been found in clinical reports quoting on the same injury[1]. For humans, biomechanical models such as the Modified Helen Hayes marker set are often used to guide rehabilitation, treatment and even surgery[2]. Anthropometry and/or mass distribution (inertial) properties are the basis of such models. Along these lines there have been numerous morphometric studies on horses and some on racing dogs however there are few that focus on the German Shepherd. Only one study provides data regarding mass distribution characteristics of the German shepherd skull, describing the principle moments of inertia and their orientation to the body and segment morphometry[3]. Therefore, the objective of this paper is to present a complete set of three-dimensional inertial properties of the German Shepherd including segment morphometrics, mass, centre of mass (COM) , inertial vectors and density of all body segments. Based on these measurements regression equations will be determined for the estimation of inertial properties in living dogs. The mass distribution characteristics obtained will be used to establish a reliable means of estimating these same properties on living animals from easily measured body parameters. The goal is to present a technique that is reasonably accurate, can be safely applied to any male German Shepherd police dog, and takes little time to acquire.

Methods: Six male German Shepherd (Alsatian) police dog cadavers (age 2 to 8yrs ; mass 36.8 +/- 1.68 kg) in good physical condition were used for the study. Each cadaver was measured and weighed, joints were placed in the midposition of the movement range and the body was frozen rigid. Joint angles were bisected in a systematic dismemberment procedure to produce 102 unit segments (17/cadaver). Each segment was weighed and segment COMs located relative to link end points using a box reference axis system (Figure 1). According to this same reference system, moments of inertia were measured about the six axes using the simple pendulum method. Finally, segment volumes were determined using the water displacement method.

Geometric models of the primary body segments have been selected to predict the principle moments of inertia. Using this method, simple morphometric measurements such as total body mass and segment length can be used in regression equations to predict the masses and moments of inertia of each segment.

Results: Morphometic data were collected for each segment (Table 1) and multiple regression equations created to predict segment mass and moments of inertia about the principle axes.

Figure:



Caption: Figure 1: Orthogonal reference box - abdominal segment

Conclusion: No previous study has provided complete data on the three-dimensional properties of the mass distribution of the German Shepherd. This paper summarizes the rationale and measurement techniques. Data from this research will be used in further study for the creation of dynamic models of canine locomotion and on the police dogs for studies on impact, training and rehabilitation.

COMPARISON OF ESTIMATED AND MEASURED MUSCULAR ACTIVITY DURING INCLINED WALKING

Nathalie Alexander [1,*] Hermann Schwameder [1]

[1]Department of Sport Science and Kinesiology, University of Salzburg, Hallein, Austria

Introduction and Objectives: Inclined walking is associated with increased joint loading [1]. Musculoskeletal models can be used to provide information about the corresponding muscle forces causing the resulting joint loading. Direct measurement of muscle forces is generally not feasible in a non-clinical setting and in healthy populations, therefore non-invasive methods based on musculoskeletal modeling should be considered [2]. One commercially available musculoskeletal modeling system for biomechanical simulations is the AnyBody Modeling System (AnyBody, Denmark), which has been used in several different studies analyzing level walking [3,4]. Before using this model for analyzing muscle and joint forces during inclined walking, it has to be verified if the model can also be applied for this task. Therefore, the purpose of this study was to compare estimated muscle activity of the inverse dynamic musculoskeletal AnyBody model with experimentally measured EMG data during inclined walking.

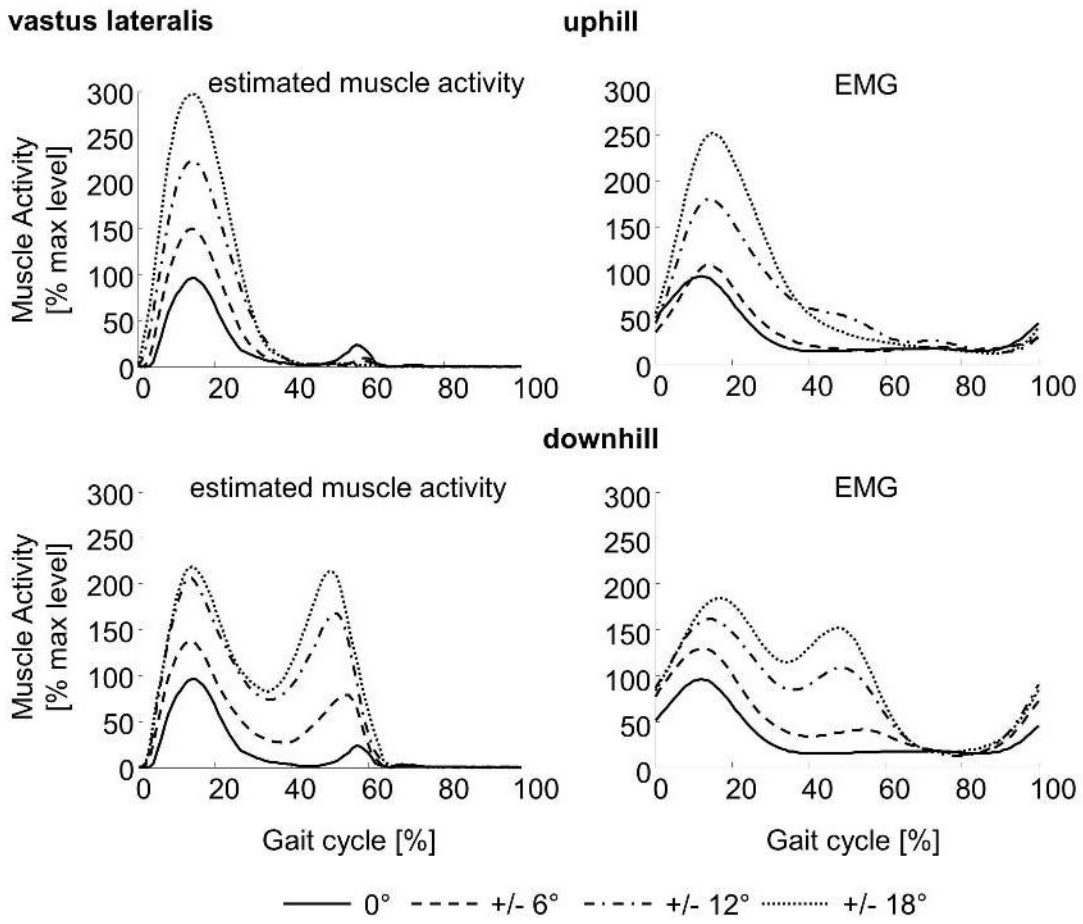
Methods: Ten healthy male participants (26.5 ± 4.2 y, 1.80 ± 0.04 m, 78 ± 7 kg) were recruited and were asked to walk on a ramp (6 m x 1.2 m) with two integrated force plates (AMTI, USA, 1000 Hz) at different inclinations of -18°, -12°, -6°, 0°, 6°, 12° and 18°. Participants had to perform 3 valid trials in a constant pre-set speed of 1.1 m/s. The trial with the speed closest to the pre-set speed was used out of the 3 measured ones for further analysis. Kinematic data was captured with a 12-camera, marker based motion capture system (Vicon, UK, 250 Hz). Muscle activity of biceps femoris (BF), rectus femoris (RF), vastus lateralis (VL), tibialis anterior (TA) and gastrocnemius lateralis (GL) were recorded from the right leg using a wireless EMG system (myon AG, Switzerland, 1000 Hz).

EMG signals containing movement artefacts were excluded. In case of GL, EMG signals of all participants had to be removed for all downhill walking trials. For the other muscles a minimum of 6 participants could be analyzed per inclination. The raw EMG data were filtered using a second order Butterworth band pass filter with a frequency range of 20-300 Hz, rectified and EMG envelope curves were calculated using a fourth-order Butterworth low pass filter at 6 Hz. The processed EMG data were normalized with respect to the maximum measured EMG value for that muscle during level walking. The musculoskeletal model used in this study is a standard model (AMMR 1.6.2, MoCapModel) available in the AnyBody Modeling System (vers. 6.0). In order to compare the EMG data with the estimated muscular activity, the latter was also normalized to the maximum value during level walking. For comparison, the correlation coefficient and the mean absolute error (MAE) were calculated between the normalized EMG envelope and the estimated muscle activity [5].

Results: Both measured and estimated muscle activity of RF and VL (Figure 1) increased with increasing inclination during uphill and downhill walking compared to level walking. Muscle activity of BF and GL increased during uphill walking, being more prominent in the EMG data. During downhill walking estimated muscular activity of GL decreased and BF muscle activity remained similar. Measured and estimated muscle activity of TA during downhill walking was highest at an inclination of -18°, with the -6° and -12° condition showing similar results and was lowest during level walking. For uphill walking measured and estimated muscle activity showed minor agreement. Correlation coefficients

between estimated and measured muscular activity were in about 85% of the conditions above 0.7 and on average 0.792 (Table 1). The average MAE over all inclinations and muscle was 31%, the lowest average MAE was found for BF (20%), while the highest was found for TA (41%).

Figure:



Caption: Figure 1: Estimated (left) and measured (right) muscle activity for m. vastus lateralis during uphill (top) and downhill (bottom) walking. Muscle activity is normalized to maximum activity during level walking.

Conclusion: The used model showed good agreement between the measured and estimated muscular activity for most conditions and muscles. Therefore, it might be used for further muscle force analyses in similar groups of participants.

Table:

inclination	TA	GL	VL	RF	BF	mean
-18°	0.83		0.91	0.84	0.95	0.87
-12°	0.81		0.87	0.70	0.82	0.80

SPASTIC SEMITENDINOSUS MUSCLE OF CEREBRAL PALSY PATIENTS STIMULATED ALONE CANNOT BE THE DOMINANT SOURCE OF KNEE MOVEMENT LIMITATION DESPITE BEING A PRIMARY KNEE FLEXOR

Filiz Ates [1,*] Ahu Nur Turkoglu [1] Fuat Bilgili [2] N. Ekin Akalan [3] Yener Temelli [2] Can A. Yucesoy [1]

[1]Biomedical Engineering Institute, Bogazici University, [2]Istanbul Faculty of Medicine, Department of Orthopaedics and and Traumatology, [3]Faculty of Health Science, Physiotherapy and Rehabilitation Division, Istanbul University, Istanbul, Turkey

Introduction and Objectives: Recently, by using our intra-operative experimental methods [1] in cerebral palsy (CP) patients we have shown that spastic gracilis (GRA) muscle has no abnormal mechanics representative of the patients' joint movement disorder [2]. Muscle forces as a function of knee angle showed that joint range of force production was not narrow and peak GRA forces were not available at flexed joint positions. However, the GRA is not a primary knee flexor. This suggests that the dominant source of high forces causing movement limitation at the joint may be the hamstrings. The goal was to test the hypothesis that the knee angle-muscle force characteristics of a primary knee flexor, semitendinosus (ST) muscle show abnormal mechanics representative of joint movement disorder.

Methods: Procedures in strict agreement with the guidelines of Helsinki declaration were approved by a Committee on Ethics of Human Experimentation at Istanbul University, Istanbul. Seven spastic CP patients (age 7.7±2.5 years) with no prior remedial surgery participated. The Gross Motor Functional Classification System scores (above II), popliteal angle values (PA=73.1±10.7), and clinical tests led to a decision that all patients required remedial surgery.

Knee angle-isometric ST force (KA-F_{ST}) data (n=10) were collected during muscle lengthening surgery. Under general anesthesia, after routine incisions to reach the distal ST tendon, a buckle force transducer was mounted over it. ST muscle was stimulated supramaximally using skin electrodes. F_{ST} was measured at various KA starting from 120° (maximal experimentally attainable flexion) to 0° (full knee extension). Using a least squares criterion, KA-F_{ST} data were fitted with a polynomial function.

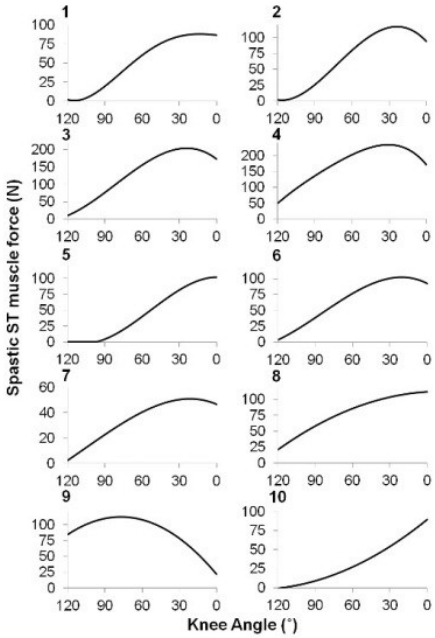
Experimental data were used to test the hypothesis objectively based on (i) joint range of muscle force production and (ii) availability of high muscle force at low muscle length. A narrow joint range together with the availability of the peak muscle force at flexed knee positions was considered to provide an *ideal match* between the patients' impaired joint motion and the experimental KA-F_{ST} data. Spearman's Rank correlation coefficient was calculated to test if PA values are correlated with KA at which F_{STpeak} was produced ($KA_{FST\ peak}$) and with the ratio between F_{STpeak} and the forces measured at knee flexion ($\%F_{STpeak|120°}$). Correlations were considered significant at $P<0.05$.

Results: The figure shows the KA-F_{ST} curves. F_{STpeak} (118.9N±56.8N) range between 50.9N (limb 7) and 234.2N (limb 4). None of the limbs showed an *ideal match* between the patients' impaired joint motion and the experimental KA-F_{ST} data. The operational joint range of force production for limb 9 ($KA_{FSTpeak}$=77°) was the narrowest. However, including that limb, for a majority of the limbs, spastic ST muscle operates within both ascending and descending portions of its KA-F_{ST} curve. The exceptions are limbs 8 and 10, which operate only in the ascending portion. Therefore, the operational joint range of force production of spastic ST is not narrow.

Negligible or quite low values of $\%F_{GRApeak|120^\circ}$ (0% for limbs 1-2, 5 and 10, and below 22% for limbs 3-4 and 6-8) indicate clearly that spastic ST muscle does not produce high forces at flexed knee positions. Due that, overall, the shapes of the KA-F_{ST} curves show considerable similarity with typical force-length characteristics of general healthy muscle. This is different than relatively larger values of $\%F_{GRApeak|120^\circ}$ shown previously for spastic GRA [2]. For limb 9, $\%F_{STpeak|120^\circ}$=75 is the highest however, still less than that reported for spastic GRA. No significant correlations were found between PA and $KA_{FST\ peak}$ and $\%F_{ST\ peak|120^\circ}$.

Recently published data indicate that for GRA muscle stimulated simultaneously with an antagonistic muscle, KA-F_{GRA} curves can indeed show abnormal mechanics [3]. This suggests that the role of inter-antagonistic mechanical interaction is a key determinant for joint function limitation in CP patients causing it to be the net result of simultaneous activity of different muscles, mechanics of each of which are not necessarily abnormal. This may also explain our present findings representing target muscle's activity only.

Figure:



Caption: The isometric KA–FST characteristics of the spastic ST muscle.

Conclusion: Our hypothesis was rejected showing that although it is a primary knee flexor, spastic ST shows no abnormal mechanics to be the dominant source of apparent knee joint movement limitation of CP patients. Contribution of other knee flexors to such movement disorder, but particularly conditions of simultaneous activity of several muscles should be further investigated.

A CRASH TEST AND CRASH TEST SIMULATION OF A NEONATE WHILST WEARING STANDARD NEONATE RESTRAINTS

Jonathan M. A. Melvin [1,*] Donal McNally [1] David Branson III [1] Don Sharkey [2]

[1]Engineering, [2]Medicine, University of Nottingham, Nottingham, United Kingdom

Introduction and Objectives:

Neonates born after less than 33 weeks gestation often require the services of specialist obstetric care units (OCU). An 11.4% annual increase in OCU admissions increased the rate of survival by 6.25% in New South Wales [1]. Because many neonatal births are unexpected, the neonate is often moved from its place of birth to an OCU. Transportation of the neonate is via an ambulance whilst inside an incubator. While most of the contents of an ambulance are designed to pass crash tests BS_EN_1789:2007 the incubator and the method of constraining the child currently do not have a corresponding test. As a result, there is an increased potential risk to the neonate in the event of an accident. In 2011/12 between 12,000 and 13,000 neonates were transported in the UK [2]. Of the 48,384 ambulances in the US over 4000 will crash each year [4] (8.27%). It is therefore reasonable to assume that an ambulance crashing whilst carrying a neonate is inevitable in the near future. Despite the risk there is no current method of simulating and evaluating crashes that include neonates, restricting the development of safer systems. The purpose of this study is to produce a madymo simulation that will enable the evaluation of injuries sustained by a neonate during a traffic collision, a result that is not possible to discover from standard test track crash investigations.

Methods:

One of the most common current constraint methods (NeoRestraint, ParAid) was tested using a dummy (LifeForm preterm manikin) on a test track, custom built at the University of Nottingham. The dummy and incubator were placed on a trolley which was accelerated to 5.8m/s at point of impact. The accelerations of the test track trolley and the dummy were recorded with an accelerometers placed on the trolley, the dummy's body and head. The crash was repeated three times and an averaged representative crash was produced from accelerometer data. The average representation data were then used within MADYMO to replicate the crash. For comparison of the MADYMO simulation to the test track crash, further accelerometers were placed in the same locations on both the crash test dummy and the MADYMO dummy. To compare the two data sets a method previously used by TNO was adapted using the following comparison criteria:

-The peak value of the curves

-The timing of the peak values

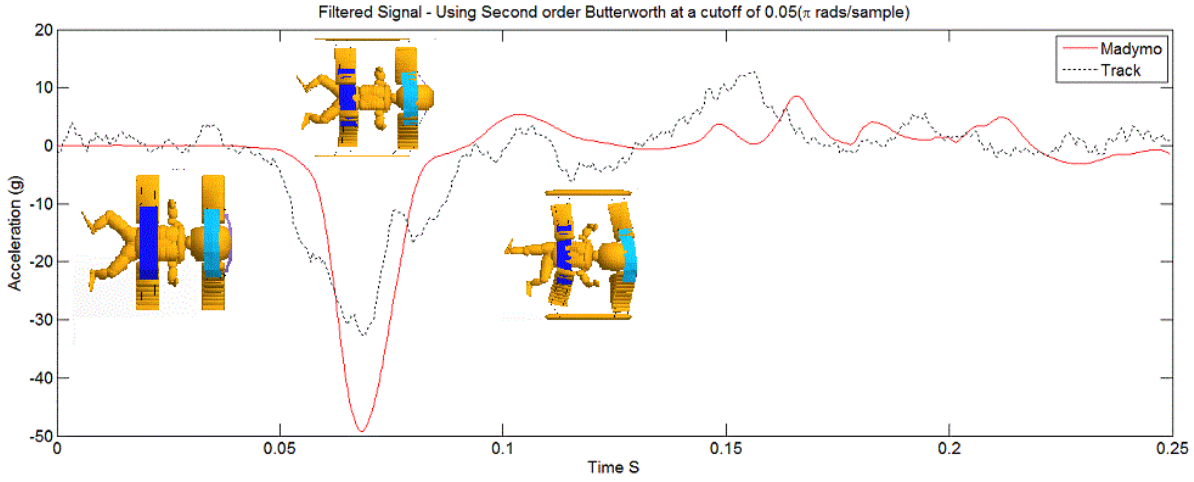
-The overall correlation of the curves

Results:

The highest peaks acceleration of the head observed in the madymo simulation was 552 m/s^2 occurring in the direction of travel. The same acceleration recorded from the track data was 459 m/s^2. The total displacement in the simulation was 0.1m whilst the track dummy moves 0.12m, thus in both cases there is a 20% difference between the track and the simulation. The head injury criterion was 163.7 with a window of 15ms.

The percentage changes observed in this investigation are greater than that previously seen in MADYMO tests but this will be reduced as the model is improved in further iterations. However, this report is still able highlight that, the scale of the accelerations exerted on the dummy are many magnitudes higher than that which a child can be expected to survive.

Figure:



Caption: A comparison of the dummies' head accelerations (test track Vs madymo simulation). With images from the Madymo crash located at time of capture.

Conclusion: Conclusion:

A track test crash and a MADYMO simulation of a neonate being transported using a standard strapping technique were developed. The accelerations and video evidence from the track test show that the child likely sustained injury. Whilst, the use of a madymo simulation enables the investigator to provide quantitative values for the injuries sustained.

Table:

Injury	value

EXTERNAL KNEE MOMENTS AND LOADING DURING JOGGING POST-ARTHROSCOPIC PARTIAL MENISCECTOMY: A LONGITUDINAL STUDY

Michelle Hall [1,*] Tim Wrigley [1] Ben Metcalf [1] Flavia Cicuttini [2] Rana Hinman [1] Alasdair Dempsey [3] Peter Mills [4] David Lloyd [5] Kim Bennell [1]

[1]Centre for Health Exercise and Sports Medicine, University of Melbourne, [2]Department of Epidemiology and Preventive Medicine, Monash University, Melbourne, [3]School of Psychology and Exercise Science , Murdoch University, Perth, [4]School of Allied Health Sciences & Centre for Musculoskeletal Research,, [5]School of Rehabilitation Sciences, Griffith University, Gold Coast, Australia

Introduction and Objectives: Meniscal injury is a strong risk factor for developing medial tibiofemoral and patellofemoral osteoarthritis [1] and arthroscopic partial meniscectomy (APM) is commonly performed to treat meniscal tears. Altered external knee moments and load-related measures have been reported post-APM during walking [2,3] and potentially contribute to the increased risk of knee osteoarthrits in this population. However, there are no studies investigating external knee moments or load-related measures during jogging in these patients who are typically middle-aged. Therefore, the aim of this study was to compare the external knee moments and load-related measures during the stance phase of jogging: i) between people 3 months post-APM and healthy controls, ii) between people 2 years post-APM and healthy controls, iii) to determine if 2-year change differed between legs (ie. APM leg, non-APM leg and controls).
Methods: Seventy-eight participants (90% male; 41.1±5 yrs; BMI 27.9±3.8 kg/m^2) with medial APM were assessed 3 months following surgery (baseline) and 64 were re-assessed 2 years later (follow-up). Thirty-eight healthy controls (82% male; 40.8±7 yrs; BMI 25.1±3.4 kg/m^2) were assessed at baseline and 23 were re-assessed at follow-up. Participants jogged barefoot and performed 3 trials at a self-selected pace while kinematic data (120Hz) were collected using an 8-camera motion analysis system (Vicon) with kinetic data recorded (1080 Hz) using 3 force plates (AMTI). The first external peak knee adduction moment (KAM) and external peak knee flexion moment (KFM), were calculated using inverse dynamics (University of Western Australia model), averaged and normalised to body weight (BW) × height (HT). The first peak vertical ground reaction force (vGRF) and maximum loading rate during weight acceptance were also assessed and normalised to body weight (BW). A mixed linear model was used to evaluate differences between legs (i.e. APM leg v controls; non-APM leg v controls and APM v non-APM leg) at baseline and follow-up. Similarly, a mixed linear model was used to assess differences in change between legs and adjusted for baseline scores. For each mixed linear model, 'participant' was entered as a random effect and 'leg' as a fixed effect. Significance was set at alpha 0.05.
Results: At baseline, peak vGRF was lower in the APM leg compared to control. Peak external moments and maximum loading rate were also lower in the APM leg compared to the non-APM leg at baseline, while the peak KAM and peak vGRF was higher in the non-APM leg compared to controls (Table 1). At follow-up, the peak vGRF was higher in the APM leg compared the to the non-APM leg (Table 1). Over 2 years, the peak KFM increased in the APM leg compared to the non-APM leg (mean difference (95% CI), 1.35 (0.66 – 2.04) Nm/BW×HT, $p<0.05$) and the peak vGRF increased in the APM leg compared to the controls (mean difference (95% CI), 0.10 (0.00 – 0.19), BW, $p<0.05$).

Figure:

Table 1. Mean (SD) for the APM group and control at baseline and follow-up

	Baseline			Follow-up		
	APM group (n = 78)			APM group (n = 64)		
	APM leg	Non-APM leg	Control (n =38)	APM leg	Non-APM leg	Control (n =23)
Jogging speed (m/s)	2.46 (0.39)	2.46 (0.39)	2.48 (0.34)	2.44 (0.40)	2.44 (0.40)	2.45 (0.36)
Peak KAM (Nm/(BW×HT)%)	4.18 (2.05)[b]	4.86 (2.21)[a]	3.67 (1.46)	4.49 (2.41)	4.85 (1.92)	3.93 (1.57)
Peak KFM (Nm/(BW×HT)%)	10.91 (2.84)[b]	12.03 (2.58)	11.29 (2.17)	12.48 (2.53)	12.24 (2.37)	11.88 (2.91)
Peak vGRF (BW)	2.22 (0.26)[a]	2.28 (0.24)[a,b]	2.36 (0.18)	2.22 (0.27)[b]	2.17 (0.29)	2.19 (0.20)
Max loading rate (BW/s)	120.98 (81.95)[b]	134.02 (96.17)	103.38 (79.73)	161.42 (0.96)	157.67 (94.80)	158.51 (87.49)

[a]p<0.05 compared to controls; [b]p<0.05 compared to controls; KAM: knee adduction moment; KFM: knee flexion moment; GRF: ground reaction force; BW: body weight; HT: height

Conclusion: Individuals 3 months following APM, appear to protect the recently operated knee from excessive loads while jogging. This is evidenced by lower peak knee moments and maximum loading rate in the APM leg compared to the non-APM leg, and a reduced peak vGRF in the APM leg compared to controls. At follow-up, the peak vGRF was higher in the APM leg compared to the non-APM leg. Although the clinical implications of a higher peak vGRF are unknown, the increase in peak vGRF is of potential concern for long-term knee joint health considering the compromised function of the meniscus. Furthermore, the increase peak KFM observed in the APM leg warrants consideration given the association between a higher peak KFM and osteoarthritic changes, albeit during gait [4,5]. This study is the first to describe knee-related loads during jogging in middle-aged individuals following APM who are at risk for developing osteoarthritis. Nonetheless, our findings should be interpreted with caution as participants jogged barefoot in a laboratory environment.

HAMSTRING SHEAR MODULUS IS ALTERED PRIOR TO STRAIN INJURY: A CASE STUDY

Matthew Q Salzano [1,*] Erica A Bell [1] Jamie E Hibbert [1] Patrick M Rider [1] Zachary J Domire [1]

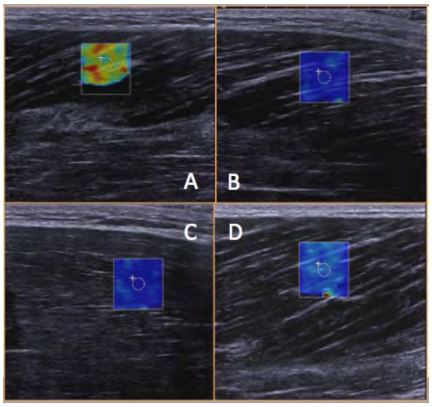
[1] Kinesiology, East Carolina University, Greenville, United States

Introduction and Objectives: Hamstring strains are among one of the most common sports-related muscle injuries. They are the most common injury during track and field competitions [1,2]. Over the course of a season, approximately20% ofa teamincurs hamstring injuries [3]. Though these injuries are common, the mechanism of injury is unknown. They often occur under high speed/ force movements, like sprinting [4]. It is also thought that hamstring strains, in regards to sprinting, occur as a result of the eccentric contraction during the terminal swing phase [5]. Though it is likely that it is not the force that causes the hamstring injuries to occur but it is the strain the muscles undergo during these movement that causes the damage [6]. However, the forces and strains in the muscle at the time of injury do not seem sufficient enough to cause injury [7]. It is possible that hamstring strains occur due to the accumulation of microdamage, similar to the mechanism behind stress fractures in bone. The purpose of this study is to prospectively track hamstring shear modulus over the course of a season in elite track athletes to determine if muscle material properties are altered prior to the occurrence of strain injury indicative of accumulated microdamage. We hypothesize that material properties will be locally altered prior to strain injury.

Methods: Ten elite sprinters (5 males, 5 females) are being tracked throughout the 2014-2015 track season. All subjects read and signed an informed consent form approved by University IRB. Previous injury history and leg dominance were recorded for each athlete. At this time, one athlete incurred a grade 1 strain in his right hamstring one-week post scans, allowing for a case study examination. Ultrasound lastography data was taken on 18 sites per athlete: proximal, middle, and distal portions of the biceps femoris long head (BF), semitendinosus (ST), and semimembranosus (SM) in each leg using an Aixplorer SuperSonic Imagine. Shear modulus measurements were taken with a 3 mm diameter region of interest from the middle of the scan area. Three measurements were performed at each site and the means are presented.

Results: Before scans, 3 male and 3 female athletes were found to have no history of hamstring strains. Of the remaining athletes, both females had history in both hamstrings, one male had history in his right and the other had history in his left. One of the non-injured male athletes strained his right SM one-week post-scans (S009). The athlete indicated his strain was close to the middle portion of the muscle, adjacent to the location of the middle SM measurement site. Table 1 shows his SM shear modulus measurements compared to the 3 other non-previously injured SMs. S009's distal portion was comparable to the distal portions of the 3 healthy subjects. The middle portion of S009 was ~2.5-3x higher than the middle portions of the other subjects, while the proximal region was also markedly higher. Figure 1 shows the picture of the Q-box of the mid-belly for the right BF, ST, and SM for S009 and the mid-belly of a healthy SM from a representative athlete (S007). The mid-belly of the injured SM contains more yellow and red than the other sites, indicating increased stiffness.

Figure:



Caption: Figure 1. Elastography comparisons between the mid-bellies of S009's SM (A), BF (B), ST (C), and S007's SM. The spectrum of blue to red designates low modulus to high modulus.

Conclusion: While only one subject is used as comparison, the evidence is strong to support that muscle material properties are altered prior to strain injury. These results also support our hypothesis that material properties are altered locally between and within muscles. Increased modulus seen in the injured subject could be for a number of reasons. One possible explanation is the swelling due to edema [8]. Another possibility is that the injured site was not directly measured, and the increased modulus is a result of increased tension as a result of nearby disruptions in ECM. Further investigation will reveal if this is unique to this athlete or universal. The ability to track hamstring shear modulus over the course of a season to determine strain risk would go far in the prevention of hamstring injuries.

Table:

	S009	**S004**	**S007**	**S008**
Distal	16.0	15.4	13.7	16.2
Middle	51.1	17.4	21.5	17.3
Proximal	36.4	21.2	12.1	12.5

SAGITTAL PLANE KNEE KINEMATICS PREDICT NON-SAGITTAL KNEE JOINT MOMENTS IN UNPLANNED SIDESTEPPING

Mark A. Robinson [1,*] Cyril Donnelly [2] Jos Vanrenterghem [1] Todd Pataky [3]

[1]School of Sport and Exercise Sciences, Liverpool John Moores University, Liverpool, United Kingdom, [2]School of Sport Science, Exercise & Health, University of Western Australia, Perth, Australia, [3]Department of Bioengineering, Shinshu University, Nagano, Japan

Introduction and Objectives: The direct measurement of anterior cruciate ligament (ACL) strain is typically not possible *in vivo* and *in silico* estimates of ACL strain are computationally demanding with unverified reliability and validity. Instead researchers rely on surrogate measures such as net peak joint moments which reasonably predict ACL injuries [1]. In sidestepping, peak knee moments can elevate ACL strain, but it is specifically the non-sagittal moments that elevate ACL forces towards injurious thresholds [2]. Increasing knee flexion angle (KFA) is seen as an effective strategy to reduce peak knee moments and therefore ACL injury risk [3]. However, to our knowledge no-has provided an empirical rationale that increasing KFA during sidestepping can reduce peak knee joint moments. One previous study [4] attempted to relate KFA at impact to the peak knee abduction moment but found no correlation in males (r^2 = 0.21) nor females (r^2=0.1). The present study aimed to investigate the mechanical relationship between KFA and the knee joint moment vector-field throughout stance in the context of ACL injury risk in sidestepping. The hypothesis was that there was no correlation between KFA and knee joint moments during sidestepping.

Methods: The hypothesis was initially tested in a sample of 34 male Australian rules football players (dataset 1) who performed three unanticipated 45° sidesteps, whilst 3-dimensional motion and force data were recorded. An established biomechanical model with joint constraints was used to calculate the KFA at impact and estimate net knee joint moments according to the ISB X [Flex./Ext.],Y [Ab./Ad.], Z [Int./Ext. Rot.] definitions throughout stance. Canonical Correlation Analysis (CCA)[5], the vector-field equivalent of linear regression, was used to examine the correlation between the knee moment vector-field (M_{XYZ}) with the KFA at impact. Post-hoc analyses of moment couples (M_{XY}, M_{XZ}, M_{YZ}) using CCA and of individual moment components (M_X, M_Y, M_Z) using linear regression were also conducted.

We verified our results in two additional datasets. Dataset 2 was of 27 females who also performed unanticipated sidestepping according to the same protocol as dataset 1. Dataset 3 was 20 male recreational soccer players who performed anticipated sidestepping.

Results: *Dataset 1*

KFA was significantly related to the knee moment vector-field (M_{XYZ}) at around 0-10% and at ~40% stance (figure 1a). The moment couples revealed that it was the non-sagittal moment pair (M_{YZ}) that explained the result at 0-10% (figure 1d). Analysis of moment components individually failed to show the correlation at 0-10% stance (figure 1e,f,g). As the significant correlation married with the time that peak loading (~0-25% stance) and ACL injuries are believed to occur, we sought to confirm these results in two similar but independent datasets.

Dataset 2

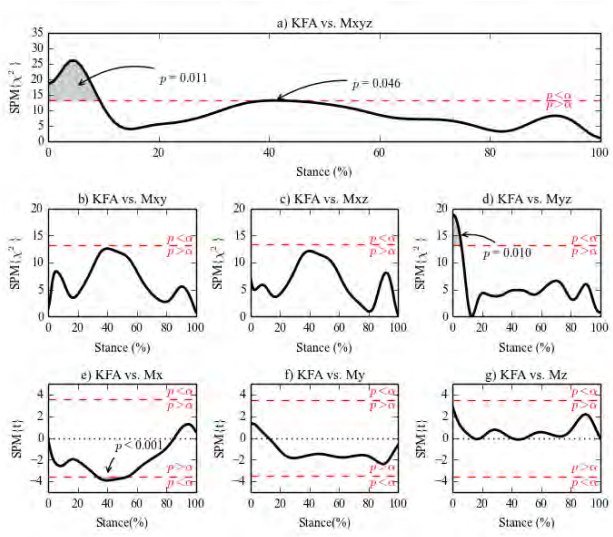
A significant correlation between the KFA and the knee moment vector-field (M_{XYZ}) was observed within the weight acceptance phase of stance, however it occurred slightly later (~10-28% stance). Post-hoc examination showed this too was explained by the non-sagittal moment couple (M_{YZ}) only.

Dataset 3

No significant correlation between the KFA and the knee moment vector-field (M_{XYZ}) was observed in this dataset.

KFA predicted non-sagittal knee joint moments in two similar but independent datasets of unanticipated sidestepping (datasets 1 & 2) but not during anticipated sidestepping (dataset 3). Examination of the knee moment vector-field revealed correlations were strong when vector combinations of moment components were considered. This suggests that the coordinate system into which the moment vector is resolved is unrelated to the moment direction of interest and may also in part, explain the weak correlations observed by McLean *et al*. [4]. These results support the recommendation to increase KFA at impact during unanticipated sidestepping as a means of reducing ACL injury risk given that high non-sagittal knee moments are known to elevate ACL strain.

Figure:



Caption: Figure 1. Relationships observed in dataset #1. (a) The relationship between knee flexion angle (KFA) and the knee moment vector-field (MXYZ). (b,c,d) The relationship between KFA and moment couples. (e,f,g) The relationship between KFA and moment components.

Conclusion: KFA during unanticipated sidestepping is significantly related to non-sagittal knee moments during the weight acceptance phase of stance where ACL injuries occur. The technique recommendation to increase KFA at impact during sidestepping to reduce ACL injury risk appears sound.

AS-0480

FOOT CONTACT ANGLE AND ITS VARIABILITY DURING A PROLONGED RUN IN RELATION TO INJURY HISTORY

Max Paquette [1,*] Clare Milner [2] Daniel Melcher [1]

[1]Health & Sport Sciences, University of Memphis, Memphis, [2]Physical Therapy and Rehabilitation Sciences, Drexel University, Philadelphia, United States

Introduction and Objectives: Runners most often utilize a rearfoot strike (RFS) pattern although some use non-rearfoot patterns (i.e., midfoot, forefoot, toe strike) [1]. A higher rate of running injuries have been linked with RFS runners [2] potentially due to higher loading rates of the vertical ground reaction force [3]. Strike patterns are often assessed using the sagittal plane foot contact angle (FCA; RFS have a greater positive FCA compared to non-RFS runners). Movement variability has been suggested to dissipate stresses and reduce cumulative load on musculoskeletal tissue [4]. Therefore, runners with increased movement variability may be at lower risk of developing a musculoskeletal injury. The objective of this study was to compare foot contact angle and its variability at different times during a 40 minute run between uninjured runners and runners with history of overuse running injury.

Methods: Twenty four currently uninjured runners participated in the study. Twelve runners had not suffered any injuries and twelve had suffered at least one running injury in the past year. Groups were matched for sex (8 men and 4 women), mass (72.5±12.5 vs 72.1±10.0 kg), and average weekly running mileage. Runners completed a 40 minute treadmill run at their self-selected “easy” run pace wearing their own shoes. A 9-camera motion capture system (Qualisys) was used to collect trunk, pelvis and bilateral lower extremity segments movements at the 10min, 20min, 30min and 40min time points of the run. Time of foot contact was identified using kinematic data. Visual3D software (C-Motion) was used to compute FCA measured as the absolute sagittal plane angle formed between a line joining the 5th metatarsal head and the inferior heel markers and the laboratory floor. At each time point, FCA and its standard deviation (SD) of five strides were averaged for all runners. A mixed design (2x4) repeated measures ANOVA was conducted with time as the within-subject factor and group as the between-subject factor ($p<0.05$). Due to the small sample size, Cohen’s d effect sizes (ES) were also computed to compare FCA and its SD between groups and among all four time points.

Results: The ANOVA revealed no group X time interactions ($p = 0.90$) or main effects of time ($p = 0.72$) or group ($p = 0.18$) for FCA. FCA showed a moderate effect size (0.58) between groups. The injury group had greater FCA (i.e., more pronounced heel strike) than the uninjured group (Table 1). The ANOVA revealed no group X time interactions ($p = 0.64$) or main effects of time ($p = 0.87$) or group ($p = 0.93$) for FCA variability. FCA variability showed a negligible ES (0.01) between groups. FCA variability showed a small ES (0.21) for less variability at 40min compared to 10min.

Conclusion: The greater FCA in the injury group indicates that these runners utilize a more pronounced RFS pattern compared to uninjured runners. RFS runners have been associated with higher risks of injuries [2] but the current finding suggests that the degree to which runners RFS may be an important factor associated with injury risk. The lower FCA variability at the 40min time point may suggest that runners reduce their movement variability toward the end of an endurance run compared to the start. Although this difference only showed a small effect size, it suggests that more research is needed to investigate the effects of fatigue on running biomechanics variability. Overall these findings provide

further evidence of a possible association of FCA and its variability with running injuries. The implications of FCA and its variability during a run for injury risk need to be investigated in a larger group of runners and with a prospective design.

Table:

Table 1. Sagittal plane foot contact angle (degrees; mean ± SD) and its standard deviation (degrees; SD ± SD) in both groups for all four data collection times during a 40min run.

		Uninjured	Injured	Time Average
Foot Contact Angle (deg)	10 min	3.57±6.80	7.34±6.26	**5.46±6.68**
	20 min	3.52±7.02	7.12±5.34	**5.32±6.37**
	30 min	3.55±7.22	7.16±5.67	**5.36±6.61**
	40 min	4.01±6.57	7.30±6.00	**5.66±6.38**
	Group Average	**3.79±6.56**	**7.23±5.75**	
Foot Contact Angle SD (deg)	10 min	0.68±0.35	0.66±0.39	**0.70±0.33**
	20 min	0.63±0.19	0.78±0.47	**0.67±0.31**
	30 min	0.64±0.29	0.63±0.28	**0.65±0.26**
	40 min	0.69±0.31	0.61±0.0.37	**0.64±0.26**
	Group Average	**0.65±0.21**	**0.67±0.19**

EFFECTS OF SPEED AND STEP FREQUENCY ON LOADING VARIABLES DURING RUNNING

Tomoya Ueda [1,*] Hiroaki Hobara [2] Yoshiyuki Kobayashi [3] Masaaki Mochimaru [3] Hiroshi Mizoguchi [4] Thijs A Heldoorn [2]

[1]Mechanical Engineering Faculty of Science and Technology, Tokyo University of Science, 2641, Yamazaki, Noda-shi, Chiba, [2]National Institute of Advanced Industrial Science and Technology, Aomi, Koto-ku, Tokyo, [3]National Institute of Advanced Industrial Science and Technology, Waterfront 3F, 2-3-26, Aomi, Koto-ku, Tokyo, [4]Tokyo University of Science, 2641, Yamazaki, Noda-shi, Chiba, Japan

Introduction and Objectives: Tibial stress fractures are one of the most common and potentially serious overuse running-related injuries in runners [1]. The stress fractures are thought to be related, in part, to abnormal lower extremity loading variables, such as vertical average loading rate (VALR) and vertical instantaneous loading rate (VILR). Several researchers reported that runners who developed tibial stress fractures had higher VALR and VILR than a group of age and mileage matched control subjects [2,3]. Thus, modifying these loading mechanics may decrease a runner's risk for stress fracture. Several studies have demonstrated that the loading mechanics is influenced by running speed and step frequency (f_{step}) [4,5]. However, the combined effects of running speed and f_{step} have not been systematically investigated. The purpose of this study was to ascertain which combination of running speed and f_{step} reduces the lower extremity loading variables.

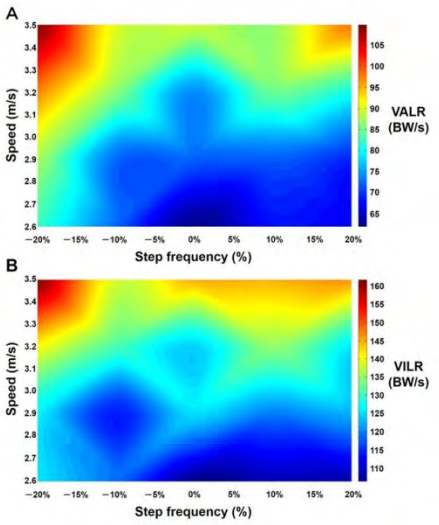
Methods: Ten male individuals with no known neuromuscular disorders or lower-limb functional limitations participated in the study. The participants were instructed to run on a treadmill (PARAGON6; Johnson Health Tech) mounted on six force plates (BP400600-2000; AMTI), from which the vertical ground reaction force (vGRF) was recorded at 1000 Hz. Running speeds were four different speeds (2.6 m/s, 2.9 m/s, 3.2 m/s, 3.5 m/s). We controlled 5 f_{step}: the preferred (0%), below preferred (-10 and - 20%) and above preferred (+10 and + 20%) with a digital audio metronome to facilitate the appropriate f_{step}. The preferred step was determined by a comfortable f_{step} which subjects ran at each speed in test trial. Then, they performed running for 20 seconds at each of 5 f_{step} in a random order at each speed with 5 min rest periods in between. 10 consecutive steps from right leg were used for the analysis. A fourth order, recursive, Butterworth, low-pass filter was used to filter the force plate data at 80 Hz. Foot-ground contact was determined at a vGRF threshold of 30 N. From the measurement of vGRF, the VALR and VILR were determined. VALR was calculated as the total change in force divided by the total change in time during 20-80% of the time to impact peak [6]. VILR was peak sample to sample loading rate during this period. When no distinct impact transient was present, the same parameters were measured using the average time of impact peak as determined for other steps with an impact transient in same trial [7].

Two-way repeated measure ANOVA and Bonferroni post-hoc multiple comparison test were performed to compare the loading variables (VALR and VILR) among 5 frequencies at 4 speeds.

Results: Statistical analysis revealed that the existence of a significant main effect of running speeds and f_{step} on VALR and VILR. However, there was no significant interaction effect between running speeds and f_{step} on VALR and VILR. We found that the minimum VALR and VILR was achieved at the combination of 2.6 m/s and 0% f_{step} (Figure 1). Since loading

variables are varied by combination of running speed and f_{step}, we may be able to recommend effective training and rehabilitation strategy to reduce the risk of running-related injury for each runner.

Figure:



Caption: Figure 1. (A); the result of VALR among 5 frequencies at 4 running speeds. (B); the result of VILR among 5 frequencies at 4 running speeds. Blue represents the least loading variables. Red represents the highest loading variables.

Conclusion: The purpose of this study was to ascertain which combination of running speed and f_{step} reduces the lower extremity loading variables. The results of the present study suggest that a particular combination of running speed and f_{step} exhibits minimum loading variables in running. Hence, ideal combinations of running speed and f_{step} could potentially reduce the risk of running-related injury.

Rehabilitation

AS-0482

EFFECT OF VIRTUAL OBSTACLES NEGOTIATION ON TEMPORAL-SPATIAL GAIT IN HEALTHY YOUNG ADULTS

Mohammad Al-Amri [1,*] Omowumi Dairo [1] Robert van Deursen [1]

[1] School of Healthcare Sciences, Cardiff University, Cardiff, United Kingdom

Introduction and Objectives: Negotiating obstacles is a complex motor-control task that is described as the most common cause of falling during walking [1-2]. Successful obstacle negotiation may be compromised in individuals with gait problems [3]. Understanding how individuals negotiate obstacles while maintaining a stable and safe walking pattern is therefore important for development of interventions based on motor learning. Virtual reality can provide controlled stimuli in a meaningful, safe environment for rehabilitation and motor-control assessment [4]. This study aimed to explore how healthy individuals respond to different presentations of virtual obstacles (VOs). The expectation was that the similar changes would occur in their motor-control as seen for real-world obstacle clearance. Changes in average values of gait parameters were used as performance indicators whereas changes in variability of these parameters were used to indicate altered motor-control.

Methods: Twenty healthy subjects (Age: 25.5±3.9 years; Height: 1.71±0.07 m; Mass: 68.7±11.9 kg; Gender: 12 male & 8 female) walked on a GRAIL system (Gait Real-time Analysis Interactive Lab, Motek Medical B.V.); which consists of an instrumented dual-belt treadmill and a 12-camera Vicon tracking system. Using the self-paced mode, subjects walked under three conditions with a simple 3D endless speed-matched scene presented onto an integrated synchronised 180° screen including projection on the treadmill: 1) Free walking (WalkFR); 2) while clearing regular spaced VOs projected on the treadmill (WalkOT); 3) while clearing regular spaced VOs by controlling spheres representing the toe markers projected on the screen (WalkOS). The VOs in this study were designed in the form of a threshold across the walkway with dimensions 1.0 m x 0.2 m x 0.1 m. Each condition lasted for 3 minutes.

The average and variability (standard deviation) of 1 minute of continuous gait were calculated for: gait speed (GS), cadence (CA), stride length (SL), stride time (ST), and stance duration (SD). A repeated measures ANOVA was used to explore changes in these variables associated with the above walking conditions. The assumption was that the order of difficulty was: WalkFR, WalkOT, and WalkOS. This was tested by means of a polynomial (linear) contrast. The level of statistical significant was set at $p<0.05$.

Results: Descriptive statistics for gait parameters (GS, CA, SL, ST, and SD) are presented in Table 1. GS and CA decreased significantly whilst ST and SD increased significantly with performing the obstacle negotiation tasks. There were no significant changes for SL.

For the gait variability, the results suggest that there were significant changes for all gait variables. Polynomial contrast analysis indicated that there were significant linear differences for GS, CA, ST, and SD related to the predicted order of difficulty: WalkFR, WalkOT, and WalkOS.

Conclusion: Reported results suggest that, as hypothesised, motor-control strategies changed with demand of obstacles negotiation in young healthy subjects. Results indicate that clearing VOs projected on the screen was more difficult than while clearing VOs projected on the treadmill. It may be that differences in demand on cognition and attention can explain

why WalkOS was more difficult than WalkOT. Further studies are needed to clarify these effects and consolidate this conclusion.

Table:

	WalkFR	WalkOT	WalkOS	p-values	polynomial contrast
Average Values of Temporal-Spatial Gait Parameters					
Speed (m/s)	1.33±0.265	1.32±0.215	1.21±0.21	0.019	0.027

TASK DEPENDENCE OF FRONTAL PLANE KNEE CONTROL MEASURED BY FLUENCY AND VARIABILITY DURING FIVE REHABILITATION EXERCISES.

Robert Van Deursen [1,*] Kate Button [1] Paulien Roos [1]

[1] School of Healthcare Sciences, Cardiff University, Cardiff, United Kingdom

Introduction and Objectives: Functional exercises following anterior cruciate ligament (ACL) injury are used to improve whole body motor control and local knee control. Observationally, in clinical practice this represents movement smoothness (fluency) and displacement (variability). However, alterations in knee frontal plane fluency determined in ACL studies seem to be inconsistent [1, 2]. To understand movement fluency and variability better and identify the role of knee control in the context of whole body control, five functional movements used in rehabilitation were compared in healthy participants.

Methods: Healthy participants performed four repetitions of five exercises: walking (WLK), jogging (JOG), double- and single-leg squatting (DLS & SLS), and single-leg hopping (HOP). Each task was executed at their preferred speed/distance. Quiet standing was also recorded. Motion data were collected using the VICON full body marker set. Key landmarks, COM, ipsilateral (IL; dominant/weight-bearing leg) and contralateral (CL) ankles and knees, pelvis, C7, IL and CL wrists, were used to explore whole body motor control by means of fluency and variability of each landmark whilst weight-bearing. Fluency was calculated as the inverse of the average number of times a landmark velocity in the frontal plane crossed zero (Fluency (s) = 1/frequency). Variability was defined as the standard deviation of the frontal plane movement trajectory. A repeated measures ANOVA and Bonferroni adjustment for comparisons were used to investigate COM differences between WLK and the other tasks. Subsequently, the eight other landmarks were compared to COM focussing on the weight-bearing knee.

Results: Results are reported for 29 healthy subjects (height: 1.73±0.11 m, mass: 73.5±16.4 kg, age: 28.0±6.9 years, gender: 10 female, 19 male). COM fluency and variability were significantly different between tasks ($p<0.001$). WLK COM fluency was largest; followed by HOP; SLS; JOG; DLS. Each task differed significantly from WLK ($p<0.001$). HOP COM variability was largest; followed by SLS; WLK; DLS; and JOG. Only JOG differed significantly from WLK ($p=0.004$). As expected, by comparison quiet standing COM fluency (0.01±0.003 s) and variability (0.5±0.4 mm) were substantially smaller compared to the 5 activities.

For walking all landmarks except C7 showed lower fluency compared to COM. For the other activities the pattern differed between stance leg landmarks and the rest of the body i.e. ankle fluency was lower or equal to COM whereas the knee and pelvis showed higher, equal or lower fluency depending on the task. The rest consistently showed higher fluency compared to COM.

For all activities IL ankle variability was significantly lower or equal compared to COM. All other landmarks showed significantly higher variability compared to COM (except two). Knee fluency ($p<0.01$) and variability ($p<0.001$) differed substantially between activities.

Conclusion: Whole body control was demonstrated across activities: COM variability was smallest compared to the constituent regions with higher variability, apparently compensating for each other. Fluency differed more unpredictably between activities. Knee control of the stance leg particularly seemed to adapt to task requirements. During double-leg squatting the knee was least tightly (slower, larger oscillations) and during jogging most tightly (faster, smaller oscillations) controlled. Therefore, to interpret knee fluency and variability in ACL deficiency and repair, this task-dependence needs to be considered.

Table:

Fluency (s)	**WLK**	**JOG**	**DLS**	**SLS**	**HOP**

IS TREADMILL WALKING WITH VIRTUAL REALITY AN ACCEPTABLE AND PLAUSIBLE TRAINING MODALITY FOR STROKE SURVIVORS?

Andrew Kerr [1,*] Jennifer Dryden [2] Craig Childs [1] Madeleine Grealy [2] Andrew Murphy [1] Philip Rowe [1]

[1]Biomedical Engineering, [2]School of Psychological Sciences and health, University of Strathclyde, Glasgow, United Kingdom

Introduction and Objectives: For many stroke survivors recovering independent walking is an important objective, however, although most survivors recover some walking ability it is often insufficient to meet the challenges of community walking[1]. Treadmill walking, through forced use of the paretic side, has some evidence as an intervention but lacks transfer to community walking[2]. With the rationale of providing a more realistic, variable walking experience, the addition of virtual reality (VR) to treadmills is a recent, promising, development. This aim of this study, therefore, was to investigate the credibility and acceptability of treadmill training with VR among stroke survivors.

Methods: This was a feasibility study testing the validity of treadmill training with and without VR through comparison with overground walking. User acceptability was assessed through independent interviews. Six ambulant stroke survivors (aged 56.5±10.6years, 116±93.3months post stroke) were recruited from local stroke clubs. They attended an introductory session for baseline measurements (over ground gait biomechanics, functional mobility and cognition) and familiarisation with the treadmill VR system (MOTEKMedical, Netherlands) including wearing a harness. They then participated in two training sessions, one week apart, each session included treadmill walking without VR (TW) and treadmill walking with VR (TWVR) e.g. road and forest paths visualisations. The final session included a second measurement of gait biomechanics which provided the data for statistical comparison. Each individual was independently interviewed before and after their participation.

Results: In general minor, non-significant, differences were observed for TM, TMVR and overground walking. There was, however, a consistent, and statistically significant (p= 0.032) finding of greater hip flexion for TWVR, see table for details. Universally, participants found the experience acceptable and enjoyable, although “challenging”.

Conclusion: This feasibility study found treadmill walking (with and without VR) to be similar enough to overground walking to justify it as a training modality for chronic stroke survivors who had already attained some independence in walking. One possible difference, greater hip flexion during treadmill walking, may be a product of harness wearing, and/or relate to the setup of the visualisations. Participants found the experience of treadmill walking acceptable. Although they preferred walking with the visualisations there were few biomechanical differences to simple treadmill walking. Further exploration of individual variability, however, should be undertaken as this may be a factor in translating gains from treadmill training to community walking. In conclusion, similarities between overground and treadmill walking (with and without VR) support its use as a training modality in stroke rehabilitation. No great advantage was evident from the use of visualisation other than participant’s preference, however these findings require further testing.

Table:

Gait variable	Overground Mean (sd)	TW Mean (sd)	TWVR Mean (sd)
Preferred speed (m/s)	0.95 (0.43)	0.72 (0.47)	0.79 (0.39)
Stride length (m)	1.07 (0.39)	0.93 (0.50)	0.95 (0.39)
Step width (m)	0.08 (0.04)	0.10 (0.03)	0.09 (0.02)
Hip angle at initial contact (degrees)	23.43 (14.07)	28.86 (11.50)	31.28 (8.51)
Knee angle at initial contact (degrees)	8.83 (7.72)	13.83 (10.56)	12.39 (10.14)
Hip max flexion angle (degrees)	28.82 (14.84)	35.72 (8.68)	37.37 (7.17)

DEVELOPMENT OF A PERTURBATION PROTOCOL TO QUANTITY GAIT RESILIENCE USING MECHANICAL, VISUAL AND AUDITORY PERTURBATIONS: A CASE STUDY

Sanne Roeles [1,*] Georgia Tarfali [1] Frans Steenbrink [2] Craig Childs [1] Philip Rowe [1]

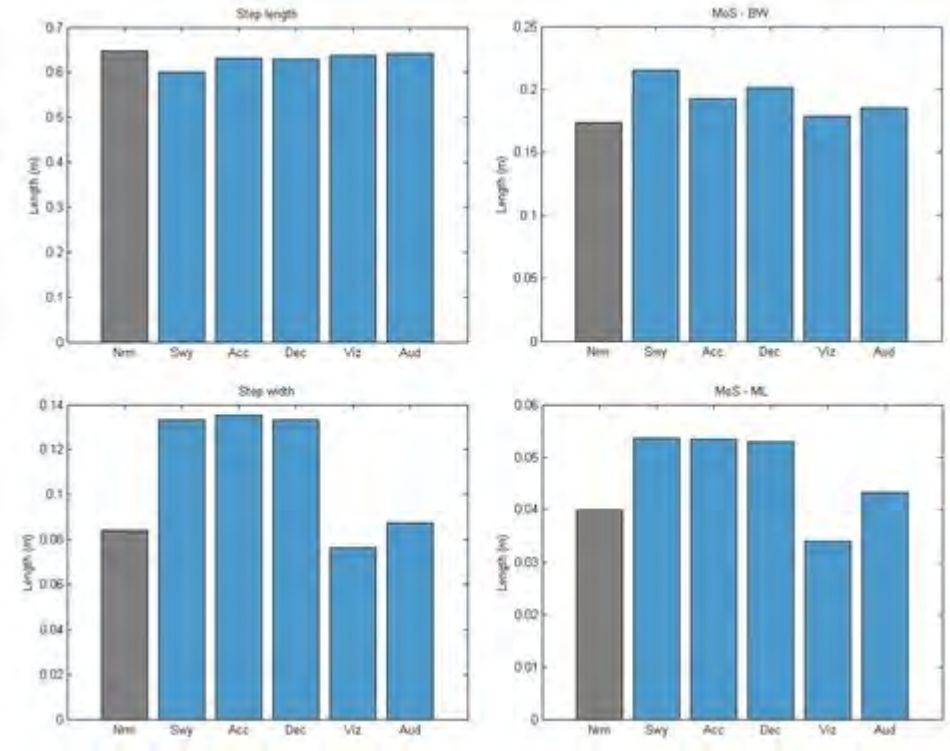
[1]Biomedical Engineering, University of Strathclyde, Glasgow, United Kingdom, [2]Rehabilitation products, Motekforce Link BV, Amsterdam, Netherlands

Introduction and Objectives: Falls are the leading cause of death due to injury in the elderly and therefore a major problem in our aging society. In order to prevent falls it is of great importance that clinicians are able to identify those who are at risk of falling and intervene early. However, capturing gait instability is difficult as the human body is well capable of compensating for impairments and hence it is difficult to distinguish fallers from non-fallers during steady state walking using currently available stability measures[1]. Most falls in the elderly occur during locomotion as gait resilience is compromised due to aging and therefore the ability to resist external perturbations during walking is also decreased. Measuring the response to external perturbations has been proposed to quantify dynamic stability and to identify fall-risk. However, perturbations used in these studies are unlikely to occur in everyday life and are dangerous and difficult to monitor. Little is known about the type of experimental perturbations that could be used for diagnosis of fallers . Therefore, the aim of this study is to evaluate the feasibility of a protocol that mimics perturbations encountered in daily life like, a push, a trip, a slip, sudden darkness or a loud noise

Methods: We evaluated gait resilience using spatio-temporal parameters and the margins of stability (MoS) which reflects the motion state of the center of mass (CoM) with respect to the border of the base of support[2]. One healthy young female walked in a virtual reality (VR) environment at comfortable speed on the GRAIL (instrumented dual-belt treadmill with a motion capture system; Motekforce Link BV, The Netherlands) while full body kinematics were collected. After familiarization and a two minute normal walking trial (Nrm), five perturbation types were imposed: 1) medio-lateral sway of the treadmill (Swy), mimicking a push; 2) acceleration of one treadmill belt (Acc), mimicking a slip; 3) deceleration of one treadmill belt (Dec), mimicking a trip; 4) sudden darkness in the VR environment (Viz) and 5) a loud noise (Aud). All perturbations were imposed at three different intensity levels and repeated three times. Prior to this series of perturbations one perturbation of the middle intensity was imposed as the initial perturbation affects the walking pattern more severely as compared to subsequent perturbations.

Results: In this case study, mean step length, step width, MoS in de backward direction (MoS-BW) and MoS in the lateral direction (MoS-ML) were calculated for the normal walking trial and five strides after the initial perturbation of each perturbation trial. Our subject did not fall and was well capable in completing the entire perturbation protocol. The results (see Figure 1) indicate that mechanical perturbations (i.e. Swy, Acc and Dec) are more challenging as compared to visual or auditory perturbations. In addition stability was more affected in the medio-lateral direction as compared to the anterior-posterior direction, even after anterior-posterior perturbations (i.e. Acc and Dec).

Figure:



Caption: Figure 1 Mean step length (upper left corner), step width (lower left corner), MoS-BW (upper right corner) and MoS-ML (lower right corner) for the normal walking trial (gray bar) and five strides after perturbations (blue bars).

Conclusion: The aim of this study was to evaluate the feasibility of a perturbation protocol that includes various types of perturbations. The perturbations were of low intensities and our subject successfully recovered from all perturbations. The mechanical perturbations clearly affected the walking pattern suggesting that, although intensities were low, the imposed perturbations were challenging. In contrast, the visual and auditory perturbations did not seem to affect the walking pattern. Although this may expected in healthy subjects, results could be different in patients as they generally rely more on external information as compared to healthy people. Altogether, this case study shows the potential of measuring gait resilience by using a perturbation protocol. Future research should aim at finding a combination of perturbation types, perturbation intensities and stability measures that are able to accurately measure gait resilience and differentiate between fallers and non-fallers.

OUTCOME AND SUSTAINABILITY OF A HIPPOTHERAPY-K INTERVENTION IN ADULTS WITH CEREBRAL PALSY ON WALKING SPEED, GAIT-PARAMETERS AND MUSCULAR ACTIVATION.

Carmen Gempp [1,*] Martina Binzen [1] Julia Hayoz [1] Miriam Dousse [1] Lukas Stammler [2] Philippe Merz [2] Ruth Obrist [3] Beat Göpfert [4 5]

[1]Physiotherapy, Health Division, Bern University of Applied Sciences, Bern, [2]BZG, Bildungszentrum Gesundheit Basel-Stadt, Münchenstein, [3]Hippotherapie Obrist, Kaiseraugst, [4]Center of Biomechanics, CMBE, University of Basel, [5]Laboratory for Movement Analysis , Children's University Hospital Basel (UKBB) Basel, Basel, Switzerland

Introduction and Objectives: Crossing a road safe on a pedestrian crossing with traffic lights needs a minimal walking speed. A common European standard is a walking speed of 1m/s (regional variation: 0.8 – 1.2m/s). Therefore the walking speed is crucial and could be used as test parameter for the outcome and sustainability of therapy interventions. Cerebral Palsy patients (CP) are often not able to accelerate there walking speed up to 1m/s, due to several reasons like, e.g. limitations in the neuromuscular control, muscular capabilities, and aerobic efficiency.

The goal of our Time-Series-Study was to analyse the outcome and sustainability of an 18 week Hippotherapy-K (Swiss Hippotherapy standard by Künzle [1]) intervention in hemiplegic adult CP-patients, with a 10m max. walking-speed-test, simulating a road crossing, and an instrumented 3D-gaitanalysis to assess changes in the gait parameters. We compared the results of the tests before and after the intervention, and 18 weeks post intervention within each subject and overall subjects. Further, during the intervention only Hippotherapy-K (once a week, 30–40min, outdoor) was done, all other physical therapies were stopped.

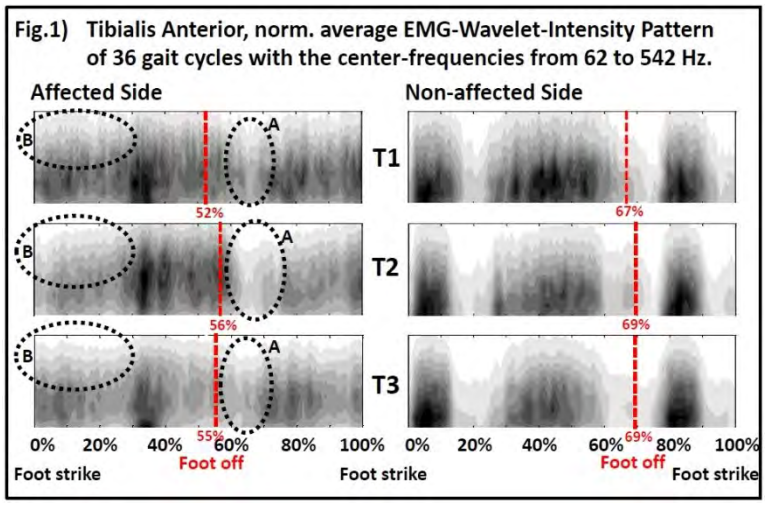
Methods: First, the 6 subjects with a hemiplegic CP (22-46y, 5m, 1f) were performing 3 times a 10m walking-test at max. speed with shoes [2], where the time for each trial was taken. Afterwards an instrumented 3-D gait analyses (Vicon, 12 cameras T20, 200Hz) with a synchronous surface EMG (Biovison, 2400Hz.) of the M.m. Tibialis anterior (TA), Gastroc. medialis (GM) Rectus femoris (RF) and Semitendinosus (ST) was done. 10 trials were collected using a whole body marker setup while walking barefoot at a self-selected speed. The time norm. data of the 3D-gait analyses and the norm. Wavelet-transformed EMG-data (WTEMG) were analysed within a gait-cycle for each subject for the 3 measurements: before the intervention (T1), used as a baseline, after the 18 weeks of Hippotherapy-K (T2) and 18 weeks post intervention (T3).

Results: The results show individual changes between T1, T2 and T3 for the 6 CP-subjects within the tests. The average walking speed for the 10m max. walking-speed-test overall subjects increase from T1 to T2 by 4% (SD: 14%) and decrease from T2 to T3 by 3% (SD: 16%) or is 1% faster than at T1. The time differences between the tests overall subjects are not significant.

The results of the 3D-gait analysis show that the general movement patterns of the subjects are changing too. The overall results showed a slightly faster walking speed with longer steps and smaller step width (Tab 1). The overall changes are not significant, but some changes within a single subject are.The WTEMG-intensity-pattern shows a subject-individual pattern and the changes between the 3 tests.

An example of a typical CP-intensity-pattern is seen in Fig 1. In the early swing phase a partial separation of the muscular activation (A) occurs in T2 vs. T1 and T3. Further in the loading response phase the frequency spectra shifts down (B) from T1 to T2 and T3.

Figure:



Discussion: The results of the study showed a delectable effect of the Hippotherapy-K intervention within the CP-patients for the 10m max. walking-speed-test and the overground walking. It showed, that some subject improve the neuromuscular control at a similar speed other increased the speed but walked less “controlled”. A factor often mentioned in physiology exercise [3,4] to increase the speed is the core stability or core strength. Shurtleff [5] showed that Hippotherapy increased the head and trunk stability. As a result, Hippotherapy could be seen as a hidden core stability training with a high number of similar but varying 3D-movements, some may even demand fine motor skills. However strength training with varying movement patterns may support the “differential learning strategy” stated by Schöllhorn [6], and may lead to an extended movement pattern with better functional neuromuscular capabilities, e.g. functional reach [5] or higher walking speed.

Conclusion: The results of the study showed that the Hippotherapy-K intervention had an effect but just a limited sustainability. Therefore we think Hippotherapy could be a complementary strength training based on the differential learning in combination with other therapies.

Table:

Parameters	**T1**	**T2**	**T3**
Walking speed [m/s]	**0.87**	**0.94**	**0.85**

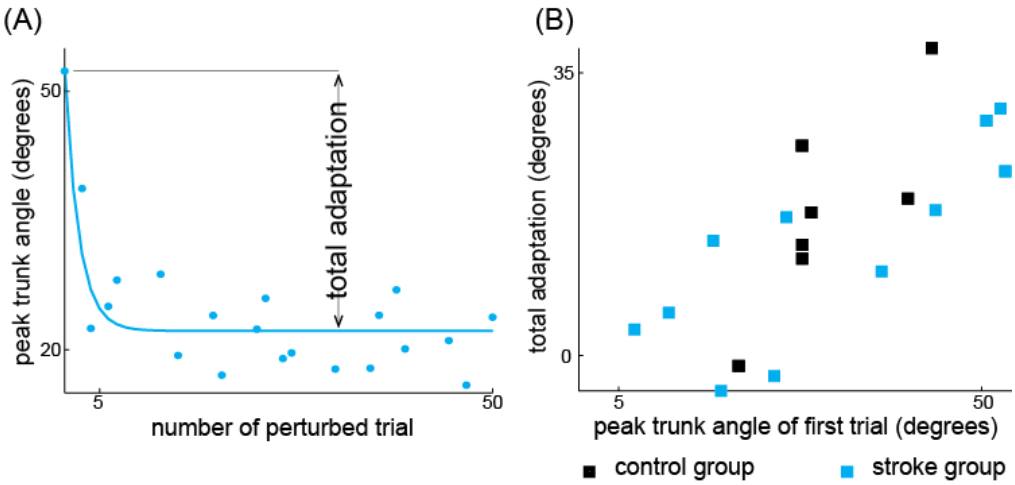
STROKE SURVIVORS ARE ABLE TO ADAPT TO A DISCRETE, UNATICIPATED DISTURBANCE DURING GAIT

Bahar Sharafi [1,*] Yasin Dhaher [1]

[1]Sensory Motor Performance Program, Rehabilitation Institute of Chicago, Chicago, United States

Introduction and Objectives: Evidence suggests that the capacity for motor adaptation is generally preserved following stroke, although the rate and magnitude of adaptation may be lower than that in unimpaired individuals. Adaptation is dependent on the development of an “internal model” of the body and the environment, driven by error feedback. A common experimental paradigm to examine the formation of internal models is through the use of a continuously applied mechanical disturbance to impose movement error. The continuous presentation of the disturbance allows the central nervous system to update the internal model so as to anticipate the requirements of movement in a perturbed environment. It remains to be seen if an internal model may be formed of a discretely applied, unanticipated disturbance. We argue that this type of disturbance simulates challenges that may be encountered during activities of daily living.
In the present study we investigated the ability to build an internal model in the presence of a discretely applied, unanticipated disturbance during gait. Given that adaptation is an essential component of motor learning, the capacity for adaptation under such conditions may be exploited to improve stroke survivors’ ability to walk independently in real-world environments. We hypothesized that stroke survivors would show short-term adaptations in their response to discrete, unanticipated gait disturbances that challenge upright posture. We further explored the hypothesis that the total magnitude of adaptation is correlated with the severity of the disturbance during the first exposure.
Methods: Peak trunk inclination as a function of number of trials was well represented as an exponential decay function (Fig. 1A). Inter-subject mean of total adaptation of peak trunk inclination was 13.73 degrees ± 3.56 degrees (standard error) in the stroke group, and 17.91 degrees ± of 4.61 degrees (standard error) in the control group. Total adaptation was significantly larger than zero in both groups, with no significant differences between groups. In each group, total adaptation was linearly related to peak trunk inclination angle during the first trial (Fig. 1B) with correlation coefficients of 0.8 and 0.82 for the control and stroke groups, respectively.
Results: Peak trunk inclination as a function of number of trials was well represented as an exponential decay function (Fig. 1A). Inter-subject mean of adaptation capacity of peak trunk inclination was 13.73 degrees ± 3.56 degrees (standard error) in the stroke group, and 17.91 degrees ± of 4.61 degrees (standard error) in the control group. Adaptation capacity was significantly larger than zero in both groups, with no significant differences between groups. In each group, adaptation capacity was linearly related to peak trunk inclination angle during the first trial (Fig. 1B) with correlation coefficients of 0.8 and 0.82 for the control and stroke groups, respectively.

Figure:



Caption: Figure 1. (A) Representative data and fit are shown for one subject. (B) Total adaptation was linearly related to the severity of deviation from upright posture following the first exposure to the disturbance.

Conclusion: Stroke survivors and healthy individuals had the ability to modulate their response to an unanticipated disturbance in order to minimize deviation from upright posture during gait. With repeated presentations of the disturbance, this deviation followed an exponential decay curve typical of error correction during a motor adaptation process. Our findings add to the evidence that motor adaptation capacity is preserved after stroke. The observed adaptation was not due to anticipatory changes in walking kinematics or lower limb EMG, as no such changes were present. Therefore we may conclude that adaptation was due to the modulation of the reactive control response. These findings suggest that the development of an internal model is possible in the presence of discontinuously applied, unanticipated, biomechanically challenging disturbances. Moreover, we found that the magnitude of adaptation was closely related to the severity of the effect of the initial disturbance, i.e., peak trunk inclination during the first trial. This finding suggests that the magnitude of disturbance may be modulated to enhance the adaptive process in individual patients.

BIOMECHANICAL ANALYSIS BETWEEN DUAL MOBILITY AND CONVENTIONAL THA DURING STAIR ASCENT AND DESCENT

Danilo S. Catelli [1,*] Sarah Reynolds [1] K.C. Geoffrey Ng [2] Mario Lamontagne [1] Paul E. Beaulé [3]

[1]School of Human Kinetics, [2]Department of Mechanical Engineering, [3]Division of Orthopaedic Surgery, University of Ottawa, Ottawa, Canada

Introduction and Objectives: THA using a dual mobility (DM) design minimizes the risks of dislocation and impingement [1-2], permitting a larger range of motion of the hip [3]. However, it is still unclear whether it would lead to an improved functional mobility.

The purpose was to compare sagittal and frontal hip angles, moments, and power of the operated limb, during stair ascent and descent, between patients who undergone THA with either a DM bearing or a standard metal-on-polyethylene (MPE) implant, along with a healthy control (CTRL) group. It was hypothesized that the improvement scores for kinematics and kinetics would be higher for the DM group than the MPE groups, during stairs ascent and descent.

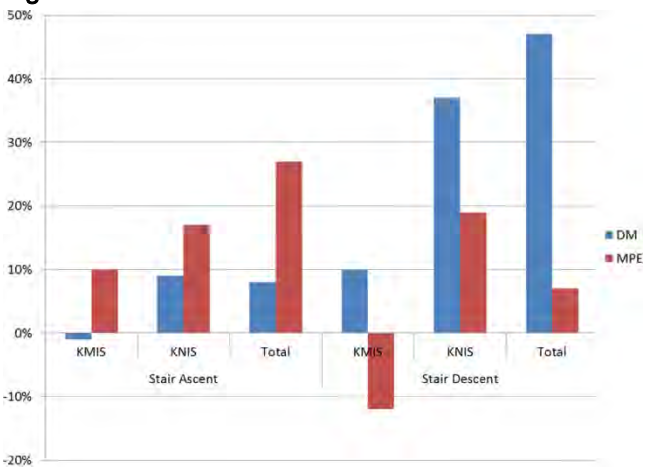
Methods: Twenty-six patients (7F/19M; age: 63±5 years; BMI: 28±4 kg/m^2) and 12 CTRL participants (6F/6M; age: 61±7 years; BMI: 25±4 kg/m^2) were recruited from the orthopaedic surgeon's clinical practice. The patients for the study were randomly assigned to either a DM or MPE cementless THA. Patients agreed to undergo motion analysis prior to and nine months after their THA. The CTRL were age-, sex-, and BMI-matched with the THA group, and underwent the same motion analysis protocol.

Participants were outfitted with 45 reflective markers and performed a minimum of five trials of stair ascent and descent at a self-selected pace. Three-dimensional joint kinematics (200 Hz) of the lower limbs were captured using a ten-camera motion analysis system (Vicon, UK) and ground reaction forces were collected (1000 Hz) using two force plates (Kistler, USA) set on the first and second steps. Kinematics and kinetics data were processed in Nexus 1.8 (Vicon, UK), with a modified Plug-In-Gait model, and then exported to a custom MATLAB script (Mathworks, USA) to calculate group averages and extract relevant variables. The marker trajectories were filtered using a Woltring filter (15 MSE), and force plate data were filtered with a low-pass Butterworth filter with a cutoff of 10Hz. All trials were time-normalized based on consecutive foot strikes of the affected limb and individual averages for each participant were calculated across the five trials.

Five hip variables were included in the analysis: sagittal (Θ_{sag}) and frontal (Θ_{front}) angles, sagittal (M_{sag}) and frontal (M_{front}) moments, and power (P_{hip}). The percentage root mean square difference (RMSD%) was calculated between pre- and post-op conditions for each THA group, and also between each THA group and the CTRL group for pre- and post-surgery. Kinematics improvement scores (KMIS) and kinetics improvement scores (KNIS) were calculated to estimate pre- and post-op differences. They were calculated as: $KMIS=\Sigma^{n}_{i=1}(KM_{pre/ctrl\ i} - KM_{post/ctrl\ i})$ and $KNIS=\Sigma^{n}_{i=1}(KN_{pre/ctrl\ i} - KN_{post/ctrl\ i})$, where KM and KN are kinematics and kinetics RMSD% of each variable, respectively. A total improvement score was reached based on the sum of KMIS and KNIS values for each task. Wilcoxon signed-rank tests compared pre- and post-op conditions and Mann-Whitney U tests compared between groups (CI=95%).

Results: RMSD% was smaller at post/ctrl than pre/ctrl for all variables, except for the frontal angle; however, statistical significance was only observed at Θ_{front}, M_{sag}, M_{front}, and P_{hip} during stair descent. There were no differences between THA groups (DM pre/post vs MPE pre/post) (Table 1). The total scores (Fig.1) showed large improvements for MPE during ascent phase (27%) and DM during the descent phase (47%). There was no improvement to KMIS for DM during ascent and for MPE during descent; however, KNIS was improved for both THA groups in both tasks.

Figure:



Caption: Fig.1. KMIS and KNIS for DM and MPE bearings during stair ascent and descent

Conclusion: Both the DM and MPE participants experienced post-op improvements, with kinetics variables of the THA groups closely resembling the CTRL. The only variable that increased at post-op was the Θ_{front} for MPE during descent, where patients showed larger hip abduction angles. The total improvement scores showed that the MPE group experienced greater improvements in stair ascent, while the DM bearing participants exhibited greater improvements during stair descent. The changes for KNIS among MPE and DM groups between pre-op and post-op testing also indicates that stair descent may be more sensitive to measuring outcomes for THA compared to stair ascent.

Table:

		DM pre/ctrl	DM post/ctrl	MPE pre/ctrl	MPE post/ctrl
Stair Ascent	Θ_{sag}	0.18	0.17	0.20	0.14
	Θ_{front}	0.40	0.42	0.46	0.42
	M_{sag}	0.24	0.22	0.25	0.2
	M_{front}	0.23	0.20	0.22	0.14
	P_{hip}	0.25	0.21	0.29	0.25
Stair Descent	Θ_{sag}	0.38	0.30	0.32	0.28

REDUCED QUADRICEPS ACTIVATION AMONG TKA PATIENTS: MUSCLE INHIBITION OR EFFICIENCY?

Catriona Czyrnyj [1,*] Sarah Reynolds [2] Geoffrey Dervin [3] Mario Lamontagne [1 2]

[1]Department of Mechanical Engineering, [2]Human Movement Biomechanics Laboratory, University of Ottawa, [3]Department of Orthopedic Surgery, The Ottawa Hospital, Ottawa, Canada

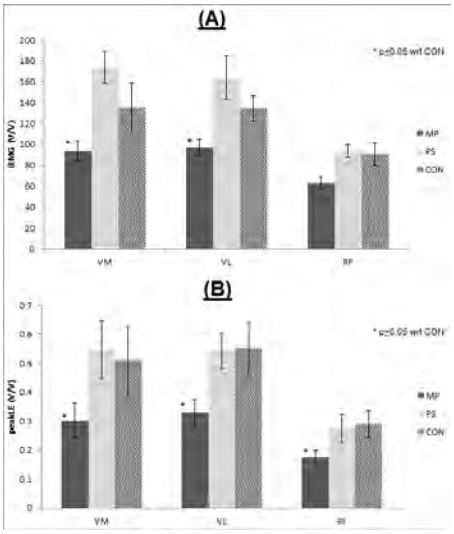
Introduction and Objectives: While it is well known that total knee arthroplasty (TKA) consistently decreases pain and increases quality of life for those suffering from knee osteoarthritis (OA), it has been shown that patients do not regain joint biomechanics to fully match those of healthy individuals [1]. Studies have shown that quadriceps weakness is widely prevalent in TKA patients, along with post-surgical quadriceps inhibition, both of which have biomechanical ramifications [1]. While many biomechanical studies have been conducted on TKA patients, little is known about the effect of TKA implant designs on muscle activity (EMG) during functional tasks. This study aimed to compare operated lower-limb muscle activity of TKA patients, having either a Medial Pivot fixed-bearing (MP) or Posterior Stabilized (PS) implant, along with healthy, age-matched controls (CON) during level gait.

Methods: Unilateral TKA patients with an MP (10M/3F; age=61.9±6.4 years, BMI=29.8±4.5 kg/m^2,post-op=9±2 months) or PS (5M/1F; age=68.3±3.6 years; BMI=29.8±4.5 kg/m^2, post-op=11±3 months) implant and healthy, age-matched controls (8M/4F; age=63.4±6.2 years;BMI=26.7±4.4 kg/m^2) performed isometric contractions (MVIC), during which peak force was collected, along with five gait trials. Surface electrodes, sampling at 1000Hz with a band pass filter (Butterworth, zero lag, 4th order, 20-400 Hz cut-off frequency), were applied to the vastus lateralis (VL), vastus medialis (VM), rectus femoris (RF), biceps femoris (BF), and semimembranosus (SM) muscles of both lower limbs. Signals were high pass filtered (Butterworth, zero lag, 4th order, 20Hz cut-off frequency), rectified, bias removed, and low pass filtered (Butterworth, zero lag, 4thorder, 6Hz cut-off frequency). The MVIC signals were averaged over a 2s moving window. Gait signals were amplitude normalized by the peak MVIC and time normalized to one full gait cycle (LE). The peakLE and integrated EMG (iEMG) were then calculated. The control group limbs were averaged for each muscle. Unpaired t-tests (α=0.05) were conducted to compare MP and PS groups with the controls.

Results: Results showed that the MP group had lower total muscle activity (iEMG) throughout the gait cycle for the VM (iEMG =93.6±10V/V), VL (iEMG =96.8±8V/V), and RF muscles (iEMG =63.1±6V/V), compared to controls (VM=135.5±23V/V, VL=135.5±23V/V, RF=90.3±11V/V) (*Figure 1*). These differences reached statistical significance for the VM (p=0.05) and VL (p=0.03) muscles, and approached statistical significance for the RF (p=0.09). Analysis of the peak linear envelope revealed that the MP group also demonstrated significantly lower (p<0.05) peak muscle activity during the gait cycle for all of the quadriceps muscles (VM=0.30±0.06V/V; VL=0.33±0.05V/V; RF=0.17±0.02V/V), compared to controls (VM=0.51±0.11V/V; VL=0.55±0.09V/V; RF=0.29±0.05V/V).When this was cross examined with the MVIC data, the MP group exhibited higher peak MVIC values than the controls for the VM (p=0.21), VL (p=0.06), and RF (p=0.14) muscles for knee extension (*Table 1).* Moreover, the MP group also showed a higher peak MVIC force than the controls during the MVIC knee extension task for the quadriceps muscles; however, this did not reach statistical

significance (p=0.15). No significant differences were found for peak or integrated EMG values between the PS group and the controls.

Figure:



Caption: Figure 1. iEMG (A) and Peak LE EMG (B) for the vastus medialis, vastus lateralis and rectus femoris during gait

Conclusion: The lower levels of quadriceps activity in the operated limb of the MP group were initially interpreted as quadriceps weakness or inhibition during gait, similar to what has previously been reported by Mizner et al. (2005). However, when compared with the peak MVIC and peak knee extension force produced during MVIC, the MP group generated higher knee extension forces and higher peak MVIC than the control and PS groups. The MP group's lower levels of quadriceps activity during gait, combined with higher peak force for knee extension, indicated that the MP group was more efficient in performing the walking task than the PS group. Preliminary observations of pre-operative data indicate similar levels for peak MVIC knee extension forces between the MP group and the healthy controls. This quasi-normal, pre-operative quadriceps strength could be the reason for better functional outcomes post-surgery, as reported by Mizner et al. [2]. Further research is needed to investigate the relationship between muscle activation and joint kinetics for comparisons variations between PS and MP implants and controls.

Table:

Group	MVIC (mV)			MVIC Force (N/kg)
	VM	VL	RF	
MP	0.187±0.1	0.223±0.1	0.162±0.1	0.452±0.2
PS	0.092±0.03	0.165±0.07	0.119±0.06	0.282±0.1
CON	0.130±0.1	0.139±0.07	0.110±0.06	0.331±0.1

PARAMETRIC ANALYSIS OF GLENOID IMPLANT DESIGN

Diogo M. Geraldes [1,*] Ulrich Hansen [1] Andrew Amis [1]

[1] Mechanical Engineering, Imperial College London, London, United Kingdom

Introduction and Objectives: Common post-operative problems in shoulder arthroplasty such as glenoid loosening and joint instability can be reduced by improvements in glenoid design, shape, material choice and fixation method [1]. Innovation in shoulder replacement is usually carried out by introducing incremental changes to existing implants, possibly overlooking other successful design combinations [2]. An automated framework for parametric analysis of different implant configurations was developed in order to efficiently sift through potential implant designs and identify the best-performing ones.

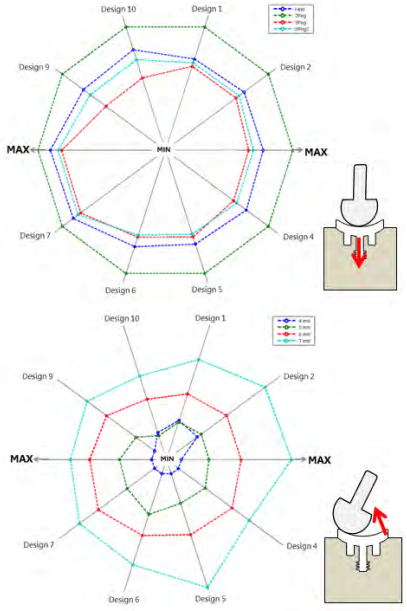
Methods: 4 different reference geometries representing the current 'gold standard' implant fixation types were generated in *SolidWorks*. Parametric variations (10 per geometry type, approximately) were automatically generated with a design table in order to assess the influence peg/keel size and position, base plate thickness or material in implant stress performance and fixation (Table 1).

The different implants were aligned and implanted with repeatability using *Rhino*. The glenoid-bone models were meshed in *Abaqus*, and boundary conditions and loading applied via a custom-made *Python* script. Finally, another *MATLAB* script integrated and automated the different steps, extracted and analysed the results. This study compared the influence of fixation type (keel vs. 2-pegged vs. 3-pegged vs. 3-pegged with central anchor peg) on glenoid components with bearing surface thickness of 3, 4, 5 or 6 mm and varying fixation feature dimensions (Table 1). A total of 40 different glenoid geometries were assigned UHMWPE ($E = 1$ GPa, $\upsilon = 0.46$) or VITA E PE ($E = 800$ MPa, $\upsilon = 0.43$) material properties and the bone-implant surface was tied. Fixed boundary conditions were applied at the distal surface of the cube and a contact force of 1000 N was applied as a distributed load. Four different loading scenarios were considered: a physiologically common central loading distribution and three edge-loading conditions (posterior, superior and inferior). Rocking-horse motion produced by edge loading is believed to be the most common mechanism of fixation failure in misaligned glenoid implants [3]. Two different bone qualities were looked at: healthy trabecular bone ($E = 300$ MPa, $\upsilon = 0.3$) and rheumatoid bone ($E = 30$ MPa, $\upsilon = 0.3$).

Results: A total of 640 models were analysed and compared over 24 hours. The data produced was filtered in order to assess how the different implant geometries ranked in bone volume preservation, implant deformation under central loading (see insert in top of Figure 1) and fixation instability due to edge loading (see insert in bottom of Figure 1) under edge loading. The influence of design parameters in the mechanical environment of the implant could be assessed. In this particular example, the normalised implant deformation under central loading (Figure 1, top) and the fixation instability (Figure 1, bottom) could be evaluated for all the different geometries simultaneously. 2-pegged geometries (2Peg) consistently produced higher deformations under central loading than the other configurations (Figure 1, top) due to lack of bone support at the centre. Thicker glenoids were shown to be less stable under all three edge loading (Figure 1,

bottom). This is thought to be due to an increase of stiffness of the whole implant, transmitting more of the displacements under edge loading to the opposite end.

Figure:



Caption: The influence of fixation type in the normalised implant deformation under central loading (Figure 1, top) and implant thickness in fixation instability (Figure 1, bottom) could be evaluated for all the different geometries simultaneously.

Conclusion: The developed method allows for simple, direct, rapid and repeatable comparison of different design features, material choices or fixation methods by analysing how they influence the mechanical environment of the bone surrounding the implant. Such a tool can provide invaluable insight in implant design optimisation by screening through multiple potential design modifications at an early design evaluation stage and identifying the best performing combinations. Future work will introduce physiological bone geometries and loading, a wider variety of reference geometries and fixation features, and look at bone/interface strength and osteointegration predictions.

Table:

Legend	Fixation Type	Nr. Fixation Features	Fixation Width (mm)	Fixation Length (mm)	Base plate thickness (mm)	Material Types	Central Peg
1	Keel	1	3, 4, 5, 6	15, 17.5, 20	4, 5, 6, 7	UHMWPE, VITAE PE	No
2	2Peg	2	7, 8, 9	7, 10, 13	4, 5, 6, 7	UHMWPE, VITAE PE	No
3	3Peg	3	4, 4.5	5, 6, 7	4, 5, 6, 7	UHMWPE, VITAE PE	Yes
4	3PegC	3	4, 5, 6	5, 7, 9, 11	4, 5, 6, 7	UHMWPE, VITAE PE	Yes

PREDICTING IMPLANT PERFORMANCE IN DISTAL FEMORAL FRACTURES: SENSITIVITY TO RESTRAINT CONDITIONS AT THE HIP

Alisdair Macleod [1,*] Hamish Simpson [2] Pankaj Pankaj [1]

[1]School of Engineering, [2]Department of Orthopaedic Surgery, University of Edinburgh, Edinburgh, United Kingdom

Introduction and Objectives: It is widely accepted that muscle contributions are key to modelling the physiological behaviour of the femur [1,2], nevertheless predictions of plate fatigue strength and the influence of screw position are made using in vitro models which neglect them [3,4]. Choosing appropriate restraint conditions to analyse a bone in isolation from the body, however, remains problematic. Speirs et al. [5] previously examined the influence of different boundary conditions on the strain environment in an intact femur; however, many studies use hinges or bi-condylar restraint and these were not considered. The influence that different restraint conditions have on predictions such as plate failure has not been examined.

The aim of the study was to examine the influence that the restraint conditions at the hip have on the prediction of distal femoral plate fixation failure.

Methods: Three-dimensional finite element models were developed and analysed using Abaqus 6.10. The femur geometry was obtained from CT data using imaging software (Living Human Digital Library). The plate was a Synthes® LISS DF. Material properties were simplified to homogeneous isotropic and were assumed to be linear elastic.

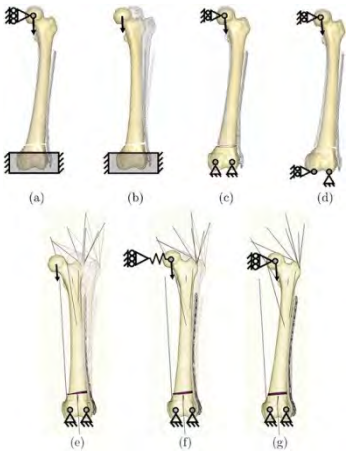
Initially, a range of hip restraint conditions commonly used in in vitro testing were examined (Fig. 1a-d). These included: clamped, pinned and hinged restraints. Three additional models were created including muscle forces acquired from Dostal et al. [6] and Sverdlova et al. [2] (Fig. 1e-g). These models were intended to be more physiological and also included healing callus within the fracture region. Hip restraint conditions in these models were selected to represent those frequently used computationally. Finally, a novel spring-based hip restraint condition was developed and evaluated.

Results: Changing the irestraint conditions at the hip dramatically influenced predictions of femoral head displacement, plate stress and joint reactions at the hip and knee. Even in the presence of physiological muscle forces and fracture callus the results are similar.

Considering an intact femur, the spring-based hip restraint produced reaction forces at the knee and hip joints that match measurements by Bergmann et al. [7] closely. Predictions of vertical and horizontal displacement at the femoral head of 0.5mm and 3.2mm respectively are very similar other recent studies [8,9].

An implanted femur with a fracture gap was found to be even more sensitive to different restraint conditions at the hip substantially altering the location and magnitude of peak stress within the plate.

Figure:



Caption: Distal femoral fracture models using different restraint conditions.

Conclusion: While we do not present the solution to the choice of boundary condition, we have shown the dramatic influence that the choice of restraint can have. The alteration in the plate stresses for different hip restraints show that predictions from in vitro tests must be treated with caution.

VARIATIONS IN MORPHOLOGY OF THE ARTICULAR SURFACES OF THE ANKLE EFFECT ITS KINEMATICS AND LOAD-TRANSFER CHARACTERISTICS

Sorin Siegler [1,*] Ramya Namani [1] Claudio Belvedere [2] Jason Toy [1] Wagdi Mankarios [1] Alberto Leardini [2]

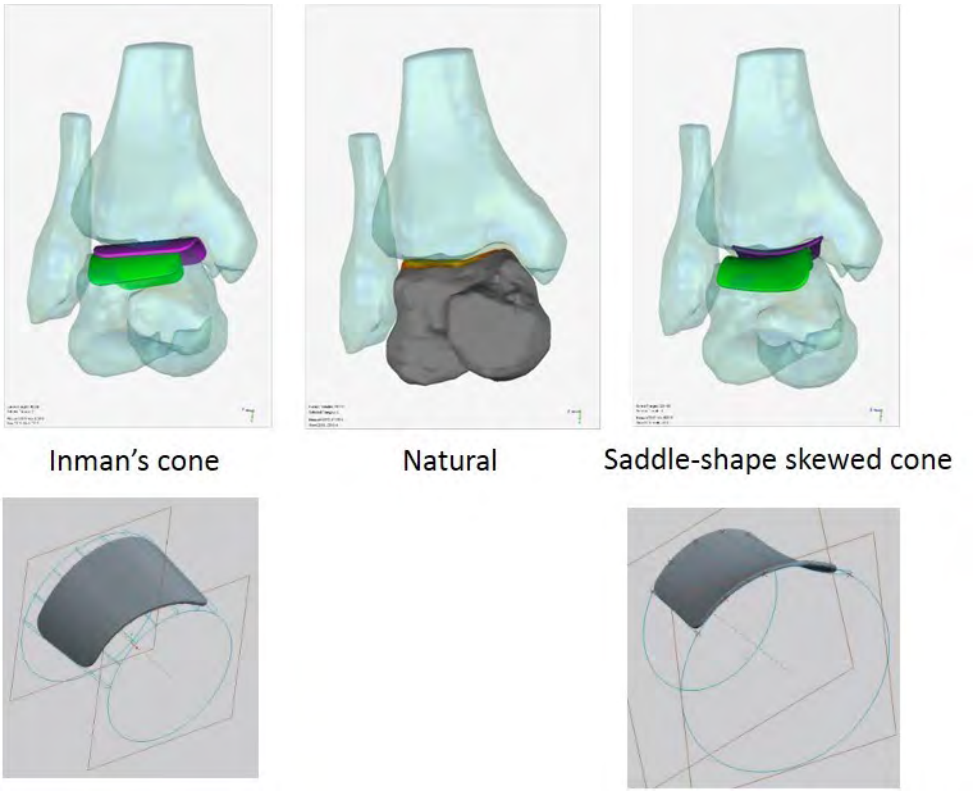
[1]Mechanical Engineering and Mechanics, Drexel University, Philadelphia, United States, [2]Laboratorio di Analisi del Movimento e Valutazione Funzionale , Istituto Ortopedico Rizzoli / Rizzoli Orthopaedic Institute, Bologna, Italy

Introduction and Objectives: Total Ankle Replacement (TAR) surgery has become a common surgical procedure for treating severe Osteoarthritis of the ankle. As TAR matures and becomes a standard of care, it is recognized that a key to its success is its ability to reproduce the natural motion of the healthy ankle. Unlike the hip or the knee, current TARs still suffer from high and premature failure rates. A key reason is believed to be their non-anatomical surface geometry design, which may produce incorrect and unnatural motion and load-transfer characteristics leading to early failure. Current TARs have articular surfaces that are either cylindrical or truncated cone surfaces following the Inman truncated cone concept postulated more than 60 years ago [1]. A recent study by the principal author demonstrated, using an image-based morphological study, that the Inman cone concept is incorrect. It indicates that each of the articular surfaces of the ankle can best be approximated by a saddle-shaped, skewed truncated cone with its apex directed laterally [2]. The goal of this study is to compare the effect of different articular surface morphology on the resulting kinematics and load-transfer characteristics through the ankle for various loading conditions and to test the validity of the hypothesis that correct surface morphology produces normal kinematics and natural load-transfer characteristics.

Methods: The study was conducted on seven cadaver ankle specimens and on three-dimensional models produced from MRI and CT scans of these specimens. Image processing software (Analyze Direct™) was used to obtain 3D renderings of the articulating bones and the regions of insertion of the surrounding ligaments. The 3D bone models were then introduced into engineering design software packages (Creo™, Geomagic™ and AutoCad™) to produce a set of three custom-fit virtual articular surfaces for each specimen: cylindrical; truncated cone with apex oriented medially according to Inman's postulate; and skewed saddle-shaped truncated cone with apex oriented laterally based on our earlier findings (Figure 1). For the simulation-based study, each of the seven 3D models, were evaluated using a dynamic simulation software (ADAMS™). The modelling and simulation details were described in earlier publications [3]. Each model was tested with the native articular surfaces and with each of the three virtual articular surfaces. Simulations were conducted with the tibia fixed and a loading/unloading moment applied to the calcaneus in the three planes of motion (dorsiflexion/plantarflexion, inversion/eversion and axial rotation). From the simulation, the following results were calculated: relative motion between the bones, distance maps describing the relative surface-to-surface distance changes and ligament forces and deformations. For the experimental validation study, the virtual TAR implants were exported to a 3D printing software and 3D physical models of each implant was produced using 3D printing. The intact cadaver was tested first in a specially design loading and measuring system [4] in which external moments were applied across the ankle and the resulting motion was measured. Each of the three implants were then surgically introduced one at a time and the test was repeated. From the results, the bone to bone motion and surface-to-surface motion were calculated.

Results: The range of motion and kinematic coupling obtained both numerically through the simulation and experimentally from the cadavers showed that an implant with surface morphology corresponding to a saddle-shaped, skewed truncated cone with apex oriented laterally produces closer to intact joint kinematics, load transfer, and ligament strain and stress then TARs with either cylindrical surfaces or those representing a symmetric truncated cone with apex oriented medially as postulated by Inman.

Figure:



Caption: 3D models of the ankle joint for one specimen under 3 conditions: natural – center, Inman's cone – left, and saddle-shaped skewed cone – right.

Conclusion: A TAR designed with articular surfaces represented by saddle-shaped skewed truncated cone with apex oriented laterally is expected to produce closer to normal kinematic and load-transfer behavior than currently existing TARs ultimately leading to less complication and smaller failure rates than those currently available. Experiments on specimens and correspondingly designed prototypes for the artificial surfaces are planned for further validation evidence.

EFFECT OF DIFFERENT TKA TIBIAL INSERT POSTERIOR STABILIZED DESIGNS ON KNEE BIOMECHANICS: A FINITE ELEMENT STUDY

Silvia Pianigiani [1,*] Raquel Alario Bernabé [2] Héctor Robledo Yague [2] Walter Pascale [1] Bernardo Innocenti [2]

[1]IRCCS, Istituto Ortopedico Galeazzi, Milano, Italy, [2]BEAMS Department, Université Libre de Bruxelles, Bruxelles, Belgium

Introduction and Objectives: Belonging to the TKA surgery, the Posterior-Stabilized prostheses (PS) have been widely used during the last three decades reporting generally excellent results in long-term studies. Nevertheless, when the patient has non-stable knee envelope, he may require larger degree of restriction in order to manage knee instability. The Semi-Constrained version of the PS prosthesis is then introduced as revision implant by means of enlarging the size of the post, so as to be more restrictive. However, there is a lack of confidence from surgeons in this last version based on the intuitive fear that its larger post could lead to a premature failure of the post-cam mechanism of the prosthesis. Thus, the post-cam engagement of both designs has been studied under two daily activities, walking and squatting, by means of a finite element analysis (FEA). Kinematics and contact pressures have been evaluated in order to analyze the efforts supported by the prosthesis.

Methods: For the two analyzed solutions, the same femoral component has been used. A standard gait cycle and the downward movement of a squatting activity up to 120° were simulated for both situations. The tibiofemoral kinetics and kinematics have been investigated comparing the contact area between components, the internal-external rotation, the position and the magnitude of the contact forces and the Von Misses stresses on the polyethylene. Special attention to the post-cam engagement mechanism behaviour has been paid.

Results: The results obtained have shown a change on the kinematics especially along anterior-posterior direction as well as an increase of contact forces on the post of the semi-constrained design. Generally, due to the increased cross-section of the semi-constrained tibial insert, larger contact forces and pressures are experienced by lateral and medial sides of the post in the semi-constrained version compared to those in the conventional one, where no contact forces can be observed. This effect is more pronounced for the squat that for the walking task. The qualitative stress distribution is shown in Figure 1.

Figure:

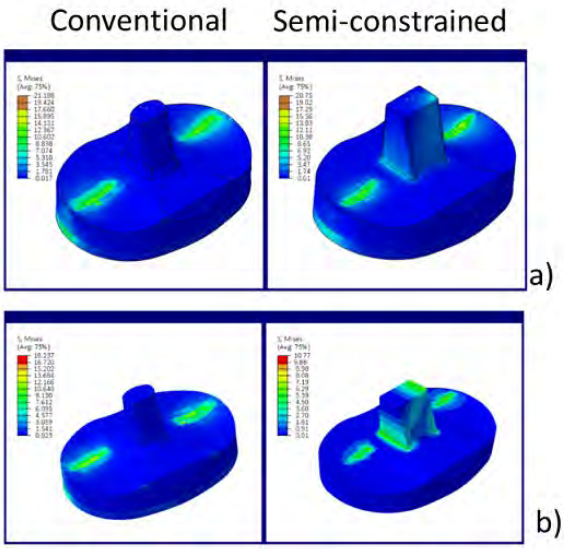

Figure 1: a) Qualitative stress distribution for the maximum flexion reached for the low demanding task; b) qualitative stress distribution for the maximum flexion reached for the high demanding task

Conclusion: By means of this study it has been shown that the modification of the geometry of the post varies the way in which the femoral component contacts the tibial insert of a PS TKA. The results show that the enlargement of the post in the medio-lateral direction leads to the modification of the center of the total force especially along the anterior-posterior direction. Generally, the main differences in outputs for the conventional and the semi-constrained designs can be associated to the difference in shapes of the post mechanism for the two designs resulting in a higher restriction of movement for the semi-constrained design that generates also a bending moment that is exerted on the post when the rotation between both components tries to take place. Even if there are some limitations of this study, for example the soft tissues are not included in the model, results are in good agreement with the literature. Less demanding motor tasks, such as gait, have shown not achieving main differences in the outputs. However, deviation in contact outputs, especially in the post, is more evident during high demanding tasks such as squat. The reported alterations could induce earlier wear of the revision design compared to the conventional one.

The authors have nothing to disclose.

PATIENT SPECIFIC LEG-FOOT MODEL FOR INDIVIDUALLY DESIGNED INSOLES

Maxime LLARI [1,*] Yves GODIO-RABOUTET [1] Jean-Paul WEBER [2] Bruno VIE [2] Yves JAMMES [2] Lionel THOLLON [1] Michel BEHR [1]

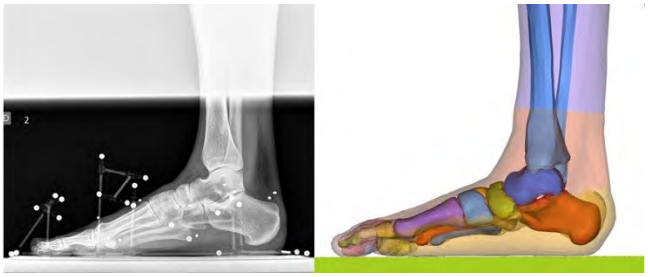
[1]LBA UMR_T 24, Aix Marseille Université, IFSTTAR, [2]Ecole de Podologie de Marseille, MARSEILLE, France

Introduction and Objectives: Whether in the field of orthopedics, sports or military applications, custom orthotics is a major economic and social challenge, and prevalence of podiatric disorders is extremely common [1, 2].
Individually designed orthosis could provide a more effective treatment in case of foot disorders (metatarsalgies, diabetes, etc) or to improve performance for sport applications [3]. To reach this objective, the development of an easy-to-use technical platform which allows characterizing patient specific foot geometry and mechanical interactions is required.
This paper presents an innovative methodology that could be used by podiatrists for the design of optimized orthotics: simplified geometry data acquisition, customized a Finite element (FE) model, mechanical validation against barometric footprint.

Methods: An experimental campaign on 8 volunteers was conducted to acquire the geometry and pressure data, using a 3D optic scanner (Artec 3D) and a Novel® Emed-n50 platform. X-ray images in frontal and sagittal planes, using lead beads as markers on 10 anatomical references, were also performed for further geometrical validation (figure 1).
A finite element leg-foot model was reconstructed using Mimics® V12.1 software (MATERIALISE) from CT scans of a human male volunteer close to the 50th percentile. The model was built in order to integrate all anatomical components which have a contribution in the foot mechanical behavior for the plantar supports. All foot joints were modeled with 6 DOF elements, based on joint limits detailed in [4] to improve the overall foot kinematics. Material properties for soft tissues and bones were determined from previously published cadaver studies [5]. Muscle activations of the triceps surae and the long flexor muscles of hallux and toes were implemented to simulate the force applied on the foot during balanced standing [6]. The foot FE model was scaled to the geometry of each volunteer by kriging and then compared to X-ray data. Plantar supports were simulated for each personalized FE model with the RADIOSS® code (Altair Engineering). Computed pressures were compared to experimental barometric data. The mechanical properties of the joints and the forces applied to the muscles were then slightly tuned by optimization to obtain the closest footprint.

Results: We were able to simulate a foot print very similar to volunteers' recordings by this coupling of a simple krigging procedure a tuning of muscle tension and joints stiffness.

Figure:



Caption: Illustration of the data acquisition procedure

Conclusion: The next step of the study is to use an optimization algorithm to determine the shape and materials of the orthosis in accordance with the best footprint to prevent any particular pathology.

This innovative methodology based on using a 3D optic scanner could easily be deployed (office podiatry, sports shops...). This could lead to develop automatic technical platforms able to collect and analyse both geometric and barometric data in order to manufacture specific shoe soles.

SPATIAL FREQUENCY CONTENT OF DIABETIC AND NON-DIABETIC PLANTAR PRESSURE AND SHEAR PROFILES

Visar Berki [1,*] Brian Davis [1]

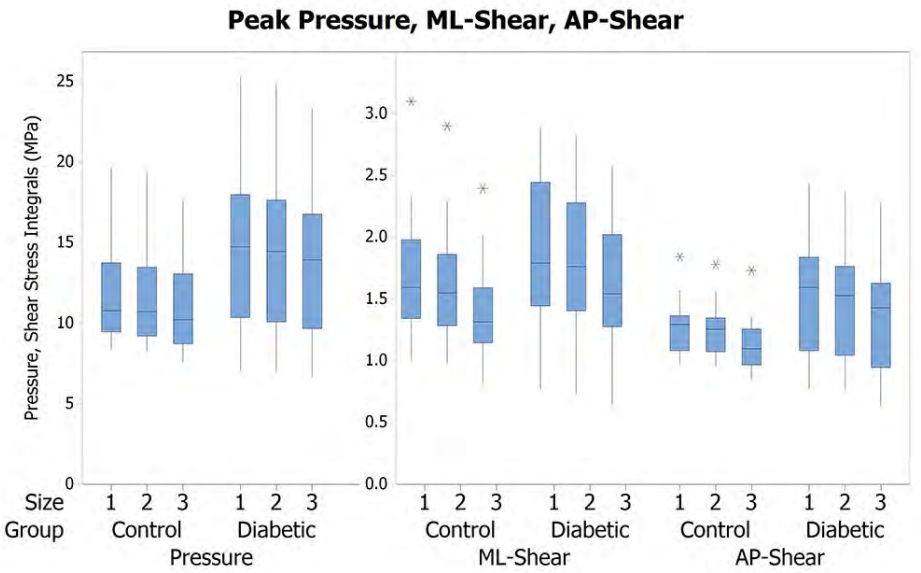
[1]Biomedical Engineering, The University of Akron, Akron, Ohio, United States

Introduction and Objectives: The measurement of plantar pressure and shear profiles (PPSPs) is increasingly being applied to the problem of skin tissue breakdown and ulceration in diabetic patients. This study assessed the issue of sensor resolution of a custom built plantar pressure and shear measuring system and simulated the effect of increasing the transducer area (from 1.59 mm^2 up to 7.95 mm^2). Discrete Fourier Transform techniques were used to determine the spatial frequencies of PPSPs. Our objectives were to determine (i) the spatial frequency content of diabetic and non-diabetic PPSPs, and (ii) the effects of increasing the transducer sizes.

Methods: Pressure and shear stress data were collected on 28 human subjects: 16 control patients (9M, 7F; Age: 47.6±5.8 years; Weight: 824 N) and 12 neuropathic, diabetic patients (7M, 5F, Age: 59.5±12 years, Weight: 961 N). Each subject walked across a custom built shear and pressure system aligned in the center of a 3 m. x 0.6 m. platform. Four steps were recorded for each subject at a sampling rate of 50 Hz. Every step consisted of multiple 2-D arrays for pressure, medial-lateral shear, and anterior-posterior shear data, representing each sampled timeframe. All timeframes of a step were combined to produce unique and complete PPSPs for every step taken. A linear interpolation method of values at neighboring grid points was used to simulate the effect of increasing transducer size on PPSPs. Three transducer sizes were simulated: 1.59 mm^2, 3.18 mm^2, 7.95 mm^2. A two-dimensional Discrete Fourier Transform was performed on each data set, for each of the three transducer sizes. To quantify the difference between transducer sizes, a comparison was made using the maximum pressure and shear stress data over the entire foot-platform contact surface. The results were tested for significance using a general linear model ANOVA, including the factors of (i) group (diabetic vs. non-diabetic), and (ii) transducer size (three levels).

Results: Peak pressure data ($p = 0.002$) and peak anterior-posterior shear stress data ($p = 0.001$) showed significant difference between diabetic and non-diabetic subjects. There was no significant difference between subject groups for peak medial-lateral shear stress data ($p = 0.077$). Transducer size did not result in significant differences for the three conditions that were tested.

Figure:



Caption: Figure 1: General linear model ANOVA, showing peaks for (i) pressure, (ii) medial-lateral shear stress, and (iii) anterior-posterior shear stress, as related to the two factors (i) diabetic vs. non-diabetic, and (ii) transducer size (smallest to largest).

Conclusion: This study showed that diabetic patients have higher spatial frequency content for both pressure and anterior-posterior shear stresses. The latter has never been shown before. These novel findings suggest that the interaction between foot and the supporting surface exhibits higher positive and negative gradients in diabetic patients compared with control subjects. While there were no significant differences when comparing sensor sizes, this is likely due to the fact that sensors that are less than 8 mm^2 can fully capture the spatial frequencies in both pressure and shear data.

CHALLENGING FOOT ALIGNMENTS CAN INCREASE INTRINSIC FOOT MUSCLE ACTIVITY

Mahdi Pourdanial [1,*] Wen-Ming Chen [1] Rezaul Begg [2] Peter Vee Sin Lee [1]

[1]Depatment of Mechanical Engineering, University of Melbourne, [2]College of Sport and Exercise Science & Institute of Sport, Exercise and Active Living (ISEAL), Victoria University, Melbourne, Australia

Introduction and Objectives: The alignment of the human foot is a key factor in its functionality. In the pronated foot axes of mid-tarsal joints become parallel that makes the foot more compliant [1]. Extrinsic foot muscles increase their activities to compensate this reduction in the passive support of the foot arch [2]. The novel foot core system suggests that intrinsic foot muscles (IFM) provide the extrinsic foot muscles with a stable base of support to perform efficiently [3]. Balancing [4] and load bearing [5] tasks are known to affect IFM activity; however there is a lack of specific studies on the stabilizing role of the IFM. Studying frontal plane motion of the foot and its interaction with IFM may help us better understand this specific role of IFM. We hypothesize that eversion of the foot will increase the IFM activity.

Methods: Twelve healthy male subjects [Average (SD) age of 29.6 (3.8)yr, height of 175.3 (4.7)cm and body mass index of 22.5 (3.6)] performed single leg balanced stance trials. To remove the effect of balance on IFM activity, subjects held onto a tripod to maintain posture balance. We designed a platform to precisely control the frontal plane alignment of the foot for 5 specific angles (-14, -7, 0, 7 and 14 degrees; Inversion to Eversion). Each angle was tested for 10 seconds and repeated twice in a randomized order.

Surface electromyography (EMG) electrodes recorded activities of four IFM (Abductor halluces (ABH), flexor halluces brevis (FHB), abductor digiti minimi brevis (ABDM), flexor digiti minimi brevis (FDMB)). EMG signals were filtered (4th order Butterworth, band pass 5 and 30 Hz) and Root-Mean-Square (RMS) value calculated for each trial. The value was then normalized to the maximum RMS recorded over a 1 s epoch for each muscle across all loading trials [5].

Optotrak motion analysis system monitored three-dimensional foot deformations based on a multi-segment foot model (Figure) [6]. The medial longitudinal arch (MLA) height was defined as the distance of the navicular marker from the plate [5]. The MLA angle was calculated based on markers of posterior and medial calcaneus and the first metatarsal head [6] (Figure).

Results: An analysis of variance (ANOVA) showed a significant effect of frontal plane angle on The EMG activities [ABH: $f=7.50$, $p<.001$, FHB: $f=10.78$, $p<.001$, ABDM: $f=3.11$, $p=.018$]. The Tukey post hoc test yielded that the mean activity of the ABH and FHB were significantly higher in full eversion of the plate compared to the neutral posture (ABH: +72%, $p=.019$, FHB: +62%, $p=.004$). All four muscles showed higher activity as the foot moved from inverted and neutral to everted position (Table). Pearson correlation coefficients were computed to assess the inter-muscular IFM activity relationship. There was strong positive correlation between ABH and FHB($r=0.43$,$p<.001$), FHB and ABDM($r=0.46$,$p<.001$) and ABDM and FBDM($r=0.63$,$p=.07$).

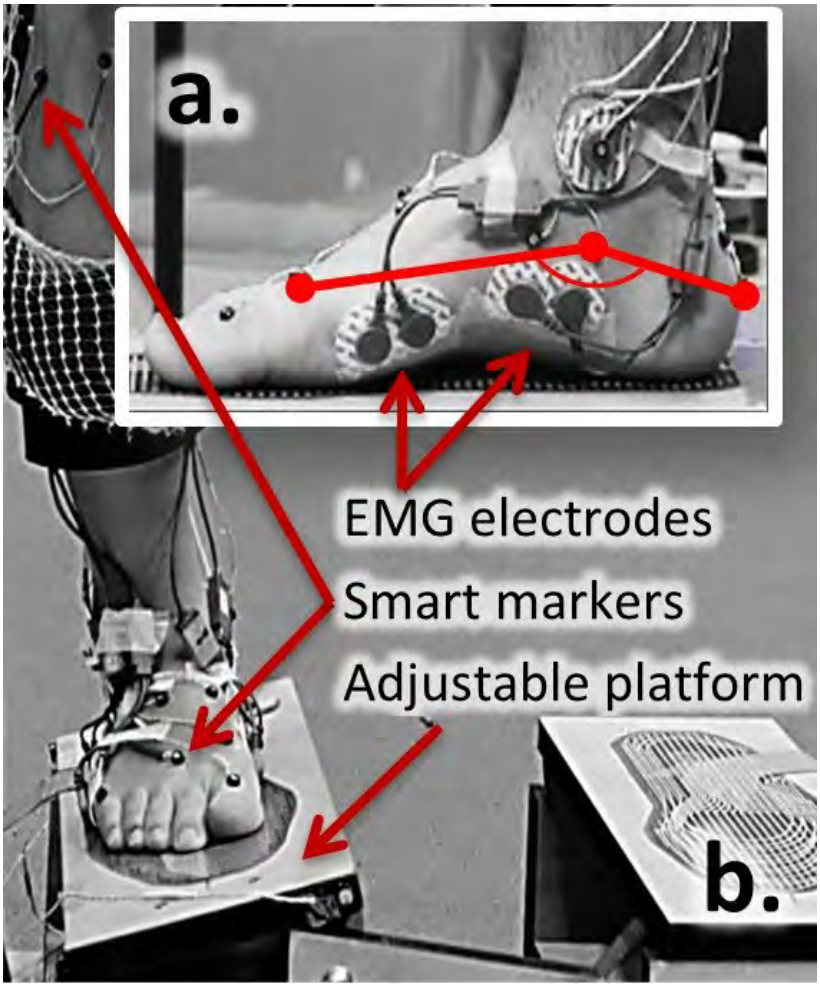
MLA height increased with increasing foot eversion. Mean MLA height was 51.5 mm for neutral position and the difference of means was -5.7mm ($p=.001$) and +6.6mm ($p<.001$) for 14 degrees inversion and eversion, respectively. MLA angle

decreased as the plate changed from Inversion (175.1 deg., p<.001) to Neutral (166.9 deg., comparison reference) and Eversion (157.3 deg., p<.001).

Discussion

All IFM displayed higher muscle activation in the everted foot. This increased activity was significant in medial IFM (ABH and FHB). The main reason might be associated with higher demand for stabilization of the foot, especially in the joints of the first ray, where medial extrinsic muscles also have their main insertions. IFM activity, however, reduced in the inverted foot due to a stiffer MLA and more stable foot due to mid-tarsal joint locking [1]. Although surface EMG is a reliable tool to measure activation of ABH, the main limitation of the study was the crosstalk for some IFM. However, high inter-muscular correlations in IFM activities observed during single leg stance using Intra-muscular EMG [4] suggests synergistic activation of the IFM, as we observed, in stabilizing foot structures.

Figure:



Caption: Test set up, a: Medial Longitudinal Arch (MLA), EMG electrodes for FHB (left) and ABH (right)

Conclusion: Forced over-pronation of the foot can increase medial IFM activation due to higher demand for stabilizing the joints in the first ray. IFM only come into play when the passive elements of the foot are not able to stabilize the foot on their own, otherwise they are mainly silent [4, 5].

Table:

Plate Angle (deg.)		Mean Normalized RMS EMG (%)			
		Medial		Lateral	
		ABH	FHB	ABDM	FDMB
Inversion	14	17.3	20.1	20.7	12.9
	7	22.0	19.7	20.2	12.1
Neutral	0	24.2	27.4	22.2	17.1
Eversion	7	35.2	38.1	29.1	19.1
	14	41.6	44.8	30.8	20.1

THE ROLE OF ARCH COMPRESSION AND METATARSOPHALANGEAL JOINT DYNAMICS IN MODULATING PLANTAR FASCIA STRAIN IN RUNNING

Kirsty Mcdonald [1,*] Sarah Stearne [1] Jonas Rubenson [1]

[1] Sport Science, Exercise and Health, The University of Western Australia, Perth, Australia

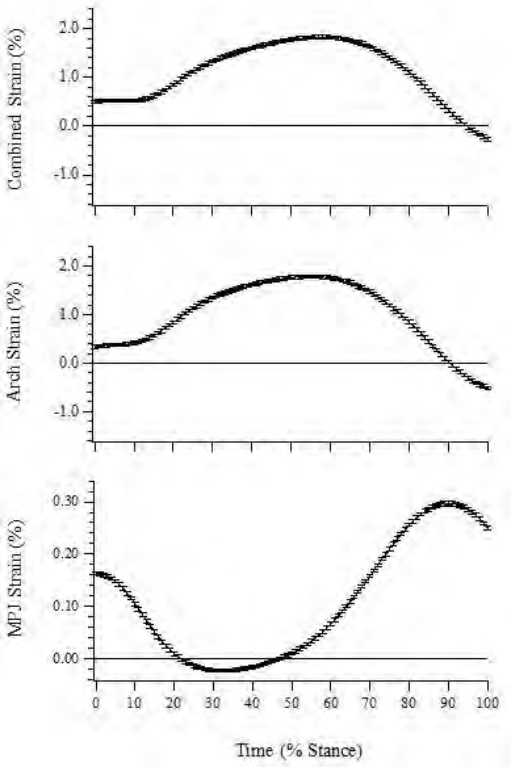
Introduction and Objectives: Elastic energy returned from passive-elastic structures of the lower limb is fundamental in lowering the mechanical demand on muscles during running. The combined elastic energy contribution of the medial longitudinal arch (MLA) ligaments has been assessed through static loading of cadaver feet [1], however the more detailed components of the arch's elastic function have not been considered during running. The purpose of this study was to investigate the two length modulating mechanisms of the plantar fascia (PLF), namely arch compression and metatarsophalangeal joint (MPJ) excursion, and to determine how these mechanisms modulate strain, and thus elastic energy storage/return of the PLF during running.

Methods: Sub-elite endurance runners (*n=18*) performed three treadmill running trials; normal shod, restricted arch compression (via an orthotic-style insert), and barefoot. Three dimensional motion capture and ground reaction force data were used to calculate lower limb kinematics and kinetics including MPJ angles, moments, powers and work. Estimates of PLF strain due to arch compression and MPJ excursion were derived using a geometric model of the arch and a subject-specific musculoskeletal model of the PLF combined with MPJ kinematics, respectively.

Results: Strain curves representing the effect of arch compression, MPJ excursion and the summation of both are presented in Figure 1 for unrestricted shod running. Peak strain for the combined effect of arch compression and MPJ flexion was significantly different between the barefoot vs. insert ($p < 0.001$), and shod vs. insert conditions ($p = 0.001$), with the barefoot condition resulting in the highest peak strain values (2.12 ±0.61%), followed by the shod condition (1.85 ±0.58%), and finally, the insert condition produced the lowest peak strain values (0.63 ±1.21%). These results were consistent with the maximum PLF strain derived from arch compression only. Maximum strain as a result of MPJ excursion did not differ between the shod and insert conditions ($p = 1.000$), however the peak MPJ-derived strain in the barefoot condition (0.32 ±0.07%) was significantly greater than both the shod (0.30 ±0.06%; $p = 0.001$) and insert (0.30 ±0.06%; $p = 0.003$) conditions.

The PLF was observed to develop strain via both arch compression and MPJ flexion. However, when we assessed the relative contributions, arch compression presented as the primary strain inducing mechanism, with the MPJ having a minor influence. Integrating the effects of arch compression and MPJ dynamics was a unique approach which led us to discover a novel function of the PLF. In the latter half of stance, arch recoil tends to shorten the PLF (positive arch power) and MPJ flexion simultaneously tends to lengthen the PLF (negative power) (Fig. 1). As a result, power is transferred between the MPJ and arch. In unrestricted shod running, we observed MPJ negative work to account for approximately 11.73% (±3.23%) of total lower limb joint energy absorption during stance phase. A component of this absorbed energy can be transferred proximally by the PLF to produce positive power in the arch.

Figure:



Caption: Figure 1. Estimated plantar fascia strain during stance phase for unrestricted shod running. Presented as the combined effect of arch compression and metatarsophalangeal joint (MPJ) angle, the effect of arch compression only, and the effect of MPJ angle only. Strain values ≤ 0 represent lengths at which the PLF is estimated to be slack.

Conclusion: The PLF was found to exhibit a typical elastic stretch-shortening cycle with the majority of strain generated via arch compression/recoil. Restricting arch compression, and hence spring function of the arch, was not compensated for by an increase in MPJ-derived strain. The PLF was found to transfer energy absorbed at the MPJ in the second half of stance to provide positive power generation at the arch (arch recoil). This previously unreported energy transfer mechanism has two important benefits; (1) additional energy is transferred to the MLA which assists propulsion, and (2) the risk of strain-induced PLF injury is substantially lower because the tissue is not required to lengthen excessively for the same power production.

FOREFOOT SPLAYING ACROSS THE TRANSVERSE METATARSAL ARCH IN DIABETIC PATIENTS

Mariam Crow [1] Brian L. Davis [1,*] Visar Berki [1] Daniela Ciltea [2]

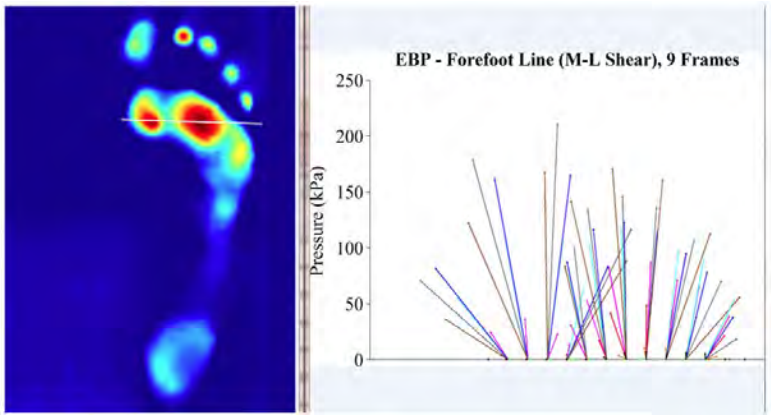
[1]Biomedical Engineering, University of Akron, [2]Endocrinology, Akron General Medical Center, Akron, United States

Introduction and Objectives: The existence of a transverse metatarsal arch (TMA) across the plantar foot has long been a subject of controversy. A number of authors, using various assessment techniques ranging from plantar pressure to anatomical analyses, have reported contradictory results. The primary objective of this study was to reconcile these findings while simultaneously comparing the effects of peripheral neuropathy on forefoot splaying in diabetic subjects.

Methods: Data were collected on 29 human subjects: 16 control patients (9M, 7F; Age: 47.6±5.8 years; mean weight: 823 N) and 13 neuropathic, diabetic patients (8M, 5F, Age: 61.6±14 years, mean weight: 943 N). Each subject walked across a custom built shear and pressure system aligned in the center of a 305 cm x 61 cm platform. Four steps were analyzed for each subject with a primary focus of medial shear under the first metatarsal head (MTH) and lateral shear under the fourth and fifth MTHs. The maximum differences in instantaneous instances were determined with the greatest in magnitude chosen for comparison, as well as the difference in peak medial shear and peak lateral shear regardless of corresponding instances as a secondary approach.

Results: The maximum differences during each analyzed step between medial shear under the first MTH and lateral shear under the fourth and fifth MTHs were significantly higher for diabetic patients (143.9 ± 51.9 kPa) in comparison to control subjects (97.1 ± 25.5 kPa)($p < 0.01$). A p-value of equal magnitude was obtained for the secondary analysis: the difference between peak values of medial and lateral shear under the first and fifth MTHs, respectively. The maximum difference at one time instance was also compared between men and female, regardless of subject group, resulting in higher pressure differences among men ((Diabetic Male: 159.2; Diabetic Female: 119.5; Control Male: 102.4; Control Female: 100.6 kPa)(p-value=0.01). Mean pressures were compared between the three transverse regions and averaged among each of the two groups. Both diabetic and control subjects displayed greatest pressure in the center region of the forefoot.

Figure:



Caption: Figure 1: Shear and pressure forces mapped across the metatarsal heads of a neuropathic, diabetic subject. Height corresponds with pressure magnitude and outward vectors indicate medial and lateral shear at 9 different instants of time (0.02 s increments).

Conclusion: The difference of medial shear occurring under the first MTH coupled with the lateral shear occurring under the fourth and fifth MTHs supports the premise that the forefoot collapses at the MTHs, or 'splays' during ambulatory gait. A TMA must exist across the metatarsal heads during stance in order for the foot to exhibit these medial and lateral shear forces at the borders of the foot. Neuropathic diabetic patients are presumed to lose the ability to oppose this collapse; therefore, causing a greater splaying of the forefoot at the TMA. The notion of the foot initially resting on a tripod is supported by the evidence of splaying. When analyzing this data alongside pressure data across the TMA, it would seem that the tripod collapses during gait resulting in highest pressure under the peak of the arch as it makes contact with the floor and the forefoot splays.

THE EFFECT OF VARIATIONS IN THE MORPHOLOGY OF THE HIP ON FEMORAL/ACETABULAR INTERFERENCE PATTERN DURING MOTION

Ramya Namani [1,*] Charanya Chandrasekaran [2] Javad Parvizi [3] Sorin Siegler [1]

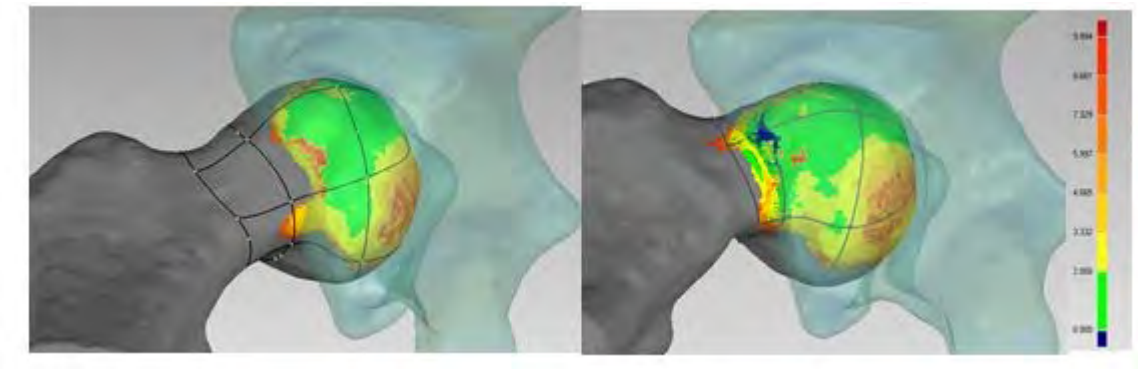
[1]Mechanical Engineering and Mechanics, [2]Biomedical Engineering, Drexel University, [3]Rothman Institute, Thomas jefferson University, Philadelphia, United States

Introduction and Objectives: Femoro-Acetabular Impingement (FAI) is a clinical condition characterized by limited range of motion due to early abnormal bone-to-bone interference and is often associated with labrum and cartilage damage often leading to osteoarthritis. The surgical treatment of FAI [1] attempts to restore normal femoral morphology by removing bone regions in the femoral neck and/or the acetabular rim believed to produce early interference. Clinical experience of this procedure indicates less than favorable post-surgical results such as persistent pain or cartilage damage often leading to Total Hip Replacements [2]. This suggests that other morphological abnormalities, in addition to the ones addressed by the surgery may be contributing to early interference. The main goal of this model-based study is to explore the effect of variations in a number of morphological parameters of the proximal femur and the acetabulum on patterns of interference at the hip joint. This is achieved by systematically changing the morphology of the 3D model of the femur and studying its effect on interference patterns during motion.

Methods: Computerized Tomography (CT) images (resolution: 0.8mm*0.8mm*2mm) from seven healthy subjects were acquired. The CT images were processed through segmentation in ANALYZE™ software to produce 3D numerical models of the femur and the acetabulum. Morphological parameters such as femoral shaft angle, femoral anteversion/retroversion, alpha angle, neck offset angle, pistol grip deformity [3, 4] were measured in the 3D models. The geometry of the 3D model was virtually changed (see Figure) to produce a change in each morphological parameter from a normal to abnormal value [3, 4]. Previously developed dynamic models are used to simulate hip motion reproducing a clinical tests for FAI [1] consisting of Flexion (100^0) followed by adduction followed by internal rotation. The interference patterns were calculated using distance maps and were compared before and after the morphological change were introduced.

Results: All morphological parameters obtained from the non-modified hip models were found to fall within the normal ranges [4] for all subjects. Virtually changing the hip morphology such as to produce coxavara, coxavalga, femoral retroversion, and abnormal alpha angle, the interference at the anterior-inferior region of femoral head-neck junction increased with 100^o flexion and 20^o adduction followed by internal rotation. Geometrical change that produced a pistol grip deformity produced early interference on the top head of the femur with increase in adduction.

Figure:



Caption: Interference of hip before (left) and after (right) inducing retroversion to femur at the simulation position of 90 degrees flexion combined with 20 degrees adduction and 30 degrees internal rotation. Blue region on retroverted femur (right) shows the region of contact

Conclusion: Morphological parameters such as femoral shaft angle, femoral anteversion, alpha angle and pistol grip deformity produce early interference at the hip and should be considered when planning FAI surgery. Future studies to validate the simulation-based results of this study will compare the morphological parameters and patterns of interference between patients with successful FAI surgery outcome and patients with post-surgical complications

MODELING MULTIJOINT CONTROL FOR REGULATION OF REACTION FORCES DURING IMPACT PHASE OF LANDINGS

Edward Wagner [1,*] Henryk Flashner [1] Jill McNitt-Gray [2] Veronica Eliasson [1]

[1]Aerospace and Mechanical Engineering, [2]Biological Sciences and Biomedical Engineering, University of Southern California, Los Angeles, United States

Introduction and Objectives: Modeling how individuals anticipate and control reaction forces during foot contact allows for simulation of landings under various conditions and independent modulation of variables that cannot be altered experimentally. The human body is often modeled as a system of segments with varying degrees of rigidity (Gruber, et al 1998). Our goal is to develop and experimentally validate a dynamic model of sufficient complexity enabling us to test hypotheses regarding the control and dynamics of the musculoskeletal system during flight and initial contact phases of landings. The aims of this study were to 1) validate a minimally complex 2D model that incorporates a foot and experiment-based multijoint control by comparing model-simulated and experimental peak vertical ground reaction forces (VGRF) and the vertical impulse during the impact phase of landings and 2) demonstrate the necessity of including a foot in the model by comparing the simulated and experimental forces during impact.

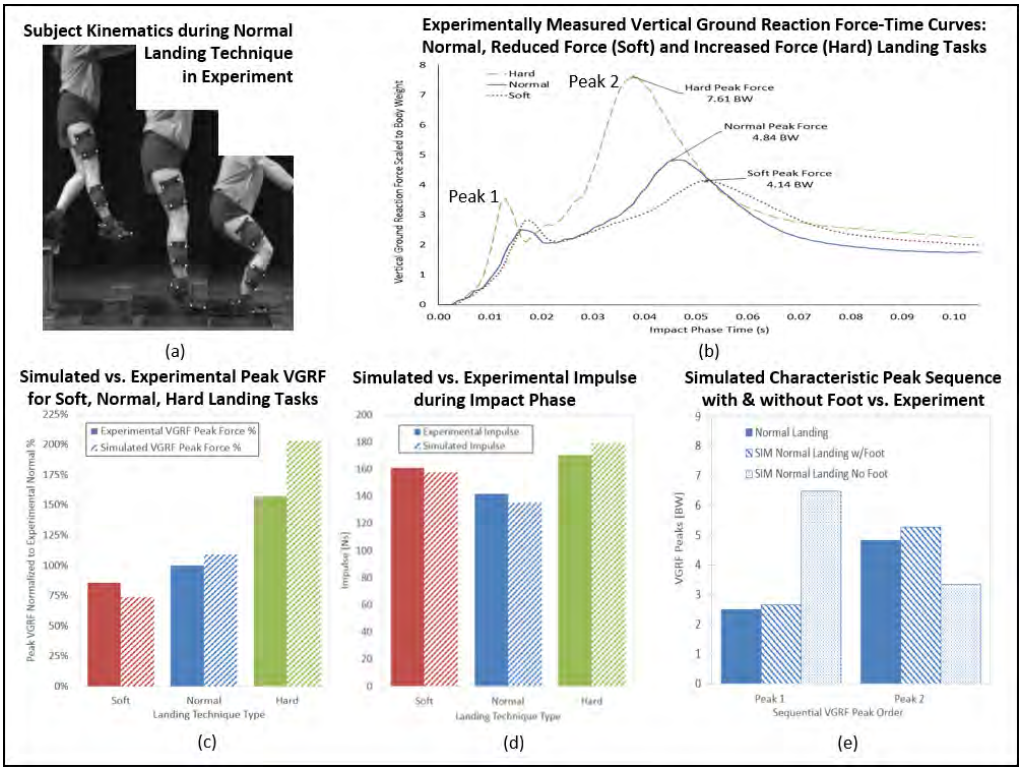
Methods: Modeling: Using simulation software (SimMech, MATLAB), a 2D model of the human body with 4-rigid links connected by ideal hinge joints was developed, comparable to the jumping model of Bobbert & vanSoest, 1994. Muscle actuators were replaced with joint torque actuators. Body segment parameters (DeLeva et al 1996) were scaled to the subject (female: 1.575m, 64.5kg). Link lengths were determined from segment endpoints digitized from video records. Torque actuators at each hinge accepted experimental ankle, knee, and hip torque-time curves as control inputs during simulation. The VGRF were applied at the toe and heel of the foot, modeled as Coulomb friction (horizontal coefficient of friction = 1) and a vertical nonlinear spring (C=2.17E6) and damper (D=2.89E4)(Gruber et al 1998).

Experimentation: Land-and-stop tasks were performed by former gymnast who provided informed consent and performed a series of drop landings from a 0.445m platform onto two force plates (KISTLER, 1200Hz) using self-selected normal, softer, and harder landing techniques (McNitt-Gray et al 2001). Kinematics (2D) during the landings were measured with ultra high-speed video (Phantom v711, 11,000fps).

Validation: Model-simulated (with/without foot) and experimentally measured peak VGRF and the vertical impulse during the impact phase were compared across landings. Differences between model-simulated and experimentally-measured VGRFs served to determine the ability of the model to simulate the effect of flight and impact phase control on the dynamics of the body during landing. The model was validated by comparing experimental results with the simulated peak VGRF and impulse of the VGRF during the impact phase (from contact forward to twice the time from contact to peak VGRF). If the simulated impulses match the experimental values within 10%, the model was considered sufficiently complex to establish the initial momentum conditions of the post-impact phase. Finally, the necessity of adding a foot to the model was determined by comparing the VGRF peak pattern from simulations with the experimentally observed toe-heel contact pattern.

Results: The simulated peak VGRF scaled in magnitude across the soft, normal, and hard landing cases, comparable to that observed in the experimental peak VGRF. Experimental peak VGRFs across the soft, normal, and hard landing cases ranged from 4.41-7.61 times body weight (BW), with a normal landing peak VGRF of 4.87BW(Fig b). The multijoint control model with a foot produced impulses during the impact phase accurate to within 5% of the experimental impulses for each case(Fig d). The sequential forefoot and heel contacts were qualitatively matched when the model had a foot, and they were reversed without a foot(Fig e).

Figure:



Caption: (a) Land-and-stop task (b) VGRF-time curves show decrease in peak VGRF and increase in impact-phase duration across landing tasks (c) Simulated peak VGRF show comparable scaling across tasks wrt experiment (d) Impulse during impact phase across landing tasks shows sufficiency of simulations for initial momentum conditions at post-impact. (e) Comparison of sequential VGRF peaks during impact phase for model w/ and w/o foot showing foot necessity for characteristic peak sequence found in experiment.

Conclusion: The experimental results confirmed that flight phase control affected peak VGRF and vertical impulse during the impact phase. As the other experimental parameters were held constant, the variation in peak VGRF across tasks demonstrates the necessity of including multijoint control in human body impact modelling. While not perfectly accurate to the experimental peak VGRF, which is a very sensitive value, the model provided accurate prediction of the impulse during impact, making it a sufficient model of the human body during drop landings. Finally, it is necessary to include a foot in the drop-landing model to reproduce the sequential dual-peak VGRF time curves measured experimentally.

ELEMENT POSITION'S EFFECTS ON THE DEGRADATION PROCESS SIMULATION OF MAGNESIUM ALLOY STENTS IN FINITE ELEMENT ANALYSIS

Yuanming Gao [1,*]Zhaowei Chu [1]Meng Guo [1]Yubo Fan** [1 2]

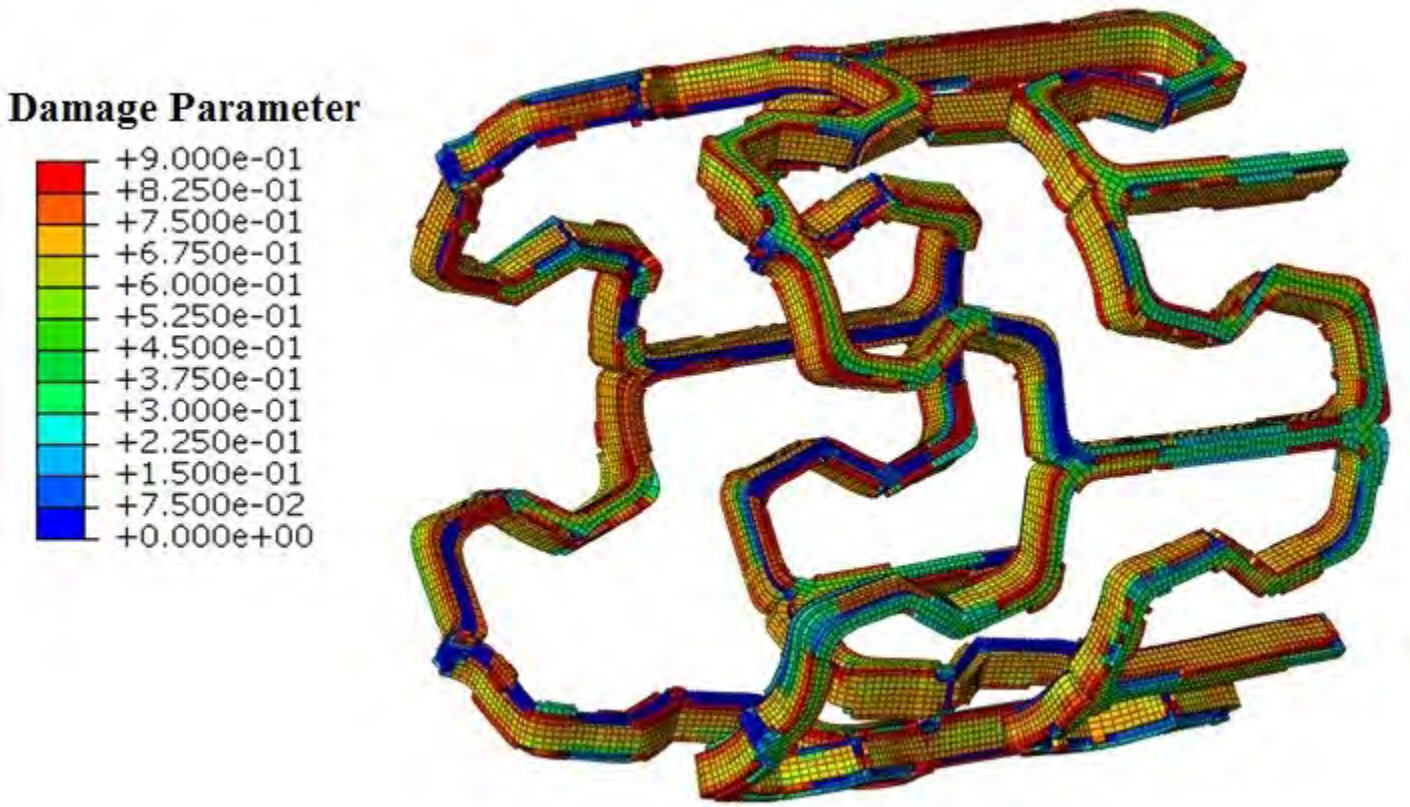
[1]Key Laboratory for Biomechanics and Mechanobiology of Ministry of Education, International Research Center for Implantable and Interventional Medical Devices, School of Biological Science and Medical Engineering, Beihang University, [2]National Research Center for Rehabilitation Technical Aids, Beijing, China

Introduction and Objectives: Biodegradable magnesium alloy stents (MAS), which have good biocompatibility and no long term health risks associated with permanent stents, have attracted intense attention in recent years. Finite element analysis (FEA) has become a powerful tool for testing stent properties due to its low costs and high efficiency compared to the conventional testing[1]. The elements located exposed exterior surfaces of the finite element models of MAS constitute the corrosion layers, and have respective number of corrosion surfaces. For example, elements on the corners of the MAS models have two or three surfaces exposed to the corrosive environment and others may have only one surface. Each of different corrosion surface numbers would cause different corrosion magnitude, especially for uniform microgalvanic corrosion processes. The objective of this study is to build up a degradable FEA model of MAS considering effects of element positions.

Methods: In this work, the corrosion of magnesium alloy is assumed to be the superposition of stress corrosion and uniform microgalvanic corrosion processes, and continuum damage mechanics was used to describe the degradation of mechanical properties during corrosion process[2,3]. Geometric model of MAS (Biotronik Magic stent) was generated based on the images in literatures. FEA models were composed of a stent, an artery vessel, a plaque and a rigid cylinder to expand the stent. Commercial code ABAQUS/Explicit, with a user material subroutine (VUMAT) devoted to calculation of the damage increment, was designed and applied in the simulations. It is assumed that uniform corrosion rate of each element is proportional to corrosion surface number of the element because the surface area exposed to corrosive environment is a very important factor for the damage rate. During simulation, once a critical amount of damage in the element is reached, the element would be removed from FE mesh of MAS. Therefor element connectivity and initial corrosion surface numbers of elements must be provided for VUMAT code and then be updated in the degradation process.

Results: In the FEA process, rigid cylinder expended the MAS and then the stent begun to be corroded and subjected to tension from the artery vessel and plaque. As damage accumulation increasing, structural weakening caused by stent degradation was shown (Figure 1). The uniform corrosion rates varied with element positions during degradation. Elements located on the corners and edges of stents, because of more corrosion surfaces, had higher rates than others. Moreover, cracks and pits appeared when fully damaged elements were removed from FE mesh of MAS, which caused neighboring elements had additional corrosion surfaces and then had higher uniform corrosion rates. Therefor the effects of cracks and pits on the degradation rate are improved by the model in this study.

Figure:



Caption: The degradation simulation of MAS. The legend is related to the uniform corrosion damage parameter.

Conclusion: The novel MAS finite element model in this work can describe more complex and precise changes of morphology and mechanical properties in degradation process. The method considering effects of element positions in FEA is helpful for not only simulations of MAS, but for simulations of other potential degradable metallic biomaterials and implants.

A NEW COMPUTATIONAL METHOD TO PREDICT THE DEVELOPMENT OF OSTEOARTHRITIS WITHIN THE KNEE JOINT

Mika Mononen [1,*] Petri Tanska [1] Hanna Isaksson [2] Rami Korhonen [1]

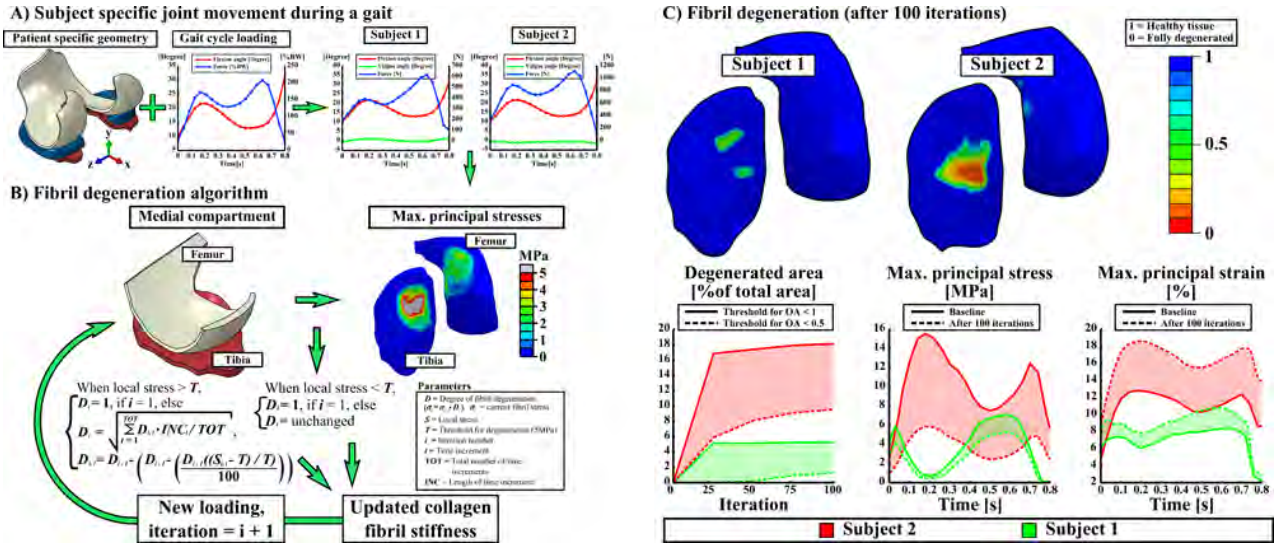
[1]Department of Applied Physics, University of Eastern Finland, Kuopio, Finland, [2]Department of Biomedical Engineering, Lund University, Lund, Sweden

Introduction and Objectives: One of the first signs of knee osteoarthritis (OA) is collagen fibrillation, leading to decreased collagen network stiffness and increased local tissue strains of cartilage [1,2]. It has been shown that high loading rates, i.e., impulsive loads within the knee joint are one of the most crucial risks for the onset and development of OA [3]. However, there are currently no methods to predict the progression of OA. Therefore, our aim was to develop and validate a computational finite element (FE) model, incorporating an adaptation algorithm, to predict collagen fibril degeneration regulated by altered joint loading due to overweight during gait.

Methods: MRI data of two right knee joints were selected from the Osteoarthritis Initiative (OAI) database. Subject 1 was a normal weighted person with no cartilage degeneration at the baseline or after 4-year follow-up (Kellgren - Lawrence grade 0), whereas subject 2 was an overweight person with no initial cartilage degeneration at the baseline, but after 4-year follow-up the KL grade had developed from 0 to 3. The knee joints were segmented manually by Mimics v12.3 and then the segmented tissues were imported into Abaqus v6.13, in which the final FE model geometries were constructed (Fig. 1A). Cartilage tissues were modeled as fibril reinforced poroviscoelastic materials with split-line and depth-wise fibril architectures and Menisci were considered as transverse isotropic materials [2]. Stresses in both knee joints were simulated during gait obtained from literature [4] (Fig. 1A). Then the medial compartment model was driven by the forces obtained from the whole knee joint models (Fig 1A). Cartilage responses (maximum principal stresses) were then analyzed (Fig. 1B). In the adaptation algorithm, collagen fibril degeneration (collagen softening) was regulated based on the local maximum principal stresses. The local collagen fibril softening occurred as a response when 5 MPa was exceeded, a failure stress observed experimentally for cartilage [5]. In the simulations of collagen degradation, 100 iterative steps were applied and the collagen fibril properties changed in an element-wise manner after each iteration step if the criterion of stress was fulfilled (see the iterative loop from Fig. 1B).

Results: After 100 iterative steps, the local collagen fibril stiffnesses were reduced substantially more in the model of overweight subject (subject 2) compared to the model of normal weight subject (subject 1) (Fig. 1C - top). This was consistent with the experimentally diagnosed stage of OA at 4-year follow up. At the tibial cartilage surface, the areas of degenerated cartilage tissue increased as a function of iterative steps in both models (Fig. 1C – bottom; left). The most severe changes in the degenerated surface area were observed in the overweight subject model. Collagen softening (degradation) caused substantially greater changes in stresses (decrease) and strains (increase) of cartilage in the overweight subject model compared to the model of normal weight subject (Fig. 1C – bottom; middle and right).

Figure:



Caption: Workflow from the subject specific gait load (A) till the fibril degeneration algorithm (B) and the results after 100 iterative degenerative simulations (C). (A) subject specific knee joint loads of a medial compartment during gait, obtained from literature, were implemented into the subject specific whole knee joint models. (B) medial compartment where the fibril degeneration algorithm was applied, stress distribution is from the subject 1 during the first peak loading force of gait. (C) top figures present the rate of fibril degeneration in the subjects 1 and 2, bottom row sub-figures indicate the percentage fibril degeneration of the medial tibial surface area with two different thresholds (left), maximum principal stresses (middle) and strains (right) at the tibial surface at themost degenerated location between the baseline and adapted models (100 degenerative iterations), respectively.

Conclusion: A novel computational adaptive FE model was able to predict osteoarthritis progression (collagen softening) as a result of abnormal joint loading (overweight), while the subject under normal loading did not experience much degenerative changes. The results were consistent with experimentally diagnosed KL grades at baseline and 4-year follow-up time point. Due to substantially reduced local collagen fibril stiffnesses in the model of overweight subject, greater changes in local cartilage strains were observed. This could lead to more severe OA in the future. However, it should be emphasized that the current work presents a new theoretical method to predict cartilage degeneration for two subjects (only the other developed OA).

COULD FOOT KINEMATICS BE USED TO PREDICT THE DISTRIBUTION OF VERTICAL FORCE IN MULTI-SEGMENT FOOT MODELS?

Iain Hannah [1,*] Zimi Sawacha [2] Annamaria Guiotto [2] Claudia Mazzà [1]

[1]INSIGNEO Institute for in silico Medicine, University of Sheffield, Sheffield, United Kingdom, [2]Department of Information Engineering, University of Padova, Padova, Italy

Introduction and Objectives: The use of a multi-segment foot in a musculoskeletal model of human gait requires the ground reaction force (GRF) to be subdivided between the modelled foot segments. A number of foot-ground contact models have been presented in the literature [1-5] but these remain in early development. As such, no single technique has been accepted as a valid way to model the complex interaction that occurs at the foot-ground interface.

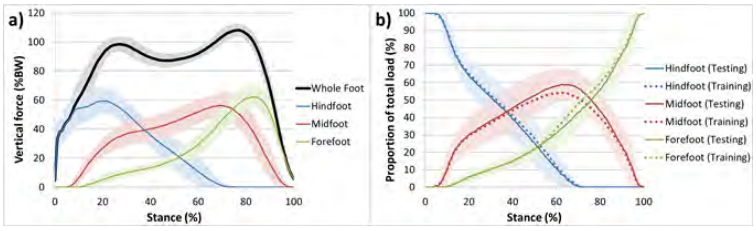
Sawacha et al. [6] found the variability of vertical load magnitudes that occur across different foot segments to be greater than that which occurs within the foot as a whole. This work thus details the development of a statistical tool which aims to use foot kinematics to predict the proportion of vertical loading that occurs in each of three foot segments during an experimental walking trial.

Methods: 20 healthy subjects (14m/6f, age: 58±5 years, weight: 74±13kg, height: 171±9cm) were recruited with each performing three walking trials at a self-selected speed. Foot kinematics, GRF and the distribution of plantar pressure were all recorded. Using the techniques reported by Sawacha et al. [6], the vertical loading that occurred during each trial was divided between the three foot segments; hindfoot, midfoot and forefoot (Figure 1b).

The subjects were randomly divided into two equally sized groups; a model testing group and a model training group. Key points on the foot segment loading curves such as the time of zero hindfoot loading, time of maximum midfoot loading and maximum midfoot load proportion were identified for each of the trials performed by those subjects assigned to the model training group. Kinematic variables were also calculated for each trial and subsequently used in a regression analysis to attempt to predict the occurrence of these points. These variables included trajectories and velocities of individual markers and marker groups, arch deformation and sole angle variation.

Results: No significant correlation could be found between the key points on the hindfoot, midfoot and forefoot loading curves and the kinematic variables measured in the experimental trials. The strongest correlation was found between the time of increased calcaneal velocity and time of zero hindfoot loading but only had an R^2 value of 42 %. Furthermore, simply fitting the average training load curves to the testing group resulted in average RMS errors of 7.6 %, 9.7 % and 6.7 % for the hindfoot, midfoot and forefoot segments respectively (sd = 2.7 %, 3.1 %, 2.9 %).

Figure:



Caption: Average distribution of vertical loading between three foot segments. a) Entire cohort (±1 sd shown), and b) in training (±1 sd shown) and testing groups.

Conclusion: The high levels of inter-subject variability exhibited in the loading curves meant that foot kinematics could not be employed to predict the distribution of vertical loading that occurs across a multi-segment foot model. This inter-subject variability was higher for the three segmented force curves than for the overall vertical load. Furthermore, the variability in the distribution of the load under the foot could not be explained by the measured kinematic variables.

The high variability in the vertical forces acting under each sub-segment of the foot is in agreement with previous literature [7] where it was associated to the differences in foot shapes exhibited even amongst healthy subjects. Nevertheless, in order to characterise the complex loading scenario that occurs at the foot-floor contact interface further consideration should be given to the shear forces that occur here, and not only to the vertical component.

CEINMS: AN OPENSIM TOOLBOX TO INVESTIGATE THE INFLUENCE OF DIFFERENT NEURAL SOLUTIONS IN PREDICTING MUSCLE EXCITATIONS AND JOINT MOMENTS DURING DYNAMIC MOTOR TASKS

Claudio Pizzolato [1,*] David G. Lloyd [1] Massimo Sartori [2] Elena Ceseracciu [3] Thor F. Besier [4] Monica Reggiani [3]

[1]Centre for Musculoskeletal Research, Griffith Health Institute, Griffith University, Gold Coast, Australia, [2]University Medical Center Göttingen, Georg-August University, Göttingen, Germany, [3]Department of Management and Engineering, University of Padua, Vicenza, Italy, [4]Auckland Bioengineering Institute, University of Auckland, Auckland, New Zealand

Introduction and Objectives: Neuromusculoskeletal (NMS) models represent the neurological, physiological, and anatomical characteristics of an individual, and can be used to estimate the forces generated inside the human body. Individual muscle forces and their contribution to joint moments can be determined using optimisation methods, which track the external joint moments and/or kinematics to estimate muscle activations and forces [1, 2]. However, these methods cannot account for variations in muscle activation patterns used in different control tasks, and by different people. EMG-driven NMS models can overcome these problems [3] but have limitations of acquiring EMG from a limited number of muscles and errors in EMG measurement.

We have created the Calibrated EMG-Informed NMS Modelling Toolbox (CEINMS), an OpenSim [4] plug-in that enables investigators to use different neural solutions for the same NMS model and measured movements. CEINMS collects EMG-driven and EMG-informed algorithms that have been previously published and tested [3, 5-7]. CEINMS can operate with any number of degrees of freedom (DOF) and musculotendon units (MTU) and can be calibrated to the individual to better predict measured joint moments and EMG patterns. CEINMS covers neural solutions from EMG-driven to hybrids between EMG-driven and optimisation-driven, and to full optimization-driven. Also, CEINMS can use as input a set muscle synergies and scaling coefficients that are linearly combined to synthesise muscle excitations [8].

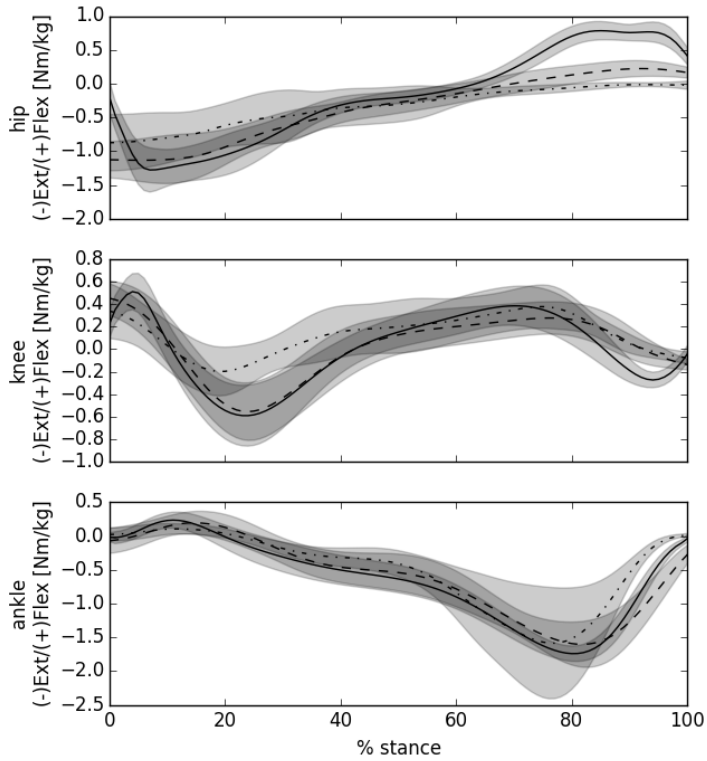
To date, it has not been possible to see if EMG-informed methods produce different muscle forces compared to static optimisation, independent of the NMS model. So we used CEINMS to examine how different neural solutions affect the predicted joint moments, muscle excitations and muscle forces using the same NMS model and motion data.

Methods: Walking data were collected from 5 subjects, using a 10-camera motion capture system and 2 force plates. Surface EMG signals were acquired from 16 muscles of a single leg. Segmental dimensions and muscle parameters of the OpenSim model were anthropometrically scaled [9] to the subjects. 3D joint angles, MTUs kinematics, and joint moments during stance phase were calculated using inverse kinematics, muscle analysis, and inverse dynamics OpenSim tools respectively. CEINMS was configured to analyse forces from 34 MTUs of the support leg, and flexion extension (FE) moments of hip, knee, and ankle. CEINMS calibrated each subjects' MTUs parameters within physiological ranges using calibration data sets. Once calibrated CEINMS estimated the joint moments using the EMG-driven [3], EMG-assisted [5], and optimisation-driven neural solutions.

Data were time-normalized and averaged across trials (6 per subject). The coefficient of determination R^2 and the root mean square error (RMSE) between the predicted and measured joint moments from the different neural solutions were used as a measure of prediction accuracy.

Results: The calibration procedure improves the estimation of hip, knee, and ankle FE moments for the EMG-driven mode (Table 1, Figure 1). The EMG-driven calibrated model well predicted the knee and ankle flexion extension moments, but poorly predicted the hip moment, while the EMG-assisted and the optimisation-driven modes both matched the experimental joint moments for the three joints (Table 1).

Figure:



Caption: Figure 1 – External joint moments from inverse dynamics (solid), uncalibrated EMG-driven (dash-point), and calibrated EMG-driven (dashed). Curves represent ensemble averages (shaded area 1 SD) of 6 walking trials from 5 different individuals.

Conclusion: CEINMS is an OpenSim toolbox to explore the effect of different neural algorithms using a consistent NMS model. CEINMS is the first software publicly available that can be configured to work with any number of MTUs and DOFs. It includes a calibration procedure to tune the model's parameters, can be used with dynamic tasks, and provides state-of-the art EMG-informed algorithms.

Table:

	Uncalibrated EMG-driven		EMG-driven		EMG-Assisted		Optimisation-driven	
	RMSE (Nm/kg)	R^2	RMSE (Nm/kg)	R^2	RMSE (Nm/kg)	R^2	RMSE (Nm/kg)	R^2
hipFE	0.56	0.65	0.39	0.84	0.07	0.99	0.04	0.99
kneeFE	0.28	0.67	0.18	0.80	0.09	0.93	0.08	0.95
ankleFE	0.44	0.86	0.24	0.88	0.10	0.97	0.06	0.99

Caption: Table 1 – CEINMS predictions for the external joint moments using the uncalibrated EMG-driven, and the calibrated EMG-driven, EMG-assisted, and the optimisation-driven modes of 6 walking trials from 5 different subjects.

WHAT IS THE RELATIONSHIP BETWEEN KNEE BIOMECHANICAL FUNCTION AND PATIENT REPORTED FUNCTION BEFORE AND AFTER TOTAL KNEE REPLACEMENT?

Lucy A Bailey [1 2,*] Paul R Biggs [2 3] Chris Wilson [2 4] Cathy A Holt [2 3] Gemma M Whatling [2 3]

[1]Trauma and Orthopaedics, Southampton General Hospital, Southampton, [2]Biomechanics and Bioengineering Centre, Arthritis Research UK, UK, [3]School of Engineering, Cardiff University, [4]Trauma and Orthopaedics, University Hospital of Wales, Cardiff, United Kingdom

Introduction and Objectives: Whilst most patients have an improvement in their function following total knee replacement (TKR) and are satisfied with the surgery, around one in six will have less favourable results [1,2,3]. Risk factors have been identified[3,4,5], but reasons underlying dissatisfaction are not clearly understood. The aim of this work was to establish the relationship between measurable gait parameters and patients' subjective function, before and after TKR.

Methods: 25 subjects underwent gait analysis, before and one year following TKR. Patient reported function was investigated using the Activities of Daily Living Scale of the Knee Outcome Survey (KOS). Three dimensional motion analysis was performed using infrared cameras and reflective marker clusters to record gait (Qualisys, Sweden). Ground reaction forces (GRFs) were measured using 2 force plates (Bertec Corporation). Knee joint kinematics and GRF data waveforms were computed for each subject pre and post TKR. Metrics including the timings and magnitudes of specific events in the gait cycle were identified. Linear regression was used to assess for correlation between motion analysis data and patient reported function.

Results: At the pre-operative visit there were multiple measured gait parameters that were shown to correlate significantly with the patient's functional score, after correcting for the affect of cadence. These included the amount of extension occurring during stance after the first flexion peak ($P=0.003$, $R^2=0.354$), the internal rotation at 90% of the gait cycle ($p=0.006$, $R^2=0.301$) and the timing of the peak lateral GRF in early stance ($p=0.004$, $R^2=0.271$).

Subjects with a higher (better) pre-operative score tended to have a higher post operative score ($p=0.0365$, $R^2=0.177$), but show less of an improvement in score than subjects who had a lower pre-operative score ($p=0.0058$). After correction for the affect of pre-operative score, there were three measured parameters in the pre-operative gait that correlated with the extent of improvement in score that was seen after surgery. These were the rate of extension in swing ($p=0.025$, $R^2=0.0.392$), total range of motion from extension at heel strike to the maximum flexion in swing ($p=0.026$, $R^2=0.314$) and time point of maximum stance extension ($p=0.019$, $R^2=0.384$).

Post-operatively, no measured parameters correlated with KOS after correcting for the affect of cadence.

Conclusion: This work adds to our understanding of the complex relationship between biomechanical knee function and patient reported function. Before surgery the two are closely related, yet after surgery it would appear that factors other than biomechanics of gait determine patient reported outcomes. These factors might include muscle strength, pain or kinetics and kinematics of other daily activities such as climbing stairs or rising from a seated position.

The identification of elements in pre-operative gait that are associated with post-operative outcome has the potential to help guide patient treatment and could help to identify and prioritize patients that are more likely to benefit from TKR.

Patients with pre-operative gait indicative of poor outcome may warrant further investigation into causes of symptoms and alternative treatment modalities; particularly in the presence of other risk factors for poor outcome. If TKR was to be undertaken, patients could be counselled appropriately, in order that they could make an informed choice about their treatment.

GAIT CHARACTERISTICS OF LOCOMOTIVE SYNDROME BY PRINCIPLE COMPONENT ANALYSIS

Baku Suzuki [1,*] Yoshiyuki Kobayashi [2] Masaaki Mochimaru [2] Hiroshi Fujimoto [3]

[1]School of Human Sciences, Waseda University, 2-579-15, Mikajima, Tokorozawa City, Saitama Pref, [2]Digital Human Research Center, National Institute of Advanced Industrial Science and Technology, Waterfront 3F, 2-3-26, Aomi, Koto-ku, Tokyo, [3]Faculty of Human Sciences, Waseda University, 2-579-15, Mikajima, Tokorozawa City, Saitama Pref, Japan

Introduction and Objectives: Aging of the population is one of the most important problems especially in Japan, but for all over the world. In this circumstance, locomotive syndrome (LS), the conditions under which people may soon need care services because of problems of the locomotive organs, was proposed by Japanese Orthopedic Association in 2007. Yoshimura et al. reported that there are over 47 million LS candidates live in Japan. Early detection of such people may decrease the number of patients needing nursing care. We aimed this study to develop the device which can discriminate whether the user is LS or not. In order to do so, first we have to know the characteristics of the LS gait pattern. The purpose of this study is, therefore, the identification of the key joint kinematics characteristics during walking that are related to LS by using principal component analysis (PCA).

Methods: Fifty-four healthy community-dwelling elderly subject (27 M & 27 F) were recruited for the study. Ten of them (6 M & 4F) were classified as the LS by using GLFS-25 questionnaire (score ≥16) [1]. The experimental protocol was approved by the local ethical committee and all the participants gave their written informed consent before participating. The experiments were performed in a room with a straight 10 meter path for the participant to walk. Three-dimensional positional data was obtained using reflective markers and a 3D motion capture system using a sampling frequency of 200 Hz. A total of 55 IR reflective markers were attached in accordance with the guidelines of the Visual 3D software. We also recorded the ground reaction force (GRF) using six force plates sampled at 1 kHz to time the gait cycle. Participants were asked to walk barefoot at a comfortable, self-selected speed. After the practice, five successful trials in which each GRF measured properly with the right foot were recorded.

The raw data was digitally filtered using a fourth-order low-pass Butterworth filter with zero lag and a cut-off frequency of 10Hz for the trajectories. The right hip, knee, and ankle joint angles on the sagittal, frontal, and horizontal planes during one gait cycle were calculated from the trajectories of the each trial. The joint angles were time-normalized by the gait cycle duration determined based on the force plate data and divided into 101 variables ranging from 0% to 100%. The calculation of the joint angles and the time normalizations were done using Visual 3D.

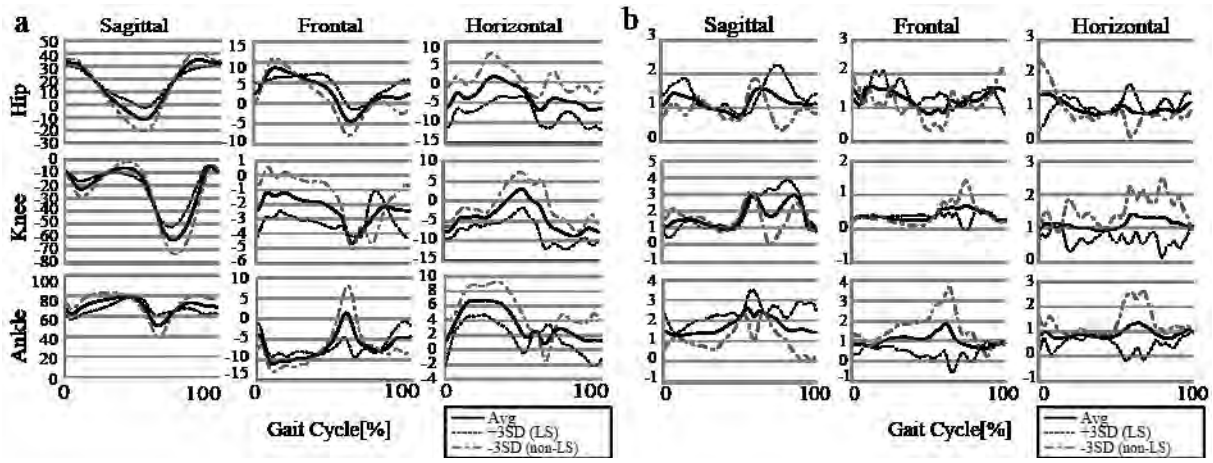
PCA was conducted to 54 by 1818 (AVGs and SDs for 101 time points, three joints, and three planes) matrix to identify the key joint kinematics characteristic of walking that is related to the LS. In order to confirm the stability of the analysis, the PCA were repeated with 54 surrogate input matrixes. Further, discrimination analysis with step-wise procedure was used to determine the PCVs related to the LS. All the statistical analyses were executed using SPSS Ver. 22.

Results: The PCA revealed that the first 52 PSVs explained more than 99% of the joint movement patterns. Among these 52 PCVs, PCV 7 (2.88% of the variance), PCV 12 (1.49% of the variance) and PCV13 (1.29% of the variance) were selected to the model. The results of surrogate PCAs are similar to the result of main PCA. Therefore, it is reasonable to

expect that the joint kinematics corresponding to these PCVs are the key joint kinematic characteristics of human gait related to the LS while walking on level ground. We therefore recombined the joint kinematics related to the PCV7, 12 and 13. As a result, LS group tended to show smaller ROM of hip, knee and ankle joint angles in sagittal plane, and greater joint kinematics variability of hip, knee and ankle joint angles during the swing phase in sagittal plane than non-LS group (figure 1).

These results are in agreement with those of previous studies regarding the joint kinematics related to fall risk (Kobayashi et al. 2014). Therefore, it is reasonable to expect that LS related not only risks of becoming need care services but also risks of falling.

Figure:



Caption: Fig.1. Joint kinematics recombined from PCV7, 12 and 13. (a) Central tendency and (b) Variability.

Conclusion: In this study, PCA was used to identify the key joint kinematics characteristics of gait related to LS when walking on level ground. Statistical analyses revealed that PCV 7, 12 and 13 among 52 generated PCVs were related to LS. The recombined joint kinematics corresponding to these PCVs indicate that LS group tend to show smaller ROM in sagittal plane and greater joint kinematics variability during the swing phase in sagittal plane than non-LS group. These observations imply us that we are able to detect people who are in LS using some sensors such as accelerometer or optical sensor to capture these features.

ESTIMATION OF SUBJECT-SPECIFIC 3D POSITION OF THE KNEE LIGAMENT ATTACHMENT SITES AND LIGAMENT LENGTH VARIATION DURING KNEE FLEXION

Elena Bergamini [1 2,*] Hélène Pillet [3] Goulven Rochcongar [3] Patricia Thoreux [3 4] Philippe Rouch [3] Valentina Camomilla [1 2] Aurelio Cappozzo [1 2] Wafa Skalli [3]

[1]Department of Movement, Human and Health Sciences, [2]Interuniversity Centre of Bioengineering of the Human Neuromusculoskeletal System, Università degli Studi di Roma "Foro Italico", Roma, Italy, [3]LBM/Institut de Biomécanique Humaine Georges Charpak, Arts et Metiers ParisTech, Paris, [4]Service de Chirurgie Orthopédique et Traumatologique, Hopital Avicenne - Université Paris 13, Bobigny, France

Introduction and Objectives: In musculoskeletal modelling and movement analysis, accurate information about the 3D position of the knee ligament attachment sites, as well their length variation during knee flexion, is critical [1]. Extensive literature exists that describes the position of both the anterior and posterior cruciate ligaments (ACL, PCL) [2], whereas few works focused on the medial and collateral ligaments (MCL, LCL) [3]. All these studies provide the attachment site positions in terms of distances to surgically relevant anatomical landmarks, rather than with respect to anatomical reference frames suitable for movement analysis applications. Furthermore, although ligament length variation during knee flexion has been dealt with in the literature [1,4], its complete characterisation along with attachment site location has not been performed yet. The purpose of this work is to provide the 3D position of the knee ligament attachment sites with respect to anatomical reference frames defined on femur and tibia bone templates, along with the ligament length variations during knee flexion. This information, associated with morphological features of the bones involved observed in a given individual, allows for subject-specific modelling of the knee ligaments.

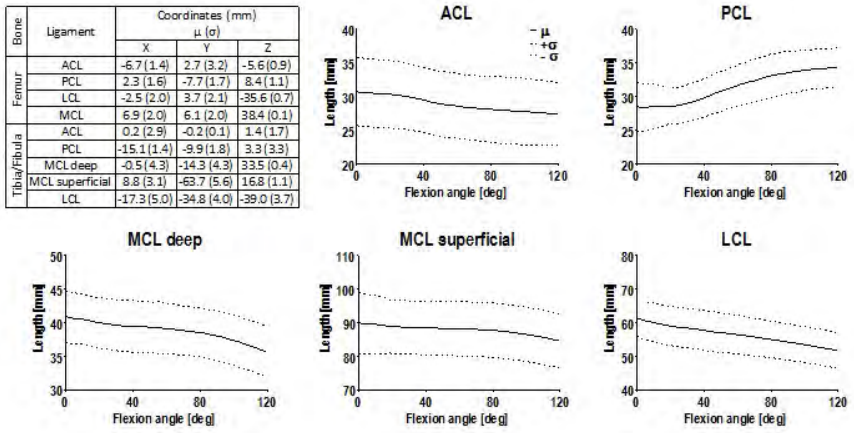
Methods: Twelve fresh-frozen specimens (6 M, 6 F, age range: 47-79 years), consisting of femur, patella, fibula, tibia and intact joint passive structures, were analysed after a thawing period of 24 hours. Two clusters of reflective markers were secured to the femur and tibia and three tantalum spheres were embedded in each bone. The specimens were set in motion (6 flexion-extension cycles, range of motion: 0-120°) using the device described in [5] and the 3D pose of both bony segments were recorded using a stereophotogrammetric system (Polaris, CDN). Two orthogonal X-ray images of each specimen were simultaneously obtained (EOS®, FR) and a 3D model of the tibia, fibula, and femur, including markers and tantalum spheres, was obtained using the reconstruction algorithm validated in [6], which adapts bone templates to match subject-specific X-ray images. Each specimen was then dissected and the attachment sites of ACL, PCL, deep and superficial MCL, and LCL were identified and marked using a radio-opaque paint. CT scans of each bone epiphysis were finally taken (General Electric Healthcare, US) and processed to obtain the 3D geometry of each attachment site, as well as the position of the tantalum spheres. The latter were used to map the attachment sites on the corresponding bone models. The centroids of the origin and insertion of each ligament were then calculated and the distance between them was determined during the knee flexion-extension. Finally, to assess the variability of each attachment site location, all subject-specific bone models were scaled and deformed using a kriging algorithm [7] to fit the bone templates used in [6]. The same transformation was then applied to the centroids of each attachment site to map

them on the same models. Anatomical reference frames were defined for tibia and femur templates according to [1], and mean (μ) and standard deviation (σ) values of the centroid 3D coordinates with respect to the latter frames were calculated.

Results: The variability of the ligament attachment sites location are in agreement with previous literature [2,3] (Fig. 1): the variability of the origins and insertions located on the femur was, on average, lower than that on the tibia and fibula. For what concerns the tibial insertion of the superficial MCL, it should be noticed that its high variability along the y-axis can be ascribed to its critical identification due to the lack of clear-cut bony prominences [8]. The trends of each ligament length variation (Fig. 1) are in agreement with previous studies [1,4], as well as μ and σ values corresponding to the ligament maximum length [4].

Figure:

Bone	Ligament	Coordinates (mm) μ (σ)		
		X	Y	Z
Femur	ACL	-6.7 (1.4)	2.7 (3.2)	-5.6 (0.9)
	PCL	2.3 (1.6)	-7.7 (1.7)	8.4 (1.1)
	LCL	-2.5 (2.0)	3.7 (2.1)	-35.6 (0.7)
	MCL	6.9 (2.0)	6.1 (2.0)	38.4 (0.1)
Tibia/Fibula	ACL	0.2 (2.9)	-0.2 (0.1)	1.4 (1.7)
	PCL	-15.1 (1.4)	-9.9 (1.8)	3.3 (3.3)
	MCL deep	-0.5 (4.3)	-14.3 (4.3)	33.5 (0.4)
	MCL superficial	8.8 (3.1)	-63.7 (5.6)	16.8 (1.1)
	LCL	-17.3 (5.0)	-34.8 (4.0)	-39.0 (3.7)



Caption: Ligament length variation patterns (μ ± σ) as a function of the flexion angle and centroid coordinates (μ and σ) in the template anatomical reference frames.

Conclusion: The present study provides the 3D coordinates of the knee ligaments attachment sites in specified anatomical reference frames of femur and tibia templates and the variation of the ligament lengths during knee flexion. By registering these templates with morphological features of the corresponding bones as observed in a given individual, subject-specific bone models with the knee ligament insertion and origin sites can be estimated with the indeterminacy provided by this investigation.

PLANTAR PRESSURE DISTRIBUTION DURING RUNNING IN CHILDREN

Paula R. Mesquita [1,*] Letícia Erna [1] Elias Trotti [1] Raphael Oliveira [1] Ana de David [1]

[1]Faculdade de Educação Física - FEF, Universidade de Brasília - UnB, Brasília, Brazil

Introduction and Objectives: The acquisition of fundamental motor skills such as walking and running, depends on the biological processes of maturation and growth, as well as on the experiences and motor repertoire acquired by the child. The muscle forces responsible for human locomotion together with external forces result in loads that are generated under the foot when in contact with the ground and represent an estimate of motion mechanical efficiency and can initiate changes in foot function by changing how charges are distributed.

Running results in greater mechanical stress to the musculoskeletal system than walking, creating more demands on the locomotor system, however children's plantar pressure distribution (PPD) has been studied mostly during walking and quiet standing. No studies evaluating PPD variables during running in children were found. Therefore, the aim of this study was to describe PPD during running and comparing children aged 4, 6, 8 and 10 years old.

Methods: Forty healthy children were evaluated. They were asked to run barefoot at self-selected speed across the PPD platform (Emed n-50, 50Hz, 4 sensors/cm², Novel GmbH) recording 5 trials for each foot. Data analysis was performed with database software HMFT (Novel GmbH), considering relative contact area (CA) and peak pressure (PP) values in five regions of the foot (hindfoot, midfoot, forefoot, hallux and toes) in addition to the total area. Only rearfoot strike trials were selected for analyses. Inter-groups differences were determined using the one-way Anova with significant differences analysed by Games-Howell post hoc test. All tests were performed with SPSS 21.0 ($p \leq 0,05$).

Results: No systematic differences were found between left and right feet for the parameters evaluated, therefore presented data refers to left foot trials.

Body mass (BM), body height (BH) and foot length (FL) significantly differed between groups ($p \leq 0,000$), children aged 10 years-old had increases of approximately 110% for BW and 35% for BH and FL when compared to 4 year-olds, which represents the growth of the children.

Peak pressure values in the total area of the foot were 60% lower for the 4 year-olds during running when compared to 10 year-olds ($p = 0,003$). Under the forefoot the 4 y-o group had values on average 67% lower when compared to groups aged 6 ($p = 0,011$), 8 ($p = 0,003$) and 10 ($p = 0,013$). Hindfoot and forefoot experienced the highest values of pressure.

Relative contact area under the hindfoot of the 4 year-olds was on average 23% smaller during running when compared to 8 ($p = 0,039$) and 10 y-o groups ($p = 0,000$). Under the midfoot of the 4 y-o group the CA was 47% higher than for the 10 year-olds ($p = 0,024$). For the remaining foot regions the values were raised between the groups aged 4 and 6 y-o and for the 6, 8 and 10 years-old groups were either maintained or reduced.

Conclusion: Values of PP showed an upward trend through the ages, especially between 4 and 10 y-o. For some foot regions values were maintained or reduced between groups with very close ages.

A tendency for higher values with increasing age was also seen for CA under every region of the foot except for the midfoot, which had decreasing values with increasing age.

The raise in PP and CA values may be related to the increases seen in body mass, body height and foot length measures, representing the growth and development of the children. On the other way the decreasing values of CA in the midfoot region could be related to the development of the longitudinal arch.

A KINEMATIC MODEL OF THE TIBIA-FIBULA-TALUS COMPLEX FROM FUNCTIONAL ADAPTATION

Michele Conconi [1 2,*] Vincenzo Parenti-Castelli [1 2]

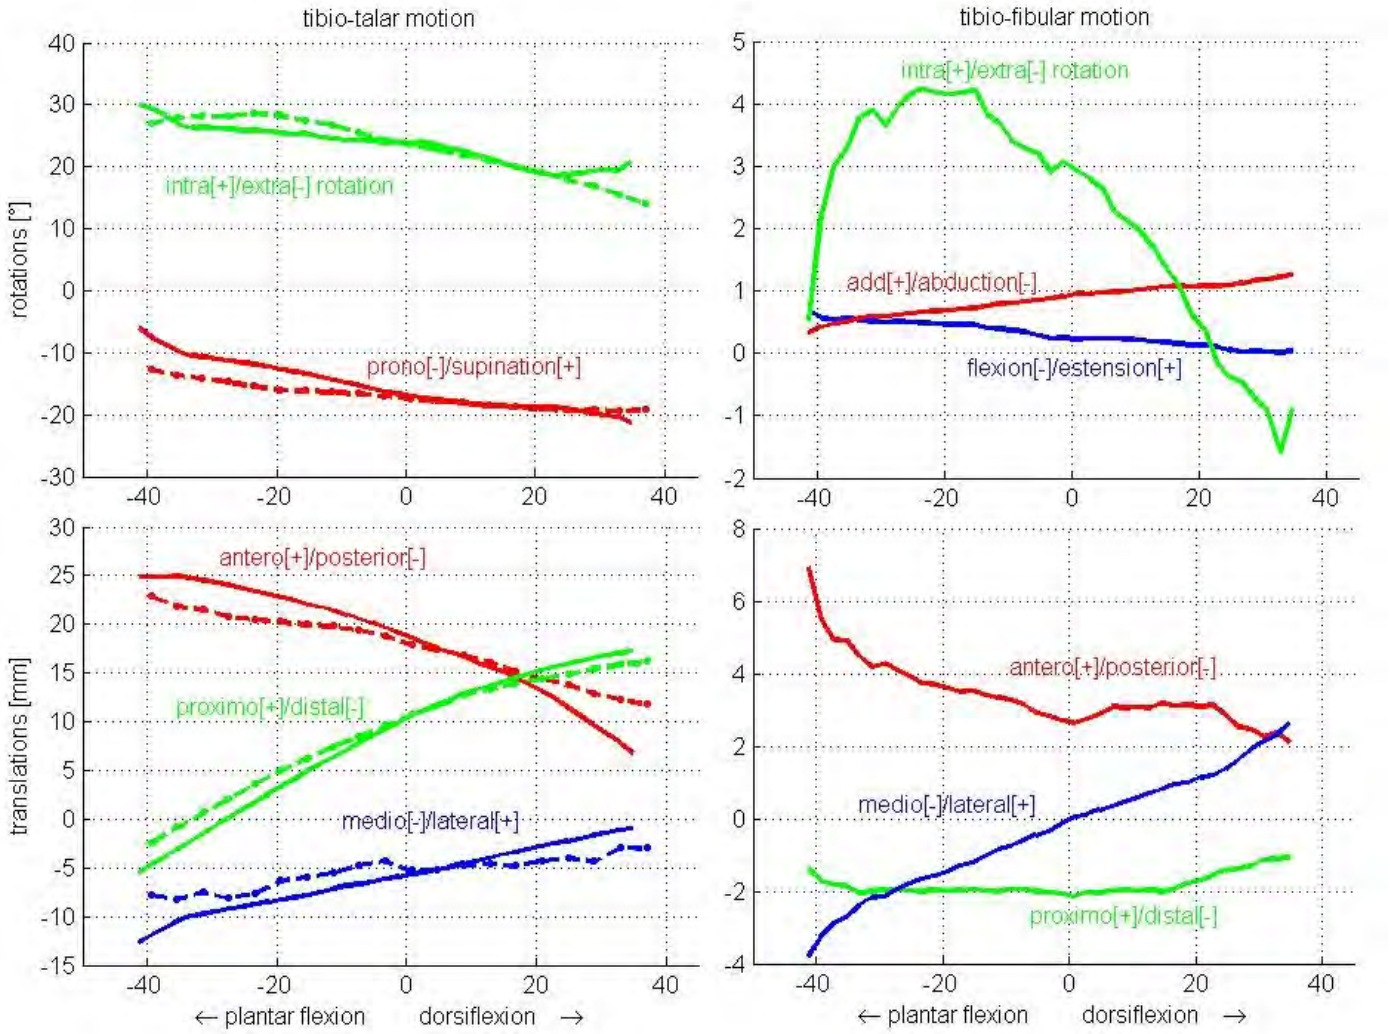
[1]Dept. of Indusrtial Engineering - DIN, Alma Mater Studiorum - University of Bologna, [2]Health Sciences and Technologies - Interdepartmental Center for Industrial Research [HST-ICIR], University of Bologna, Bologna, Italy

Introduction and Objectives: Several direct techniques exist for the in-vivo registration of the bone relative motions [1]. However, their applicability is limited by their invasiveness and/or by the cost associated with the specific equipments and time required. Alternatively it is possible to define kinematic models based on the patient anatomy and use them for the indirect evaluation of the bones movement. A possible approach in this direction exploit the capability of the joint tissues to modify their structure in response to the mechanical environment to which they are exposed [2-4] (functional adaptation). Although there is still room for discussion [5], functional adaptation seems to produce structures that use optimally their material, providing the necessary strength with the smallest amount of tissue. If the rules governing this process are known, it is possible to revert the reasoning and reconstruct the mechanics for which a joint is optimized from its architecture. In particular, it has been hypothesized [6] that contact surfaces adapt to optimize the capability to distribute contact loads. In [7], a measure of joint congruence has been presented that allows estimating the capability to distribute an applied load from purely geometrical considerations, namely form the knowledge of the shape of the articular surfaces and their relative position and orientation (configuration). A kinematic model of the adapted motion can thus be obtained as the envelope of maximum congruence configurations evaluated at different values of the flexion angle.
This approach has been validated in vitro on the tibio-talar (TT) joint with good results [8]. The aim of this work is to evaluate if this approach holds for the tibia-fibula-talus complex as well.

Methods: As described in [9], the TT motion was registered and the articular surfaces of the talus, distal tibia and fibula were digitalized during a in-vitro experiment. The articular surfaces were thus taken from MRI of another subject, while the reference tibio-fibular (TF) motion was taken from the literature [10].
Congruence was evaluated as the ratio between peak pressure and total contact force which, within the elastic foundation contact model, becomes a purely geometrical relation, as described in [7]. The congruence of the tibia-fibula-talus complex was evaluated as the sum of the congruence of the TT, fibio-talar and proximal TF articulations.
Since the ankle joint may be considered as a single DOF joint [11], the TT and TF motions describe a spatial trajectory in which can be parameterized, for instance, by the dorsi-plantar flexion angle. The trajectory of the TT and TF adapted motion was thus found as the envelope of successive maximum congruence configurations obtained varying the flexion angle within its physiological range.

Results: Fig. 1 shows the predicted TT and fibio-talar motions (continuous lines). Dotted lines represent TT experimental motion. Tab. 1 report the mean absolute errors (MAE) between computed and experimental TT motion, with and without considering the fibula.

Figure:



Caption: Computed (-) and experimental (.) tibio-talar and tibio-fibular motion.

Conclusion: The inclusion of the fibula did not modify the model capability to predict the TT motion. Qualitatively, the TF motion is in agree with what reported in the literature, the fibula moving posteriroly and laterally during the dorsiflexion motion, and rotating mainly about the intra-extra rotational axis. These results support the extendibility of the model to the multibone joints.

Table:

	Add/abduction	Intra/extra rotation	Antero/Posterior	Proximo/Distal	Medio/lateral
Without fibula	2.05	1.04	1.81	1.09	1.91
With fibula	1.73	1.68	1.99	1.13	1.66

Caption: MAE between computed and experimental tibio-talar motion.

DISCRIMINATION OF FALLERS AND NON-FALLERS USING THE VARIABILITY OF THE MAGNITUDE OF THE SACRAL ACCELERATION VECTOR

Yoshiyuki Kobayashi [1,*] Hiroaki Hobara [1] Thijs Heldoorn [1] Masaaki Mochimaru [1]

[1] Digital Human Research Center, National Institute of Advanced Industrial Science and Technology, Tokyo, Japan

Introduction and Objectives: Recent advancement of *Micro Electro Mechanical Systems* technology enables us to predict the potential risk of fall during daily walking in individuals. Researchers proposed various techniques to discriminate the fall risk of people using sensors. Doi et al. (2013) recently reported that the harmonic ratio of upper trunk acceleration during walking measured by tri-axial accelerometer attached on the upper trunk can discriminate the fallers and non-fallers with the sensitivity of 68.8 % and the specificity of 84.2 %.

It is quite difficult to attach the sensor accurately in practical situation; some may place the sensor in wrong location and some may place the sensor with wrong alignment. Of these errors, sensor alignment error may solve quite easily when the discrimination algorithm uses the magnitude of the acceleration vector as the input signals. Recently, we found that the variability of the joint kinematics for fallers was larger than that for non-fallers especially during the late-stance to early swing phase in gait cycle regardless of the joints and planes. Therefore, the purpose of this study was to test the hypothesis that the magnitude of the acceleration vector may predict the personal fall risk quite accurately.

Methods: Forty healthy community-dwelling elderly subjects (20 M & 20 F) were recruited for the study. Twenty of them (10 M & 10 F) experienced one or more falls during the year prior to the experiment. These participants were classified as fallers, and the others as non-fallers. The falling history of each participant was obtained before the experiment. The experimental protocol was approved by the local ethical committee and all the participants gave their written informed consent before participating. The experiments were performed in a room with a straight 10 meter path for the participant to walk. Three-dimensional positional data was obtained using reflective markers and a 3D motion capture system (VICON MX, VICON) using a sampling frequency of 200 Hz. A total of 55 IR reflective markers were attached in accordance with the guidelines of the Visual 3D software (C-Motion Inc.). We also recorded the ground reaction forces (GRFs) using six force plates (BP400600-2000PT, AMTI) sampled at 1 kHz to time the gait cycle. Participants were asked to walk barefoot at a comfortable, self-selected speed. After the practice, five successful trials in which each GRF measured properly were recorded.

The raw time series trajectory data was digitally filtered using a fourth-order Butterworth filter with zero lag and a cut-off frequency of 10Hz. The magnitude of sacral acceleration data were computed from filtered data. During this calculation, gravitational acceleration has added to the signal. The magnitude of sacral acceleration data were time-normalized by the gait cycle duration determined based on the GRFs and divided into 101 variables ranging from 0 to 100%. The intra-subject mean (AVG) and the standard deviation (SD) for each time point within the five sets of data obtained from each participant were calculated from time-normalized magnitude of acceleration data. Discrimination analysis was used to build the model to discriminate potential personal risk of falling using the data. When build the model, participants were separated into two homogeneous groups, and the accuracy was assessed each other using cross validation method.

Further, in order to ensure the robustness of the method, we calculated the average of the time-series SD data during late-stance to early swing phase of gait cycle respectively, and used these variables as the independent variable.

Results: The results of cross validation revealed the sensitivity of 80.0 % and the specificity of 85.0 % (Table 1), which is higher than the results of previous study (Doi et al. 2013). This may be due to the selection of independent variables. Indeed, Doi et al. (2013) used a harmonic ratio calculated from the acceleration data of entire gait cycle, while we used the average of the time-series SD data during early swing phase of gait cycle based on the results of previous study. Another advantage of our method is the function that users do not have to concern about the alignment of the sensors unless the location is fixed; thus, this would be strong advantage especially during the practical use, such as smart phone based system.

Caption: The results of the cross validation.

Conclusion: In the present study, we test a method to build the discrimination algorithm using the magnitude of the sacral acceleration vector to predict the potential personal fall risk during daily walking. With the assessment of the robustness and the accuracy of the proposed method, we found that the accuracy of the prediction was higher than those reported in previous study.

Table:

	Fallers	**Non-Fallers**	**Total**
High Risk	**16**	3	19
Low Risk	4	**17**	21
Total	20 Sensitivity:80%	20 Specificity:85%	40

THE INFLUENCE OF TRANSDUCER ANGLE ON ULTRASOUND MEASUREMENTS OF INTER-RECTUS DISTANCE ON WOMEN POST-PARTUM

Nicole Hills [1,*] Nadia Keshwani [1] Linda McLean [1,2]

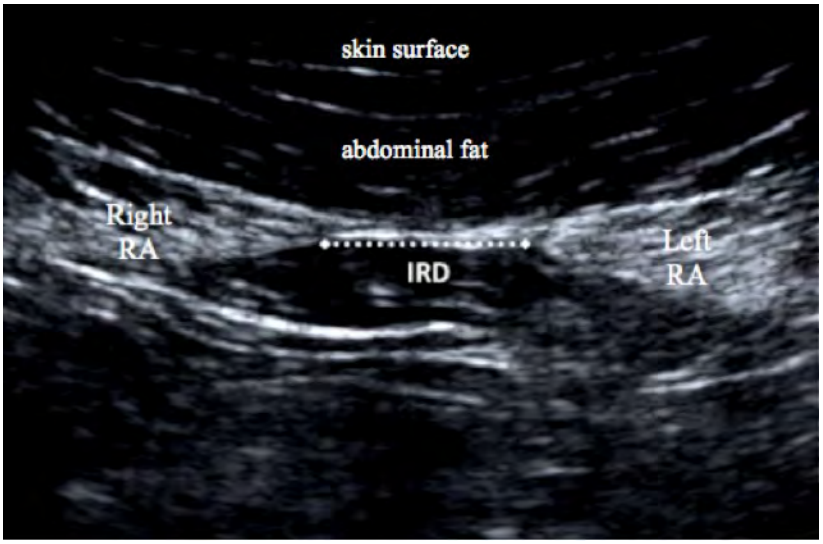
[1]School of Rehabilitation Therapy, Queen's University , Kingston, [2]School of Rehabilitation Sciences, University of Ottawa, Ottawa , Canada

Introduction and Objectives: To compensate for the expansion of the uterus in mid -to late-pregnancy, the rectus abdominus muscles must move laterally; therefore the separation between the two heads of the rectus abdominus muscle, or the inter-rectus distance (IRD), is increased [1]. An increased IRD beyond two centimeters at the umbilicus [2] is referred to as Diastasis Recti (DR), and is estimated to be present in 35 to 68 percent of women post-partum [3]. This separation can persist for many years following a pregnancy [4], and is associated with reduced abdominal strength and endurance [5] and lumbo-pelvic dysfunction [6]. Ultrasound imaging (USI) has been shown to provide valid and reliable measures of IRD at and above the level of the umbilicus when compared to measurements obtained intra-operatively [7]. However, no study has explored the effect of errors in transducer angle during these evaluations. Therefore, the purpose of this study was to determine if transducer head angle relative to the skin and underlying linea alba has an effect on the apparent IRD measured using USI in women who have previously delivered babies.

Methods: Fourteen healthy female volunteers who had previously delivered babies participated. USI images were captured at the superior border of the umbilicus by two different raters beginning with the probe held perpendicular to the anterior abdominal wall (zero degrees) and then at probe angles of 5, 10 and 15 degrees to the perpendicular both the cranially and caudally. IRD was measured from each image offline and was determined as the linear distance between the medial borders of the two heads of the rectus abdominis muscle. The data were not normally distributed, therefore a Friedman's Two-Way Analysis of Variance by Ranks was used to test for systematic differences between the two examiners and among transducer angles. A two-way repeated measures analysis of variance was performed to investigate potential interactions between examiner and angle, since such an analysis cannot be done using non-parametric tests. In this case the residuals were inspected for normality and it was determined that they were normal using the Kolmogorov-Smirnov test. An alpha level of 0.05 was used for all statistical tests.

Results: The Friedman's two-way ANOVA revealed no significant effect of transducer angle ($H=2.00$; $p = 0.920$), but did reveal a significant difference between examiners ($H = 7.37$, $p = 0.007$). The two-way repeated measures ANOVA revealed no significant interaction between transducer angle and examiner ($F = 0.12$, $p = 0.994$) and, consistent with the non-parametric analysis, did not show a significant effect of transducer angle ($F = 1.56$, $p = 0.162$) and did show a significant examiner effect ($F = 62.11$, $p < 0.0005$).

Figure:



Caption: Ultrasound image of the inter-rectus distance (IRD) measurement and rectus abdominis (RA) muscle

Conclusion: The results suggest that error in transducer angle is not a major problem when measuring IRD using transabdominal ultrasound imaging. Although it appears that different examiners may induce a measurement bias. This measurement bias should be investigated further in future studies.

THREE-DIMENSIONAL SCANNING FOR IMPROVED BRA DESIGN

Celeste E. Coltman [1,*] Julie R. Steele [1] Deirdre E. McGhee [1]

[1]Biomechanics Research Laboratory, University of Wollongong, Wollongong, Australia

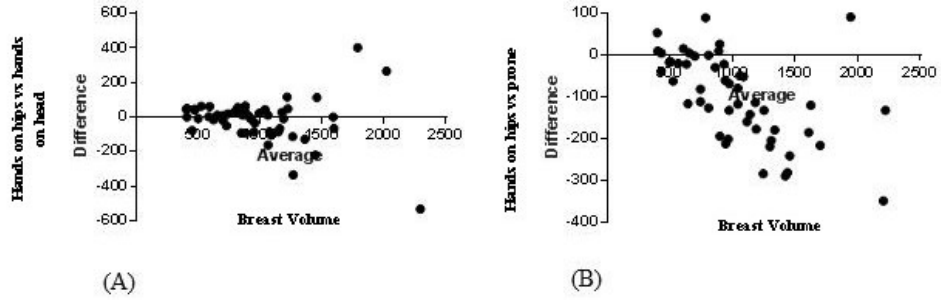
Introduction and Objectives: Three dimensional (3D) scanning has potential to significantly improve bra cup design, sizing and fit by increasing accuracy in measuring parameters such as breast volume [1,2]. Accurate breast volume measurement depends on the ability of a scanner to visualize the entire breast. Inaccuracies have been reported when measuring the volume of large ptotic breasts due to the tendency of the inferior aspect of the breast to contact the abdominal wall when women are scanned in a standing position [1,3]. As this compromises the ability of the scanner to visualize the entire breast, it is likely that breast volume is underestimated. To improve breast visualization during 3D scanning, a prone position, where the breasts hang away from the trunk, has been proposed when scanning women with large ptotic breasts [3]. The objective of this study was to quantify the difference in breast volume determined when scanning women with large ptotic breasts in a standing compared to a prone position. It was hypothesized that scanning large ptotic breasts in a prone position would allow complete visualization of the breasts and, in turn, a greater breast volume, compared to scanning women while standing.

Methods: Participant's were 49 women (mean age 37.1±13.0yr; mean BMI 29.5±5.2kg/m^2; average cup size F, range D-I; average band size 16, range 8-18). Adhesive markers were placed on participants' skin around the outline of each breast. The breasts were scanned using a hand held scanner (Artec™) while participants assumed three positions: i) standing, hands on hips, ii) standing, hands on head [1,2], and iii) lying prone. A 3D model of each breast was created from each scan and breast volume was calculated (mL; Geomagic software, 3D Systems, USA). Breast visualization was rated as "complete" or "incomplete" and the level of breast ptosis was characterized by measuring sternal notch to nipple distance [4] and by grading the ptosis from 0-3 [5]. A repeated measures ANOVA with one within factor (scanning position) was used to determine any significant (p <0.05) differences in breast volume among scanning positions. Bland-Altman plots were used to determine difference in agreement between scanning position for breast volume data. Frequency of "complete" and "incomplete" breast visualizations in the scanning positions was also compared.

Results: Breast volume ranged from 302-2,265mL (mean 1,038±450mL). Ninety per cent of participants were classified as having ptotic breasts (mean stage 2; range stage 1-3) and the sternal notch to nipple distance ranged from 20.8-35.2cm (mean 28.5cm). The prone position allowed complete breast visualization in 100% of participants, compared to only 5% of participants in either standing position. Breast volume measured in the prone position was significantly greater than that measured in either standing position, which were not significantly different to each other (Table 1). Bland-Altman plots showed good agreement in breast volume data measured in the standing positions but poor agreement with a negative bias between breast volume measured in the standing position (hands on hips) and the prone position. The negative bias and consequential underestimation of breast volume in the standing positions increased as breast volume and ptosis increased (Fig 1). The error of underestimation in breast volume of both standing positions compared to the prone position was as high as 473mL at an individual level and 103mL at a group level. This equated to ~3% underestimation of breast

volume for participants at the smaller end of the breast volume (size) spectrum (volumes 400-500mL) and 7-10% for breast volume at the larger end of the spectrum (volumes >500mL).

Figure:



Caption: Bland-Altman plot (bias and limits of agreement ± 1.96*SD) for breast volume measured in the two standing scanning positions (A), and the standing with hands on hips and prone scanning positions (B)

Conclusion: The volume of large ptotic breasts is likely to be underestimated when women are scanned while standing, particularly for women with large breast volumes (>500mL). This error has the potential to negatively affect bra sizing, design and fit and should be accounted for when data are extracted from 3D scans to manufacture and size bras.

Table:

Scanning Position	Right breast volume (mL)	Left breast volume (mL)	
	Mean ± SD (95% CI)	Mean ± SD (95% CI)	
Standing hands on hips	973 ± 409 (857-1,090)	954 ± 419 (853-1,074)	
Standing hands on head	990 ± 432 (867-1,113)	963 ± 382 (854-1,071)	
Lying prone	1,072 ± 470* (939-1,206)	1,057 ± 437* (933-1,181)	

*Indicates statistically significant difference in breast volume compared to the standing positions.

THE IMPACT OF LOADING AND BOUNDARY CONDITIONS IN FINITE ELEMENT ANALYSIS OF MR ELASTOGRAPHY

Lyam Hollis [1,*] Lauren Thomas-Seale [2] Noel Conlisk [1] Neil Roberts [3] Pankaj Pankaj [4] Peter Hoskins [2]

[1]Cardiovascular Sciences, [2]Medical Physics, [3]Clinical Research Imaging Centre, [4]School of Engineering, University of Edinburgh, Edinburgh, United Kingdom

Introduction and Objectives: Magnetic Resonance Elastography (MRE) is an MRI-based technique utilising a phase encoding gradient to track an externally induced shear wave. Local estimates of wavelength are related to the material properties using an inversion algorithm. The technique can be replicated *in silico* using finite element analysis (FEA) allowing a high level of control over input parameters and thus providing a useful pathway for testing and development of MRE post-processing software. Despite this there is limited literature investigating how variation of modelling parameters affects shear modulus measurements and how the process can optimised. This study aimed to investigate the effects that boundary conditions, loading conditions and interaction definitions between two model sections have on measurements made of the shear modulus using the MRE inversion algorithm.

Methods: All simulations were performed using *Abaqus/Explicit.* Boundary and loading conditions were investigated using a 50x50x50mm^3 box (model 1). Material properties were defined as linear elastic with a uniform shear modulus varied between 3-33kPa and a density of 1000kg·m^{-3} throughout. A set of infinite elements was applied to the lower surface to allow waves to propagate to infinity. Boundary conditions were applied to the side surfaces. The conditions investigated here were encastred and symmetric. The load was applied to the upper surface at a frequency of 200Hz over a region that varied in area from 10-40mm^2. A second model (model 2) of geometry 200x200x50mm^3 aimed to investigate how the load size affects measurements. Infinite elements were applied to both the lower and side surfaces and the load was applied over a region on the upper surface varied in area from 10-100mm^3.

To investigate interactions between regions a third model was created (model 3).This was an 80x80x50mm^3 box with a 10mm radius cylinder running through the centre. The background shear modulus was defined as 3kPa whilst the insert shear modulus was varied between 4-9kPa. Symmetric boundary conditions were applied to the lower and side surfaces. A load covering a 45x45mm^2 region was applied to the upper surface at a frequency of 100Hz. The effects of using a tie constraint, merging the two parts and defining a frictional interaction between the insert and the background were investigated. The frictional coefficient was varied from 0.5-1.25.

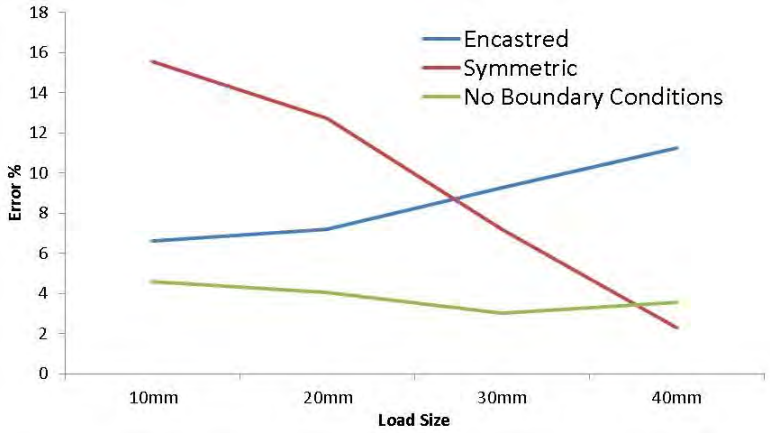
In all instances once the simulation had run displacement data from a two-dimensional slice taken directly through the centre of the model was exported to *Matlab* where it was assessed using the 2-d direct inversion algorithm.

Results: Shear modulus measurements from the inversion algorithm tended to be overestimated for all prescribed shear modulus except 3kPa, which was underestimated, in both the encastred and symmetric boundary conditions. Increasing the prescribed shear modulus increased the size of the error (with encastred boundary conditions and a load size of 40mm^2 the error for the 9kPa is 4% compared with 11% at 33kPa). Whereas for the symmetric boundary conditions the size of the error decreases as the size of the load was increased, the size of the error increases with increasing load size

for encastred boundary conditions. In model 2 the size of the error increased with decreasing load size. Whilst the size of the error is larger at smaller load sizes for the symmetric boundary conditions than it is when no boundary conditions are applied, as the load size increases, the size of the error converges (figure).

Results from the tie constrained interactions and the merged insert and background parts in model 3 were almost identical to one another. In both instances increasing the prescribed value for the shear modulus resulted in an increase in the measured value for the shear modulus, whilst the measured value for the background remained consistent (table). For the frictional interaction measurements of the insert shear modulus were highly variable and often overestimated by as much as 1000%. Visual inspection of the wave images showed minimal propagation in this region.

Figure:



Caption: Load size dependant error in shear modulus measurement for the a shear modulus of 21kPa

Conclusion: Boundary and loading conditions have a clear influence over modelling data from MRE. For technique development it is preferable to reduce these effects to as great an extent as possible whilst maintaining short computational time. For these reasons this work suggests that using symmetric boundaries in concordance with a large loading region is optimal. With respect to interactions between two sections there seems to be little difference between merging parts and defining a tie constraint between them. In contrast defining a frictional interaction does not allow significant wave propagation in the insert and should be avoided.

Table:

	Tie		Merged	
	Background	Insert	Background	Insert
4kPa	3174	4347	3173	4340
5kPa	3171	5548	3170	5541
6kPa	3162	6775	3161	6766
7kPa	3152	8029	3152	8018
8kPa	3147	9277	3146	9264

HOW REPRODUCIBLE IS THE LOCALIZATION OF CRUCIATE AND COLLATERAL LIGAMENTS INSERTION POINTS BY USING MRI?

Silvia Pianigiani [1,*] Pasquale Salandra [2] Walter Pascale [1] Bernardo Inncoenti [3]

[1]IRCCS, Istituto Ortopedico Galeazzi, Milano, [2]Università Politecnica delle Marche, Ancona, Italy, [3]BEAMS Department, Université Libre de Bruxelles, Bruxelles, Belgium

Introduction and Objectives: The cruciate and collateral ligaments are ones of the main players in the stability of the knee joint and, for this reason; they are subjected daily to high mechanical stress. Therefore, they are more prone to injury than other soft tissues. The importance to correctly and univocally identify the ligaments position is mainly related to the clinical practice and, besides, a correct localization of them could be determinant for the surgical practice or in the development of knee specific models for biomechanical analysis. To provide information on the status of these ligaments, the use of MRI images became a common practice. However, in the literature, there are not in depth studies based on this kind of identification using MRI.

For these reasons, the aim of this study is to propose and to validate a new procedure able to localize, in a reproducible and repeatable manner, the insertion points of cruciate and collateral ligaments based on MRI.

Methods: The new proposed procedure requires to identify the insertion areas of the two cruciates and the two collaterals. In particular, two points are needed for the cruciate ligaments (the anterior and the posterior extremities of the insertion area) and one point for the collateral ligaments (considered as the mid-point of the insertion area). These points, according to literature studies, could be also considered appropriate for the correct description of the insertion footprint of these ligaments. A detailed description of the procedure to be used to identify these points has been made together with an illustrative tutorial video.

The validity, the reproducibility and the repeatability of the new technique were determined. In particular, the INTRA and INTER-Class Correlation (ICC) analysis has been performed on 10 legs, by three different operators. The operators were asked to apply the procedure in two ways: only after reading the description, instructional, manual and also after viewing the tutorial video. Moreover, the procedure has been applied on two different qualities images (MRI with magnetization at 0.4T and at 1.5T) to check if the proposed method could be considered image-quality independent. The data describing the insertion point localizations from the different operators have been collected and normalized before comparison.

Results: Results for the obtained ICC indexes, before and after watching the tutorial video, were subdivided for image–quality, for the analyzed ligament and for the location of the insertion attachment (femur or tibia).

For the highest image-quality, both intra and inter ICC indexes results higher than 0.87 with exception for the medial collateral ligament for both femur and tibia and the lateral collateral ligament for the tibia localization. All the indexes increases after the operators viewed the tutorial video (up to 127%). In general, the quality of the image improves the reproducibility in localization up to 80%.

Conclusion: The aim of this study was to develop and prove the efficacy of a new procedure to identify insertions of knee ligaments from MRI images. The obtained results of the intra and inter ICC analysis evidence that the proposed procedure

can be considered highly suitable. In particular, the cruciate ligaments insertions could be defined independently from the quality of the medical image and the operator. More attention should be taken into account for the distal insertion of the medial collateral ligament.

AERODYNAMICS OF ISOLATED SKI JUMPING SKI

Mikko Virmavirta [1,*] Juha Kivekäs [2]

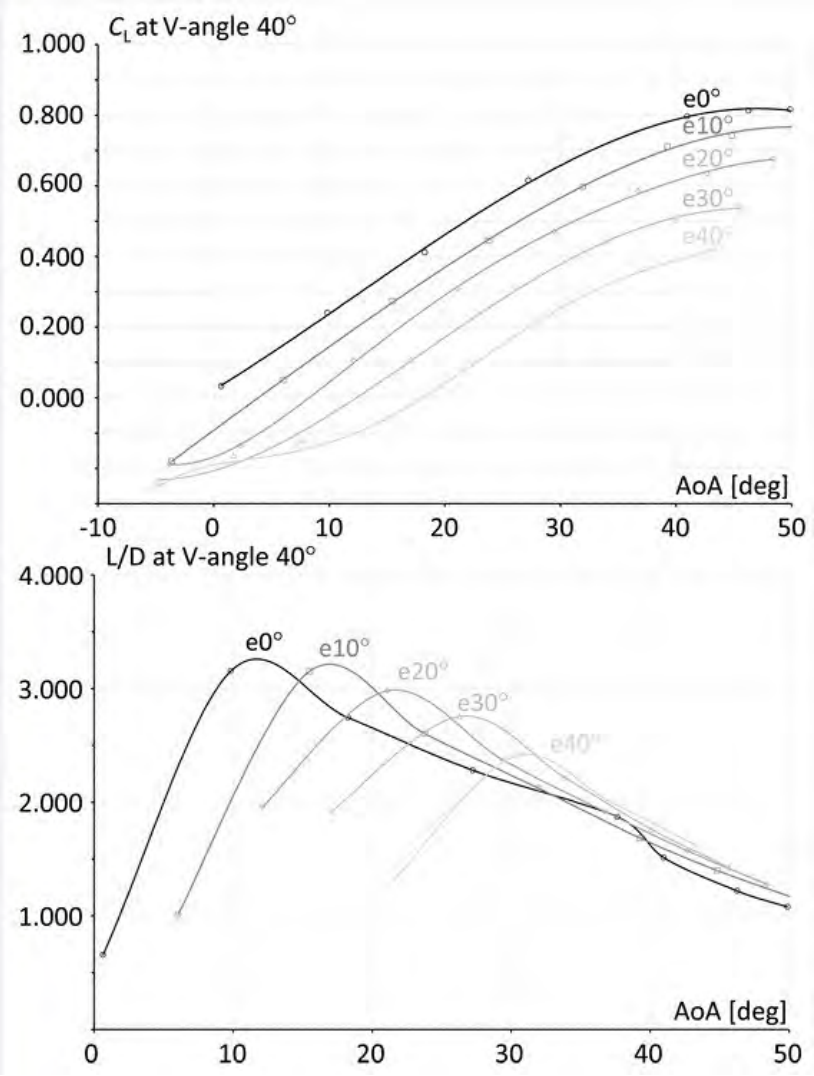
[1]Department of Biology of Physical Activity, University of Jyväskylä, Jyväskylä, [2]Arteform Ltd, Espoo, Finland

Introduction and Objectives: In ski jumping the flight style changed early 1990's when V-style replaced the traditional one in which skis were held parallel and close to each other. As there was an urgent need among coaches for more information about the merit of this new flight style, several studies were conducted during these early years of V-style jumping. First and probably the most important study of V-style was published by Mahnke and Hochmuth [1]. They performed series of wind-tunnel experiments while investigating the benefits of the V-style compared with the traditional style. Cutter [2] conducted the comprehensive tests with a scale model (1:5.5) in the subsonic wind tunnel at the United States Air Force Academy Aeronautics. In this study V-angle of 22.5° with ankle angle of 20° (which was considered the maximum feasible for a ski jumper to turn skis more flat against the direction of motion) provided the best L/D ratio of 1.55. Significant improvement in L/D was found when ankle angle changed from 0 to 20 degrees especially in the lower angle of attack region (AoA). As the skis became more effective, the trim AoA (balanced pitching moment) reduced as well. Since about 2010 ski jumpers have used the curved sticks in the back part of their ski bindings in order to turn skis more flat and improve aerodynamics of the jumper/ski system. However, the true effect of edge angle of skis has not been well studied. Therefore, the purpose of this study was to examine the combined aerodynamic effect of V and edge angles of ski jumping ski in wind tunnel.

Methods: The tests were carried out in the Otaniemi LS-wind tunnel with a cross section of 3.68 m^2. Tests were done with a real 100% size ski jumping ski (Elan 242 cm) with a realistic speed around 28–30 m/s. A single isolated ski was suspended to the 6-component wind tunnel balance. The AoA and yaw-angle were automatically adjustable during the test run. These angles could be run through with a predefined script in the control computer. The edge angle was manually adjusted before each run. The balance recorded all 6 reaction components (forces and moments) and another system recorded wind tunnel speed (total and static pressures). All reaction results were converted to non-dimensional coefficients according to usual practice of aerodynamics. The suspension system was designed to slightly resemble the ankle and leg of the ski jumper but no other interactions from jumper's body were included to this test.

Results: Increasing the yaw-angle of isolated ski (0 > 20°, corresponding V-angle 0 > 40°) increased the aerodynamic lift up to 30° V-angle especially with 0° edge angle but slightly also with 10 and 20° edge angles. Increasing V-angle increased the sensitivity of ski to changes in edge angle i.e. the effect of edge angle is more negative with large V-angles. Figure shows that for maximizing L/D in the region of AoA 30° it may be reasonable to have edge angle on skis. Pitching moments (C_m) were positive but they decreased as the edge angle of ski increased.

Figure:



Caption: The effect of edge angle of ski (e) on the aerodynamic lift (CL) and the lift-to-drag ratio (L/D) measured through the different angles of attack (AoA) at V-angle of 40 degrees. L/D values are given only for positive CL values.

Conclusion: In ski jumping the essential region of the AoA for L/D is 20 - 30° (early flight phase) and for C_L, 30 - 45° (latter part of flight phase). It seems that edge angle decreases the aerodynamic lift (C_L) and lift-to-drag ratio (L/D) regardless of V-angle. Increase in V-angle increases the lift force and lift-to-drag ratio. Turning the skis more flat against the direction of motion may increase the positive pitching moment which may affect the stability of the flight.

MUSCLE AND TENDON ADAPTATION IN ADOLESCENT ATHLETES: A LONGITUDINAL STUDY

Falk Mersmann [1,*] Sebastian Bohm [1] Arno Schroll [1] Heide Boeth [2] Georg Duda [2] Adamantios Arampatzis [1]

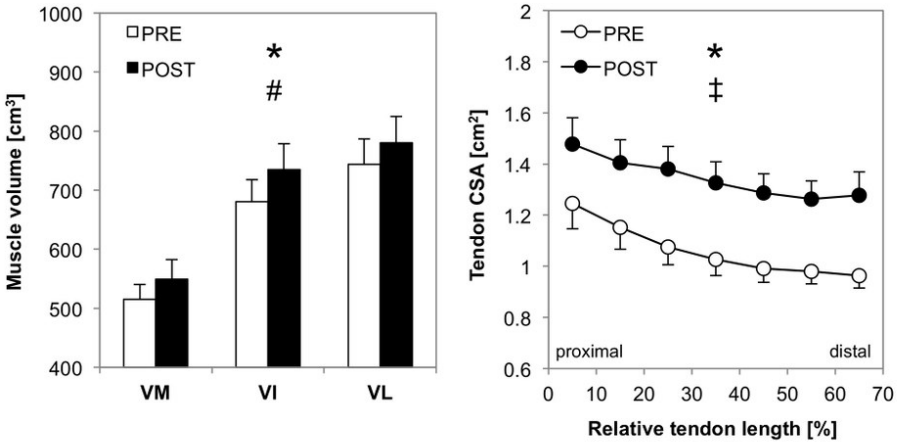
[1]Department of Training and Movement Sciences, Humboldt-Universität zu Berlin, [2]Julius-Wolff Institute, Charité - Universitätsmedizin, Berlin, Germany

Introduction and Objectives: There is evidence that on the transcriptional level of growth factors tendons feature delayed responses to mechanical loading compared to muscle [1] and differences regarding the mechanical stimuli eliciting adaptation [2]. Since adolescence may be regarded as a critical phase of tissue plasticity, as the adaptation process of the muscle-tendon unit is affected by both environmental mechanical stimuli and maturation [3], young growing athletes might be at an increased risk to develop imbalances in the time course of adaptation within the muscle-tendon unit. A recent study on the knee extensor muscle-tendon unit of adolescent volleyball athletes provided evidence for this assumption [4], reporting a marked deficit of tendon cross-sectional area (CSA) in contrast to the already adult-like muscular capacities and morphology. This might pose a risk of tendon overload injuries. The present consecutive longitudinal study investigated the development of the morphological and mechanical properties of muscle and tendon of adolescent volleyball athletes in a time period of two-years. Regarding the morphological properties, we hypothesized a non-uniform development of the muscle and tendon, with greater morphological changes in the tendon, compensating the initial deficit compared to muscle properties.

Methods: Magnetic resonance images of the dominant leg of nine female and nine male trained adolescent elite athletes (Pre: Age 16±1 years, height 188±7 cm, mass 77±10 kg; Post: Age 18±1 years, height 190±8 cm, mass 80±13 kg) were obtained with a time lag of two years. The vastus lateralis (VL), intermedius (VI) and medialis (VM) muscle as well as the patellar tendon (PT) were segmented and analysed with regard to muscle length, muscle volume, maximum anatomical CSA and tendon CSA (in 10 % intervals from 0 to 70 % of the tendon length from proximal to distal). A repeated measures analysis of variance was used to identify effects of the within-subjects factors time (i.e. pre, post) and muscle (i.e. VL, VI, VM) or tendon position (i.e. intervals) respectively. The muscle strength and tendon mechanical and material properties were assessed using a dynamometry and ultrasound approach, including kinematic and electromyographic recordings for the calculation of the knee extension moments, and are currently being analysed.

Results: There was a significant effect of time on muscle anatomical CSA ($p < 0.05$; Pre: VL 29.6±6.5 cm^2, VI 28.3±5.8 cm^2, VM 25.7±5.2 cm^2; Post: VL 30.7±6.3 cm^2, VI 29.5±6.7 cm^2, VM 27.9±6.3 cm^2), muscle volume and tendon CSA ($p < 0.05$; Fig. 1). The increase of tendon CSA (+ 27 %) in the adolescent athletes was substantially greater than the increases in muscle volume and anatomical CSA (+ 6.5 % and 5.6 % respectively). Muscle length on the other hand did not change significantly over time ($p > 0.05$; Pre: VL 38.7±2.5 cm, VI 40.9±1.5 cm, VM 36.9±2.5 cm; Post: VL 39.5±3.6 cm, VI 41.6±2.8 cm, VM 36.5±2.1 cm). Muscle length, anatomical CSA and volume differed significantly between muscles as well as the tendon CSA across the analysed length of the tendon ($p < 0.05$), but there were no significant time by muscle or time by position interactions ($p > 0.05$) on neither muscle nor tendon morphological parameters.

Figure:



Caption: Means and standard errors (error bars) of vastus medialis (VM), intermedius (VI) and lateralis (VL) muscle volume (left) and patellar tendon cross-sectional area (CSA, right) of adolescent volleyball athletes at 16 (PRE) and 18 (POST) years of age. * significant effect of time; # significant effect of muscle; ‡ significant effect of position

Conclusion: In the present study, the relative increases in tendon CSA in the adolescent athletes exceeded the morphological changes of the muscle by factor four. With regard to the results of the preceding study [4], this indicates that during the late adolescence of elite athletes the initial morphological deficits of the patellar tendon are compensated by tendon hypertrophy and that morphologic adaptations of tendons may unfold rather long-term compared to muscle. The identified time delay of the morphological adaptation of the tendon with respect to the muscular development during adolescence may have implications for the aetiology of tendon overuse injuries. Further analyses of the dynamometry/ultrasound data will give insight into the development of the functional, mechanical and material properties of the knee extensor muscle tendon unit of adolescent elite athletes.

DO FOOT ORTHOSES AND FATIGUE MODIFY IMPACT ACCELERATION DURING RUNNING?

Angel Gabriel Lucas Cuevas [1,*] Andres Camacho [2] Raul Llinares [2] Jose Ignacio Priego Quesada [1] Jose Antonio García Perez [1] Pedro Pérez Soriano [1]

[1]GIBD, Department of Physical Education and Sports., University of Valencia, Valencia, [2]Polytechnic University of Valencia, Alcoy, Spain

Introduction and Objectives: Running involves the runner striking the ground around 600 times per kilometre, where the musculoskeletal system has to attenuate the shock wave generated at each foot strike [1,2]. The repetitive and accumulative effect of this stress could overload the musculoskeletal system and lead to overuse injuries. Moreover, the ability of the body to deal with those impacts may deteriorate when the runner gets fatigued. Foot orthoses have been suggested to relieve pain, improve comfort, redistribute plantar pressure, and reduce impact acceleration and loading rate during running [3-5]. However, great controversy exists regarding the effectiveness of prefabricated orthoses in reducing impact loading compared to custom-made orthoses during running. The aim of the study was therefore to analyse the influence of custom-made insoles (CMI) and prefabricated insoles (PI) and the fatigue on impact acceleration parameters during running.

Methods: 40 recreational runners (21 males, 19 females) took part in the study. Two tri-axial accelerometers were attached firmly to the forehead and the anteromedial aspect of the tibia. Kinematic indicators (stride length, stride rate) as well as impact acceleration parameters (head and tibia peak acceleration [maximal amplitude], head and tibia impact magnitude [the difference between the positive and the negative peak], head and tibia loading rate [slope from ground contact to peak acceleration], and shock attenuation [reduction in impact acceleration from the tibia to the head]) were measured at 3.33 m/s before and after a 15-min fatigue run while using three different types of insoles: a) the original insole of the running shoe as control insoles (CI); b) prefabricated insoles (PI); and c) custom-made insoles (CMI).

Results: Effect of insoles

In the pre-fatigue state, a lower tibia and head impact rate was observed with custom-made orthoses compared to prefabricated orthoses (234.61 vs 319.99 G/s; 51.98 vs 58.33 G/s, $p<0.05$, respectively). In the post-fatigue state, the use of prefabricated orthoses led to a higher head impact rate compared to the custom-made and the control orthoses (58.31 vs 51.47 G/s; 58.31 vs 51.34 G/s, $p<0.05$, respectively). Also, the use of prefabricated insoles provoked a higher shock attenuation compared to the control insoles (70.55 vs 66.82 %, $p<0.05$).

Effect of the fatigue

There was a reduction of head impact magnitude when running fatigued with the control orthoses (pre vs post: 2.43 vs 2.31 G, $p<0.05$), as well as an increase in shock attenuation with the prefabricated orthoses (pre vs post: 67.37 vs 70.55 %, $p<0.05$).

Neither the insole condition nor the fatigue state influenced the kinematic parameters.

Conclusion: In the present study, the use of custom-made insoles decreased head and tibial loading rate during running compared to the prefabricated insoles. Since increases in loading rate could result in a stiffened pathway along which the

shock wave has to travel, thereby leading to an increased risk of overuse injury [6], custom-made insoles could be acting as a protective mechanism. Moreover, the fatigue state did not have a strong influence on the acceleration parameters measured, except for a slight increase in shock attenuation with prefabricated insoles when running fatigued. This result is in agreement [7] and is contrary to [8] previous studies. The discrepancy among findings is believed to be due to the different type of fatigue induced.

The use of custom-made insoles were able to reduce both tibial and head loading rate during running. In long-distance races where the accumulative and repetitive loads could be deleterious for the musculoskeletal system, a decrease in impact loading at each foot strike as a result of wearing custom-made insoles could play an important role in the prevention of overuse injury prevention in running.

AS-0519

QUANTIFYING ICE HOCKEY GOALTENDER LEG PAD KINEMATICS AND ITS EFFECT ON PERFORMANCE

Ryan J. Frayne [1,*] Jim Dickey [1]

[1]Kinesiology, University of Western Ontario, London, Canada

Introduction and Objectives: Reebok-CCM Hockey holds a large share of the goalie equipment market in the National Hockey League (NHL) and in other leagues. In part, their success is due to their multiple fit options for different body types and goaltending styles. However, personal protective equipment (PPE) design comes with technical and scientific challenges, such as the effect that it has on the human body. For example, PPE can increase: i) cardiovascular and metabolic cost [1]; ii) an individual's sweat rate leading to potential cognitive difficulties [2]; and iii) musculoskeletal demands [3]. In addition, goaltender PPE factors such as the leg channel width, pad stiffness and strap looseness may affect a goaltender's performance. Therefore, the purpose of this study was to identify how various styles of goalie pad move with respect to the goaltenders body and how this affects a goaltender's performance.

There were three main objectives of this research: 1) describe the motions of the goal pad with respect to the goaltender's leg in different styles of goal pad, 2) Quantify peak vertical butterfly drop velocity in the various goal pad styles, 3) Understand the relationship between strap looseness and butterfly drop velocity in various goal pad conditions.

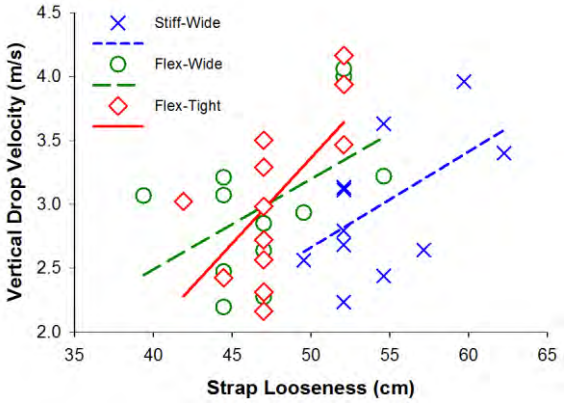
Methods: Following a standard warm up, 12 junior level goaltenders (ranging from the Canadian Hockey League to Junior C) performed five butterfly drop and recoveries in three different goal pad conditions: a flexible pad with a wide leg channel, a flexible pad with a tight leg channel and a stiff pad with a wide leg channel. All movements were performed on a 3.4 m x 2.3 m synthetic ice surface while a 10 camera (Eagle, Motion Analysis Corp, CA, USA) high speed passive motion capture system recorded a custom-made reflective marker set located on the goaltender's pelvis, thigh, leg, left skate and goal pad.

Goal pad motion with respect to the leg, from initiation of butterfly drop to ice contact, and from ice contact to full recovery, were extracted for further analyses. Vertical butterfly drop velocity was calculated using the first derivative with respect to time of the uppermost-lateral marker located on the thigh section of the goal pad. To understand the effect of strap looseness on performance, a series of correlations were performed between the looseness of each strap located on the pad (boot, thigh and top and bottom calf strap) and the peak vertical butterfly drop velocity. Strap looseness was determined as the length of the strap from the most medial aspect of the pad to the subject selected strap hole. Descriptive statistics were calculated to depict the motion of the pad with respect to the leg. A one-way analysis of variance was used to analyze peak vertical drop velocity in the three goal pad conditions. Correlations between pad condition and peak butterfly drop velocity were calculated for all pad conditions.

Results: During the butterfly drop and recovery the Stiff-Wide goal pad had the greatest range of motion with respect to the leg. In particular, the transverse plane had ~26° of lateral rotation (starting at ~2° and ending at ~ 28°), during the butterfly drop. Frontal plane rotations were smaller and showed that goaltenders apply force to the medial knee riser upon initiation of the butterfly drop. The mean peak butterfly drop velocity was 3.0 m/s, 3.05 m/s and 2.98 m/s for the Flex-Wide, Flex-Tight and Stiff-Wide pad conditions respectively; however, these differences were not statistically significant.

The top calf strap was the only strap location that resulted in moderate correlation coefficients for the relationship between strap looseness and butterfly drop velocity: 0.51, 0.65 and 0.55 (Figure) for the Flex-Wide, Flex-Tight and Stiff-Wide respectively. The only significant correlation coefficient was the Flex-Tight goal pad condition P=0.024.

Figure:



Caption: Relationship between peak vertical velocity during the butterfly drop manoeuvre and the looseness of the top calf strap.

Conclusion: The wide leg channel provides less support around the calf compared to the Flex-Tight pad condition. Therefore, the larger ranges of relative motion for the Stiff-Wide goal pad condition were expected. The less constricted Stiff-Wide and Flex-Wide pads resulted in lower correlation coefficients with butterfly drop velocity compared to the Flex-Tight pad condition. Butterfly drop velocity in the Flex-Tight pad is more sensitive to the effect of strap looseness. For example, a tight leg channel combined with a tight strap will restrict the goal pad from freely moving with respect to the goaltender's leg. Ultimately, this will slow pad velocity because the pad will be limited to the motion of the goaltender's leg. In contrast, to increase the butterfly drop velocity and improve performance, goaltenders should use a loose strap set up.

AS-0520

THE EFFECT OF AGE, SEX, AND HIP STRENGTH ON INTER-SEGMENT COORDINATION VARIABILITY IN RUNNERS

JJ Hannigan [1,*]Li-Shan Chou [1]

[1]Department of Human Physiology, University of Oregon, Eugene, United States

Introduction and Objectives: The majority of literature on running biomechanics and injuries has investigated individual joints without considering inter-joint or inter-segment coordination [1]. Continuous relative phase (CRP) has been suggested as a measure to quantify coordination in runners as it is a continuous variable that includes both spatial and temporal information [1]. Additionally, decreased coordinative variability in the lower extremity has been demonstrated in runners with patellofemoral pain (PFPS) [1] and iliotibial band syndrome (ITBS) [2] compared to healthy controls.

Age and sex have also been suggested as factors in developing a running-related injury [3]. However, while age- and sex-related differences in running kinematics have been studied in single joint analyses, the effect of age or sex on coordinative variability in runners has not been investigated. Additionally, while decreased hip strength has been suggested as a factor in developing knee pain [4], the relationship between hip strength and inter-segment coordination is unknown. Therefore, the purpose of this study was to quantify the relationship between age, sex, and hip strength on inter-segment coordination variability in runners.

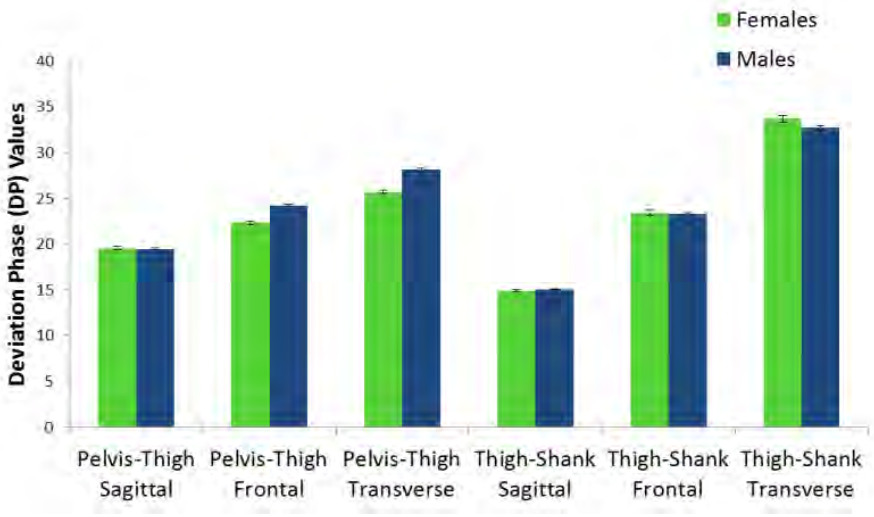
Methods: Reflective markers were placed on 23 female (age: 27.43 ± 10.02 years) and 37 male runners (age: 29.97 ± 10.73 years). Runners ranged in age from 18 to 51 years old. Whole-body kinematic data were collected at 200 Hz using a 10-camera motion capture system (Motion Analysis Corp.) during continuous overground running.

Trunk, pelvis, thigh, and shank segment angles and velocities during stance were calculated using a custom LabView program. These values were interpolated to 100% of stance phase and normalized to values between -1 and 1. Phase portraits were constructed from these normalized segment angles (θ) (x-axis) and velocities (ω) (y-axis) so that phase angles (φ) could be calculated using the formula $\varphi = \tan^{-1}(\omega/\theta)$. Continuous relative phase (CRP) was then calculated by subtracting the phase angle of the distal segment from the proximal segment [5] in the sagittal, frontal, and transverse planes. Variability of the CRP, termed the deviation phase (DP), was quantified for each runner by averaging the standard deviation of the CRP at each data point [6]. Hip abduction, flexion, and external rotation strengths were measured isometrically using a Biodex dynamometer (Biodex Medical Systems). For each test, subjects pushed against the dynamometer with maximal force three times for five seconds. Mean peak torque was calculated for each limb and normalized by body mass for analysis. Sex differences in DP values for trunk-pelvis, pelvis-thigh, and thigh-shank coordination were calculated using independent sample *t*-tests. Pearson correlation coefficients quantified the relationship between DP values and both age and hip strength, $p < .05$ for all statistical tests.

Results: Significant weak to moderate positive correlations were seen between age and DP values (Table 1). These correlations were largest in trunk-pelvis ($r = 0.380$) and pelvis-thigh ($r = 0.299$) frontal plane variability.

No differences in trunk-pelvis, pelvis-thigh, or thigh-shank DP values were seen between sexes (Figure 1). Additionally, no significant correlations were found between hip strength and DP values.

Figure:



Caption: Figure 1. Mean DP values for selected couplings. No sex-differences in DP values were observed, $p > .05$.

Conclusion: Weak to moderate positive correlations were found between age and coordinative variability, as measured by DP values. While this suggests that coordinative variability may increase with age, previous research suggests that increased variability may be injury-protective [1,2].

While no significant differences were seen in coordinative variability between males and females, it is important to emphasize that this study only examined CRP variability, not the CRP pattern itself. Also, this study did not analyze coordinative variability of adjacent segments between different planes of motion (ex: transverse plane pelvic motion with frontal plane thigh motion). Further investigation on sex differences in inter-segment coordination appears warranted based on sex differences already cited in single-joint analyses. The relationship between hip strength and knee pain also justifies further research into the role of strength in inter-segment coordination.

Table: Table 1. Pearson correlation coefficients between age and DP values.

	Trunk-Pelvis DP	Pelvis-Thigh DP	Thigh-Shank DP
Sagittal Plane	0.226*	0.269*	0.268*
Frontal Plane	0.380*	0.299*	0.238*
Transverse Plane	0.181*	0.220*	0.125

Caption: *Indicates a significant correlation, $p < .05$.

GROUND REACTION FORCES IN ELITE UPPER-LIMB AMPUTEE RUNNING

Stefan Litzenberger [1,*] Franziska Mally [1] Steffen Willwacher [2] Bjoern Braunstein [2 3] Anton Sabo [1] Gert-Peter Brueggemann [2]

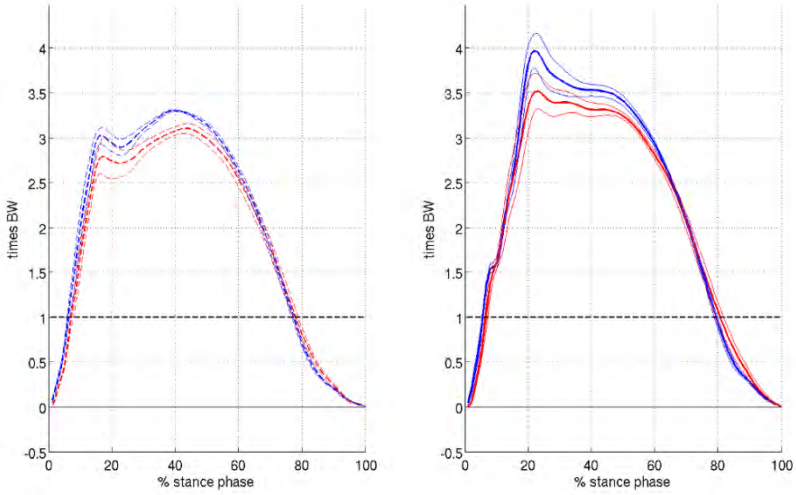
[1]Department for Sports Engineering & Biomechanics, University of Applied Sciences Technikum Wien, Vienna, Austria, [2]Institute of Biomechanics and Orthopaedics, German Sport University, [3]German Research Centre of Elite Sport, Cologne, Germany

Introduction and Objectives: Whereas able-bodied athletes can easily be compared to each other without any further regulations, disabled athletes have to be ranked regarding their impairment to avoid inequality within a group. The International Paralympic Committee (IPC) mostly bases its classification process on experience and scientific work. For upper-limb amputees, however, there has been a recent change in classification, which was partly based on scientific work conducted almost three decades ago with methods no longer considered state-of-the-art and done with able-bodied athletes at running speeds significantly lower than those of disabled elite athletes [1,2,3,4,5,6]. From these studies it was concluded that no difference in net vertical momentum between impaired and sound side would be found because during running both arms act synchronously in their upward- and downward movement, respectively, which ultimately would lead to no differences in ground reaction force (GRF) between both feet. Until now no research has been done with upper-limb amputees at elite-level running speeds. We hypothesized that contrary to findings of studies so far, differences in the GRF of an upper-limb amputee athlete can be observed.

Methods: For this research an elite paralympic 400m and 800m runner (PB 400m: 0:48,45, PB 800m: 1:50,92) with a below elbow amputation on the right upper-limb was tested. GRFs were collected with four floor level mounted Kistler force plates aligned consecutively along the running track sampling at 1000 Hz. The subject was advised to do runs at two running speeds (8m/s and 5.4m/s) until four valid ground contacts were recorded for each foot and speed. Stance phase (SP) duration in ms was obtained and data for each ground contact were time normalized to 100% of SP duration and amplitude-normalized to times body weight (BW). Mean and standard deviation as well as maxima and occurrence of the maxima in the SP of vertical, antero-posterior and medio-lateral GRF were calculated and statistically evaluated.

Results: Stance phase duration between left and right foot did not differ significantly for both running speeds (5.4m/s: left: 174 ± 3 ms, right: 181 ± 8 ms ; 8m/s: left: 127 ± 2 ms, right: 125 ± 2 ms). Minor differences in the mean GRF for antero-posterior but not for medio-lateral were found for both running speeds. Maxima of vertical GRF, however, revealed statistically highly significant (alpha = 95%) differences between left and right foot for 5.4 m/s (l: 3.3 ± 0.01 BW, r: 3.1 ± 0.02 BW) and significant differences for 8 m/s (l: 3.97 ± 0.08 BW, r: 3.52 ± 0.05 BW). Furthermore the characteristics of the vertical GRF changed between the two running speeds (Fig.). Whereas the maximum vertical GRF at 5.4 m/s could be observed at approx. 40% of SP it was located at approx. 22% for a running speed of 8 m/s.

Figure:



Caption: Mean vertical GRF (GRF_z) in times BW plotted over % of stance phase, thick: mean, thin: ± SD, left: 5.4m/s, right: 8m/s, blue: left foot, red: right foot

Conclusion: The data obtained in this research shows that there are significant differences in vertical GRF between the sound and impaired side of an upper-limb amputee athlete. Hence the hypothesis investigated can be verified. The data confirms that the difference is significant and increases with increasing running speed (difference at: 5.4 m/s: 6%, 8 m/s: 11%). This leads to the assumption that the vertical momentum of both arms is significantly different depending on whether the impaired or sound arm is in backward or forward motion and whether intial contact (or toe off) is made with the ipsilateral or contralateral leg, respectively.

The outcome of the presented research strongly supports the hypothesis that - especially for middle distance running - the contribution of the arms is an important factor. It is furthermore an addition and an update with state-of-the-art measurement systems to the ground-breaking work of [1] and [2].

However, it has to be pointed out that the present study was only performed with one amputee athlete and hence results cannot be generalized. A comparison of a higher number of amputee athletes is rather difficult to perform given the relatively small number of athletes competing on world-class level with this special impairment.

Nonetheless it could be shown that upper-limb amputation has a significant impact on the running mechanics which is not considered in the IPC's classificaton process.

MECHANICAL CONSTRAINTS OF FINGER INDEPENDENCE: LINKING TENDON DISPLACEMENT WITH JOINT MOVEMENT

Nathalie van Beek [1,*] Josien C. van den Noort [2] Peter Veltink [2] Ruud Selles [3] Dirk-Jan Veeger [1 4] Huub Maas [1] Dick Stegeman [5]

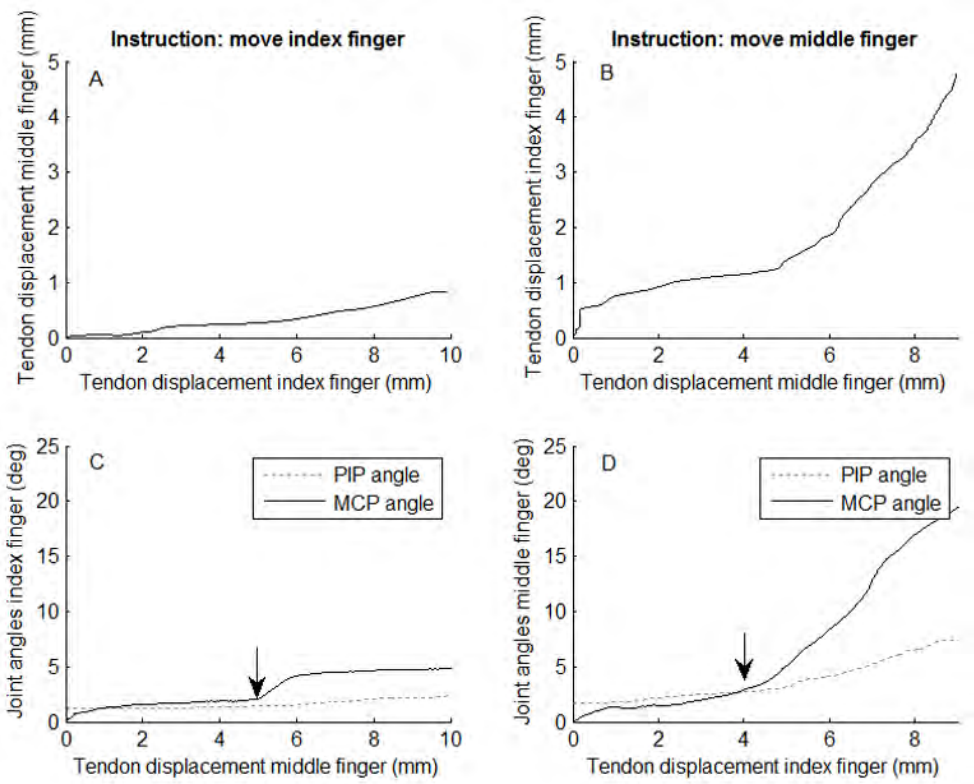
[1]MOVE Research Institute Amsterdam, Faculty of Human Movement Sciences, VU University Amsterdam, Amsterdam, [2]Biomedical Signals and Systems, MIRA Institute, University of Twente, Enschede, [3]Department of Plastic Surgery and Department of Rehabilitation Medicine, Erasmus MC University Medical Center, Rotterdam, [4]Department of BioMechanical Engineering, Delft University of Technology, Delft, [5]Department of Neurology/Clinical. Neurophysiology, Radboud University Medical Centre, Nijmegen, Netherlands

Introduction and Objectives: The human hand has evolved to be able to perform skillful actions which enables us to manipulate objects. Despite this dexterity, it has been shown that we are not fully capable of independent control of individual fingers of the hand. Both peripheral mechanical factors and central neural factors can be held responsible for this limitation of independent finger control[1]. The peripheral factors include tendinous connections between the finger tendons [2] and myofascial linkages between neighboring extrinsic muscles [3]. Even though the mechanical and neural constraints are well-described, it is still unclear how much each constraint influences finger independence. The aim of this study was to quantitatively determine the effects of the mechanical connections on finger interdependence.

Methods: Subjects (n=3,age 24-27yr, another 7 subjects are being analysed) were instructed to flex their index and middle finger individually until the tip of the finger touched the palm of the hand. Non-instructed fingers were not restrained to allow involuntary finger movement. Displacement of the flexor digitorum superficialis tendon of the index and middle fingers was measured with B-mode ultrasound at wrist level. Kinematics of the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints was measured using an instrumented glove (PowerGlove, University Twente). For both instructed and non-instructed fingers, range of joint flexion of the MCP and PIP joints and tendon displacement were calculated.

Results: Ranges of movement of MCP and PIP joints were similar for both instructed fingers (Table1). As expected, joint movements in the non-instructed fingers were observed. A lower PIP movement was found in the non-instructed middle finger compared to that of the non-instructed index finger, suggesting a higher level of independence for the index finger (Table 1). Finger interdependence was confirmed also at the tendon level, as tendon displacements of the non-instructed fingers were observed (Table1 & Fig.1A/B). To assess if mechanical factors contribute to finger independence, joint movements of the non-instructed fingers were plotted as a function of tendon displacement of the instructed finger (Fig.1C/D). Across all subjects a similar pattern was found: little to no joint change during the first phase of instructed tendon displacement followed by a steep increase of joint angle (see arrows on Fig.1C/D). Similar results were found for tendon displacements of the non-instructed fingers.

Figure:



Caption: Fig.1: Tendon displacement of the non-instructed finger plotted as a function of tendon displacement of the instructed finger (A/B). Joint angle (MCP and PIP) of the non-instructed finger plotted as a function of tendon displacement of the instructed finger (C/D).Typical example (n=1), arrows = moment of joint angle increase.

Conclusion: Similar to previous studies [e.g. 4], the index finger showed a higher level of independency than the middle finger. A novel finding is that finger interdependency observed at joint level can also be observed at tendon level. When the joint angle of the non-instructed figure is plotted against the tendon displacement of the instructed finger the results first show a phase where there is hardly any joint movement. Then, a deflection of the curve was observed where the joint angle begins to increase. This pattern may be explained by the tendon interconnections first being slack but then pulled taut after a certain displacement of the instructed finger tendon. As such a pattern is not expected from neural factors, this suggests that mechanical connections between fingers play an important role. A late phase of increased displacement also suggests that mechanical connections only become of significance during larger finger movements.

Results as presented allow quantification of the mechanical connections between the index and middle finger, which may influence finger independence. For a complete picture of the factors contributing to finger interdependence , also neural factors will be addressed in future studies. LEG FLEXION STRENGTH RECOVERS WITH MECHANICAL PROPERTIES OF THE SEMITENDINOSUS TENDON AFTER RESECTION FOR ACL RECONSTRUCTION

Stephen M. Suydam [1,*] Daniel Cortes [2] Lynn Snyder-Mackler [3] Thomas Buchanan [4]

[1]Biomechanics, [2]Biomedical Engineering, [3]Physical Therapy, [4]Mechanical Engineering, University of Delaware, Newark, United States

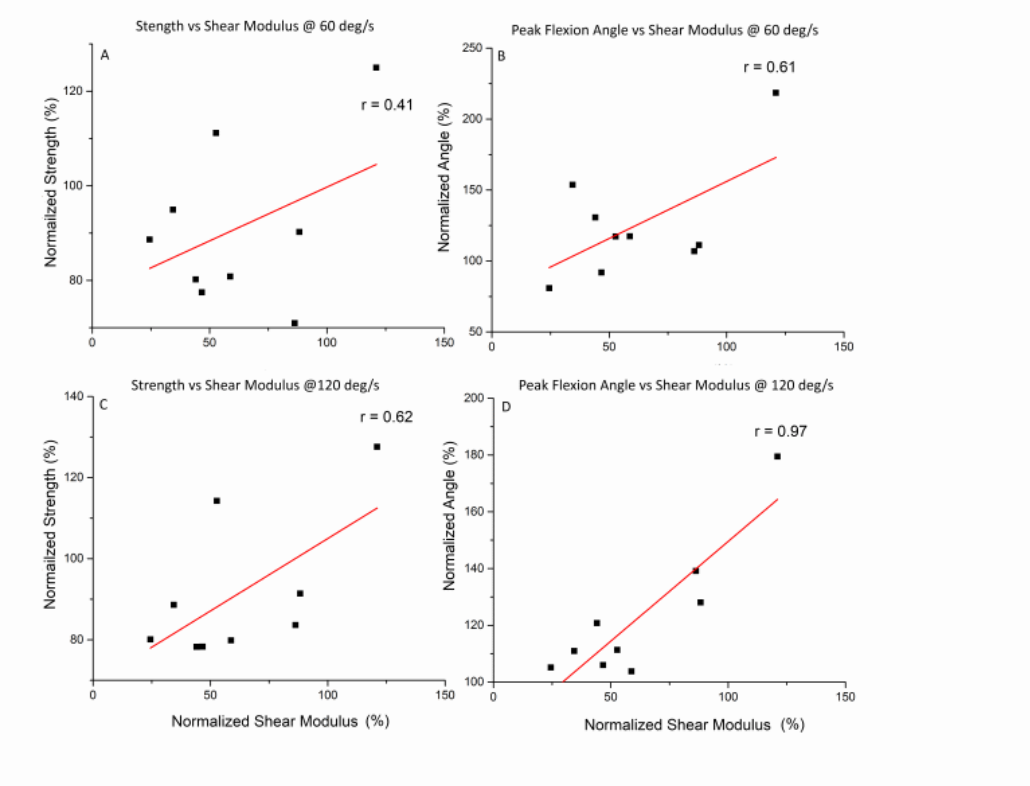
Introduction and Objectives: An ACL rupture is a life altering injury and more than 175,000 ACL reconstructions occur in the United States each year. Following reconstruction only 64% of patients returned to their pre-operative competitive level and 10% of patients sustain a re-rupture[1]. The semitendinosus (ST) autograft is a common, effective repair technique, but the resection of the ST tendon results in long term knee flexion strength deficits. The recovery of these hamstring strength deficits may aid in the reduction of re-injury rates and return patients to pre-injury function. Studies have shown more than 80% of patients regenerate their ST tendon and therefore the potential exists to have ST muscle function restored. While the appearance of tendon has been imaged with MRI and ultrasound, there has been no correlation between the presence of regrowth in these images and strength recovery[2]. The return of tendon elastic properties facilitates its ability to pass force from the muscle to the joint. Continuous shear wave elastography (cSWE) has been used to determine the mechanical properties in terms of shear elastic modulus of tendon *in vivo*[3]. This study aims to show that strength recovery is related to the restoration of ST tendon elastic properties using cSWE.

Methods: Ten subjects who had ST tendon resections as part of an ACL reconstruction were evaluated between 6-24 months post-op. Shear elastic modulus was determined using cSWE. Six ultrasound RF data sets were collected with an external actuator generating a sinusoidal shear wave at 6 frequencies (323, 340, 358, 379, 403, 430) and a high frame rate ultrasound. Shear wave speeds through the tendon were calculated through post processing with signal decomposition software. Shear elastic modulus was calculated through the optimization of a Voigt model using the frequencies and shear wave speeds from each of the 6 data sets as inputs. The peak torque was evaluated during an isokinetic contractions at 60 and 120°/s. The flexion angle at which peak torque was generated was used to assess remaining deep knee flexion weakness. Pearson correlations between shear modulus and strength were determined with a covariate adjustment for time. The correlation is between the percent change (involved/uninvolvedx100) of the shear modulus and the strength variables.

Results: Nine subjects of ten regrew their ST tendons. The regrown tendons had an average recovery of 59% of their shear elasticity compared to the uninvolved side. The shear modulus of the tendon was positively correlated to both the recovery of the strength and knee flexion angle at which peak torque is generated (Figure 1). The strength during the faster contraction (120°/s versus 60°/s) was more strongly correlated with the shear modulus than the slower contraction (r=0.62 vs r=0.41). The recovery of strength correlation with elastic properties demonstrates the potential to recover to pre-injury strength after ACL reconstruction. The hamstring acts to prevent tibial translation, one of the primary mechanisms of the ACL, which is bolstered by strength recovery. The recovery of the peak flexion strength at higher speeds is beneficial since the pivoting maneuvers, which typically result in non-contact ACL tears, are at these increased

speeds. The recovery of deep knee flexion strength with shear modulus may help prevent re-rupture and return pre-injury competitive levels. An increase in compressive loads at decreased flexion angle have been linked to ACL rupture. The peak torque joint angle moving from the shallow knee angles into a greater degree of deep knee flexion leads to a relatively decreased compressive load in the high risk knee flexion arrangement.

Figure:



Caption: The correlations between the bilateral strength difference at 60 deg/s (A) and 120 deg/s (C) and the difference in flexion angle at which peak torque is produced for 60 deg/s (B) and 120 deg/s (D). Note the strong positive correlation for each of the graphs and the very strong correlation for flexion angle at 120 deg/s.

Conclusion: The recovery of the ST tendon is strongly correlated to the recovery of the leg flexion strength and the angle at which peak knee flexion torque is generated. The restoration of the ST tendon mechanical properties may aid in protecting the reconstructed ACL and the patients' ability to return to their previous level of sport. The knowledge that, after an ACL reconstruction involving the ST tendon, hamstring strength recovers with the mechanical properties of the tendon could influence post-operative treatment and surgical technique choice.

CAN DRAWING IN AND ABDOMINAL CRUNCH EXERCISES NARROW THE INTER-RECTUS DISTANCE?

Patricia Mota [1 2,*] Augusto G. Pascoal [1] Ana Isabel Carita [3] Kari Bø [4]

[1]CIPER - LBMF, Univ Lisboa, Fac Motricidade Humana, [2]Physiotherapy, Universidade Atlantica, [3]BIOLAD, Univ Lisboa, Fac Motricidade Humana, Lisboa, Portugal, [4]Sports Medicine, Norwegian School of Sports Sciences, Oslo, Norway

Introduction and Objectives: Gestational diastasis recti abdominis (DRA) can be defined as the separation of both recti abdominis muscles (RA) starting in the last trimester of pregnancy and extends up to 8-16 weeks postpartum [1, 2]. DRA is quantified by the inter-recti distance (IRD), i.e. the horizontal distance between the internal borders of both RA. To date there is scant knowledge about the effect of the abdominal strengthening exercises on DRA particularly, about which exercises are most effective in IRD reduction. Abdominal crunch exercise has been considered a risk exercise for development DRA[3]. Lately some core training theories recommend the use of the drawing-in exercise both in general population and during pregnancy and after childbirth [4]. It has been proposed that during the drawing-in exercise the activation and training of transversus abdominis will draw the bellies of both RA together, improving the linea alba integrity and the increment of fascial tension which will allow efficient load transference and torque production [4]. However, no evidence was found in literature that supports this statement. Thus the aim of this study was to evaluate the acute effect of the abdominal isometric contraction on DRA performed in two abdominal strengthening exercises, the drawing-in and abdominal crunch exercises.

Methods: This longitudinal study following first time pregnant healthy women population (N=84) in predefined points of time from gestational week 35 till 6 months postpartum. Ultrasound images were recorded on 3 different locations on the linea alba around the umbilicus (2 cm below; 2 and 5 cm above) and on 3 conditions of the abdominal muscles contraction: at rest and in an isometric end-position of the drawing-in and the abdominal crunch exercise. The IRD was measured offline at gestational week 35 and at 3 postpartum time points: 6-8, 12-14 and 24-26 weeks postpartum. A paired sample t-test ($p<0.05$) with Bonferroni adjustment for multiple tests was used to assess the differences between the IRD on 3 condition of the abdominal muscles contraction and on the 3 locations on the linea alba, at 4 measurement time points.

Results: The results showed that during pregnancy the abdominal crunch and the drawing-in exercises induce an acute narrow effect on the IRD. In all time points of postpartum, the drawing-in exercise induced an acute widening effect on IRD when comparing with IRD in resting position. The differences were significant for all locations except for 2 cm above the umbilicus at 6-8 and 24-26 weeks postpartum, and for 5cm above the umbilicus at 6-8 and 24-26 weeks postpartum. During the abdominal crunch the IRD was reduced, and the differences were statistically significant during pregnancy and postpartum on all probe location tested except for 2 cm below the umbilicus at 24-26 weeks postpartum.

The results showed that partial recovery of DRA occurs after childbirth. For every location tested, the IRD values were narrower at 6 months compared to 6-8 weeks postpartum, which is in accordance with previous studies [1, 2].

Strengths of the study are the number of subjects followed, measurement at three abdominal locations, and the use of a reliable method to assess IRD and blinding of the investigator. We measured IRD during two commonly used exercises in pregnant and postpartum women.

A limitation of the study is the lack of pre-pregnancy assessment of the condition. However, measurement of nulliparous women planning to become pregnant is a challenge, and there are few studies in this group of women worldwide.

In our study the only structural parameter measured was the IRD, which may not reflect all of the structural changes that may take place in the fascial and muscular structures of the abdominal wall. The measurements of other structures (muscle length, thickness) could be of value in future research.

Conclusion: During the execution of the exercises, the drawing in exercise widened the IRD in postpartum women and the abdominal crunch narrowed the IRD both during pregnancy and in the postpartum period.

This study was funded by Fundação para a Ciência e a Tecnologia (FCT) under the project PEst-OE/SAU/UI447/2014.

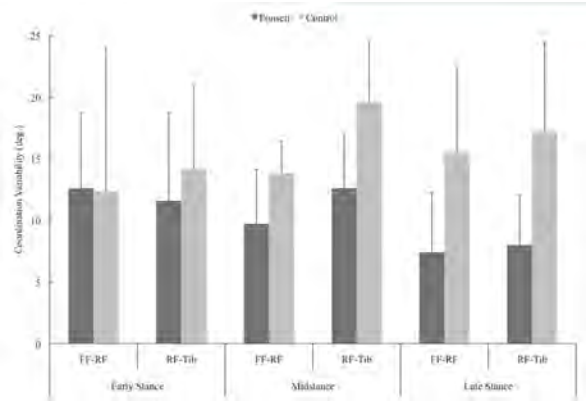
MULTI-SEGMENT FOOT COORDINATION VARIABILITY OF THE PONSETI TREATED CLUBFOOT

Amy Whited [1,*] George Gorton [2] David Drvaric [3] Katherine Boyer [1] Joseph Hamill [1]

[1]Kinesiology, University of Massachusetts Amherst, Amherst, [2]Motion Analysis Laboratory, [3]Shriners Hospitals for Children, Springfield , United States

Introduction and Objectives: Compared with typically developing feet (CON), long-term follow up of Ponseti treated clubfeet (PCF) report an increased prevalence of osteoarthritis (OA), limited rearfoot inversion/eversion, ankle dorsi/plantarflexion motion and reduced ankle power during late stance [1,2,3]. The underlying mechanisms that contribute to differences in biomechanics and function between PCF and CON require further characterization specifically after a prolonged period post-treatment. Coordination variability (CVar) outcomes provide an assessment of foot and lower extremity function by expressing the range of available combinations of segment coordination used to achieve an endpoint foot posture during walking. The ability to use a larger number of segment coordination combinations (greater CVar) is optimal for adaptable and pain-free movement [4,5]. A lack of CVar is associated with reduced function and adaptability and may be a strong indicator of the presence of pathology [4,5]. Differences in CVar between PCF and CON may provide information regarding the level of residual functional pathology in PCF. The objective of this study was to examine differences in forefoot-rearfoot and rearfoot-tibia CVar during walking in children with PCF compared to CON.
Methods: Eight children previously treated for a clubfoot with the Ponseti casting technique and six typically developing children were included in this analysis. All participants signed the institutional review board-approved consent form. Participants walked overground at a preferred speed while three-dimensional kinematic and kinetic data were recorded. A modified vector coding technique was used to determine CVar throughout stance for forefoot-rearfoot inversion/eversion (FF-RF) and rearfoot inversion/eversion-tibia internal/external rotation (RF-Tib) couples. CVar was averaged over early stance (ES,0-33%), midstance (MS,34-66%) and late stance (LS,67-100%) for each group. Data were analyzed with independent samples t-tests to determine if CVar was significantly different between groups. Effect Size was calculated to determine the clinically relevant differences in CVar between groups throughout stance [6]. A large effect was considered to be >0.8, a moderate effect was >0.5 and a small effect was <0.3.
Results: During ES, FF-RF and RF-Tib CVar was not significantly different between groups. There was reduced FF-RF and RF-Tib CVar for the PCF group during MS and LS (Figure 1). There was a large group effect on FF-RF CVar during MS and LS; however, differences were only statistically significant during LS (Table 1). There was a large group effect on RF-Tib CVar with statistically significant differences between groups during MS and LS (Table 1).

Figure:



Caption: Figure 1. CVar (group mean ± SD) for FF-RF and RF-Tib coordination couples. *Significant difference between PCF and CON ($p<0.05$).

Conclusion: PCF demonstrated reduced CVar throughout MS and LS. This finding indicates the presence of residual clubfoot pathology in PCF and suggests a reduced functional capacity to permit adaptive foot postures during walking. Previously reported results of limited rearfoot inversion/eversion, ankle dorsi/plantarflexion motion, reduced ankle power during LS and increased OA prevalence supports the results. Limited range of motion due to joint stiffness or abnormal foot structure may inhibit the range of RF-Tib segment coordination combinations available during MS and LS and may be indicative of the lack of ankle power generation. With reduced CVar, coupling combinations are constrained and may predisposed PCF to repeated stress in the same general area resulting in degenerative changes to the soft tissue over time.

Table:

	FF-RF			**RF-Tib**		
	CON	PCF	Effect Size	CON	PCF	Effect Size
ES	12.33±11.68	12.64±6.07	**0.03**	14.22±6.67	11.59±7.07	**0.38**
MS	13.81±2.61	9.69±4.39	**1.18**	19.63±4.92	12.58±4.41*	**1.51**
LS	15.51±6.90	7.44±4.81*	**1.38**	17.21±7.19	7.97±4.03*	**1.65**

SHEAR WAVE SPEED MEASUREMENTS IN PASSIVE AND ACTIVE STROKE-IMPAIRED BICEPS BRACHII

Sabrina Lee [1 2,*] Sam Speer [2] William Rymer [2]

[1]Physical Therapy and Human Movement Sciences, Northwestern University, [2]Rehabilitation Institute of Chicago, Chicago, United States

Introduction and Objectives: Stroke survivors routinely experience long-term motor and sensory impairments. In parallel with neurological changes, material properties of muscles in the impaired limbs may also change progressively, such as muscle stiffness [1]. However, these stiffness measures are estimates derived from individual joints stiffness or whole muscle groups. Using shear wave ultrasound elastography, shear wave speed (SWS), which is related to the shear modulus, can be estimated in individual muscles[2]. Accordingly, the purpose of this study was to compare material properties, by measuring SWS in spastic paretic muscles at rest and at different activation levels with contralateral muscles in stroke survivors and in age-matched controls subjects.

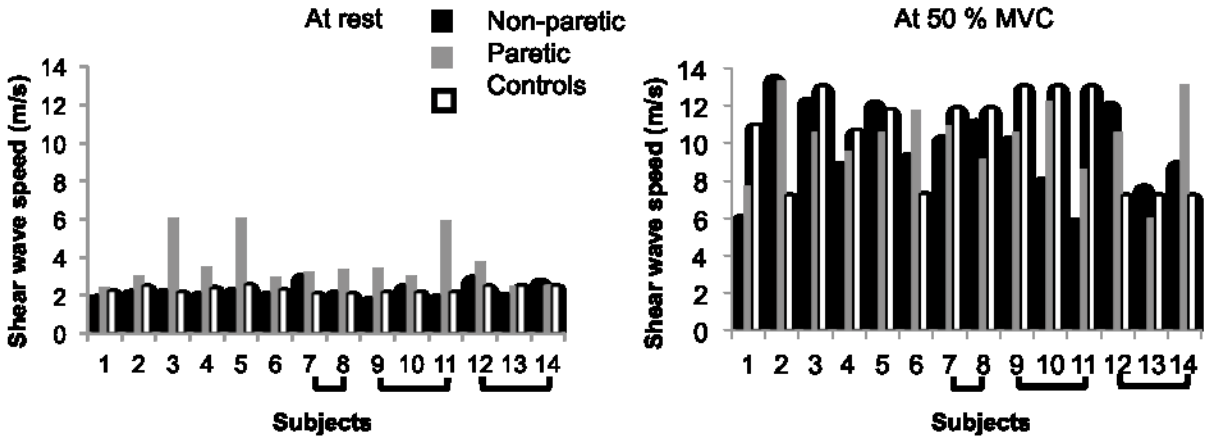
Methods: Fourteen stroke survivors participated in this study (age: 58.9±7.4yrs; height: 1.68±0.10m; body mass: 85.5±18.2kg; time post-stroke: 11.4±11.6yrs.; Fugl-Meyer: 4-48, 19±15). We tested nine subjects who were gender and age-matched to the stroke survivors (age: 57.9±7.1yrs; height: 1.64±0.10m; mass: 74.4±11.2kg;).

Subjects were seated upright with their upper arm resting on a plastic support, the forearm secured in a fiberglass cast, and the wrist and forearm held in a neutral position in a ring-mount interface mounted to the table. The shoulder was positioned so that the humerus was abducted 45 degrees and the elbow positioned at 90 degrees.Subjects performed a series of isometric elbow flexion contractions at different activation levels (0, 10, 25, 50, 75, 100% maximum voluntary contraction (MVC)) while force and torque were measured at the wrist (load cell). Muscle activity (electromyography), and ultrasound images (Aixplorer, SuperSonic Imagine) of the biceps brachii were captured. Mean SW velocity was calculated from a 12mm by 12mm region of the ultrasound images.

We calculated the slope and r^2 of the linear fit between SWS and % MVC until 50%MVC as the SWS at 75% and 100%MVC reached the maximum the ultrasound system is capable of measuring (16m/s). An Analysis of Variance was used to compare the SWV at the different % MVC levels, slope, and r^2 non-paretic, paretic, and gender, age-matched controls.

Results: Our main findings show that at rest, the SWS was on average 40% greater in the paretic muscle compared to either the contralateral non-paretic muscle or the muscle of control subjects (Fig.1, p=0.003, p=0.002), and no significant difference in SWS between the non-paretic muscle and control muscle. In active muscle (10, 25, 50%), there was no significant difference in SWS between the non-paretic, paretic, and control muscles (Fig.1). The slope of SWS versus %MVC (up to 50%MVC) and R^2 values was 10% and 15% greater, respectively, in the non-paretic muscles compared to that of the paretic muscle, but was not significant (Table 1, p = 0.06).

Figure:



Caption: Figure 1. Mean shear wave speed at rest and at 50%MVC (force) for the non-paretic (black) and paretic (gray) muscle of individuals who have had a stroke and muscle of gender, age-matched controls (white). Brackets indicate the same control subject.

Conclusion: We demonstrate that shear wave speed is faster in the biceps brachii of the paretic limb than in the contralateral non-paretic limb of stroke survivors when the muscle is at rest. This suggests that paretic muscles have potentially altered muscle material properties, specifically stiffness in both passive and active muscles, but primarily in passive states. This can be a result of increased collagen in the perimysium and abnormal accumulation of the extracellular matrix[3].

Interestingly, this difference in SWS between three muscle groups disappears once the muscle was active. One source of active stiffness is short-range stiffness. Thus, it is possible that the non-contractile elements contributes minimally to stiffness in active muscle and the active short-range stiffness is not altered in stroke-impaired muscle.

These findings allow us to have a first glimpse into active and passive stiffness of stroke muscle. Quantitative measurements of muscle stiffness in individual muscles, is important for more accurately assess muscle function and for understanding the fundamental mechanisms of impairment that occur after a stroke, for aiding clinical decisions, and for guiding rehabilitation interventions.

Table:

Muscle	SW velocity at rest	SWV at 50%MVC	Slope (ms^{-1}%MVC^{-1})	R^2
Paretic	3.65(1.31)	10.33(2.03)	0.12(0.04)	0.73(0.12)
Non-paretic	2.30(0.38)	9.79 (2.36)	0.15(0.05)	0.81(0.12)
Control	2.29(0.18)	10.42(2.28)	0.13(0.05)	0.89(0.16)

Caption: Table 1. Mean shear wave (SW) speed at rest and %MVC, slope of SW vel and %MVC, and R2. Mean (SD).

LOADING OF HIP MEASURED BY HIP CONTACT FORCES AT DIFFERENT SPEEDS OF WALKING AND RUNNING.

Georgios Giarmatzis [1,*] Ilse Jonkers [2] Mariska Wesseling [2] Sam Van Rossom [2] Sabine Verschueren [1]

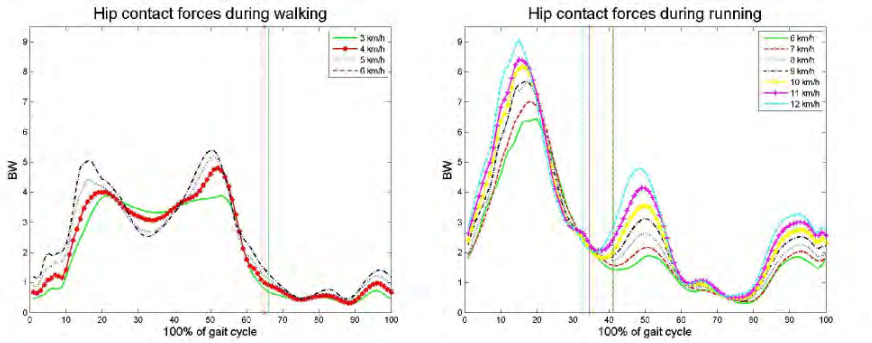
[1]Musculoskeletal Rehabilitation, [2]Human movement biomechanics, KU Leuven, Leuven, Belgium

Introduction and Objectives: Exercise plays a pivotal role in maximizing peak bone mass in adulthood and maintaining it with aging, by imposing mechanical loading on the bone that can trigger bone mineralisation and growth [1]. Hip fractures are the most devastating and linked to highest morbidity rates when compared to the rest of the osteoporotic related fractures together [2]. Still, the optimal type and intensity of exercise that best enhances hip bone strength remains poorly characterized, partly because the exact loading of the hip produced by the diverse types of exercises is not known. Thus, the goal of this study was to quantify peak hip loading during walking and running at different speeds and acquire a better insight into the biomechanics of the motion in question.

Methods: 20 young healthy adults walked and run on a split-bet treadmill, in a speed range of 3 – 12 km/h, with an increment of 1 km/h. By means of integrated motion capture as an input to musculoskeletal modeling in Opensim, kinematics, kinetics and hip contact forces (HCFs) were calculated. Muscle forces were obtained by solving the static optimization algorithm. The cost function was set to minimize the squared sum of all muscle activations.

Results: Ensemble curves of HCFs during walking and running are shown in Figure 1. During walking, HCFs have a two peak profile whereby the first peak (Peak1_HCF) during heel strike increases from 4.03 BW to 5.26 BW and the second (Peak2_HCF) during toe-off from 4.1 BW to 5.4 BW, by increasing speed from 3 to 6 km/h (Table 1). During running, there is only one peak HCF (Peak_HCF) during mid-stance that increases from 7.11 BW to 9.48 BW, by increasing speed from 6 to 12 km/h (Table 1). Speed related profiles of peak HCFs and ground reaction forces (GRFs) reveal a different progression of the peaks. Larger percentage increase from 3 to 6 km/h was identified for peak HCF when compared to peak GRFs during walking and running. Larger variability of peak HCFs was calculated during walking (~ 13 – 24.5%) and running (~ 16 – 20%) than in peak GRFs (~ 3 – 8% during walking and ~ 8 – 10% during running). Regression analysis of peak HCFs and coinciding hip moments for each speed showed that hip adduction moment best predicts Peak1_HCF (mean R^2 = 0.6) during walking and Peak_HCF (mean R^2 = 0.7) during running, whereas hip extension best predicts the Peak2_HCF during walking (mean R^2 = 0.58).

Figure:



Caption: Figure 1

Conclusion: Based on our analysis, peak HCFs increase significantly with increasing speed during walking and running. Further analysis showed that speed has a stronger impact of speed on peak HCFs than on peak GRFs. Discrepancies in variability and speed progression of peak HCFs and GRFs question the notion of peak GRF as predictor of peak skeletal loading. As a consequence, clinically relevant outcomes were also investigated as possible predictors of peak HCFs. Results from regression analysis of peak HCFs and hip moments indicate the major influence of muscle activity on peak HCFs, since muscles exhibit high force output to equilibrate external moments. The present study contributes hereby to a better understanding of musculoskeletal loading during walking and running in a wide range of speeds, offering valuable information to clinicians and scientists exploring bone loading as a possible non-pharmacological osteogenic stimulus. Through modeling, a deeper insight into joint forces was established, illustrating that ground reaction forces and external moments can only partially describe the true musculoskeletal bone loading and that muscle action used to balance external joint moments is the most important factor in affecting bone loading during different exercises. In future research these results can be utilized in more elaborate techniques, such as finite element analysis, in order to fully understand the mechanisms underlying bone reaction to load.

KINEMATIC VERSUS NEUTRAL ALIGNMENT IN TOTAL KNEE ARTHROPLASTY: BIOMECHANICAL AND CLINICAL ASSESSMENTS

Claudio Belvedere [1,*] Andrea Ensini [2] Silvia Tamarri [1] Paolo Barbadoro [2] Michele d'Amato [2] Alberto Leardini [1]

[1] Movement Analysis Laboratory and Functional-Clinical Evaluation of Prostheses, [2] 1st Orthopaedic and Traumatologic Clinic, Istituto Ortopedico Rizzoli, Bologna, Italy

Introduction and Objectives: In Total Knee Arthroplasty (TKA), one long-held tenet of prosthesis component implantation is that knee Neutral Mechanical Alignment (NMA), i.e. of 0°±3°, must be targeted to restore physiological lower limb biomechanics and to obtain better clinical results and implant survival rates. Recent studies have shown that knee natural alignment can differ from NMA and that a postoperative NMA does not improve TKA survivorship [1]. Furthermore, knee trans-epicondylar axis is questioned as the best possible reference in prosthesis alignment [2].

As a result, a novel implantation approach has been recently proposed, referred to as Kinematic Alignment (KA), based on pre-arthritic knee alignment. This is performed by suitably modeling knee posterior condyles as cylinders and by using the trans-cylindrical axis, i.e. trough the two cylinder centers, as a reference in femoral component alignment [2]. Accordingly, KA is thought to allow more natural soft tissue balance and better knee function than NMA.

Recently, patient specific instrumentation (PSI) has been introduced possibly to achieve more accurate prosthesis positioning [3] also via KA, in addition to traditional NMA. Particularly, KA via PSI seems to be more effective in restoring physiological knee kinematics and lower limb muscle activity [2], but only preliminary results have been reported.

The purpose of this study is to analyze the biomechanical behavior of the two above-cited alignment approaches. In this perspective, joint kinematics and electromyography will be assessed in two patient groups, one operated according to NMA via with the conventional instrumentation, the other according to KA approach via PSI.

Methods: 36 patients planned for TKA were divided into two equal-size groups and implanted with a cruciate-retaining fixed-bearing prosthesis (Stryker® Orthopedics, Mahwah, NJ-USA) targeting NMA via convention instrumentation (group A) or KA via PSI (group B).

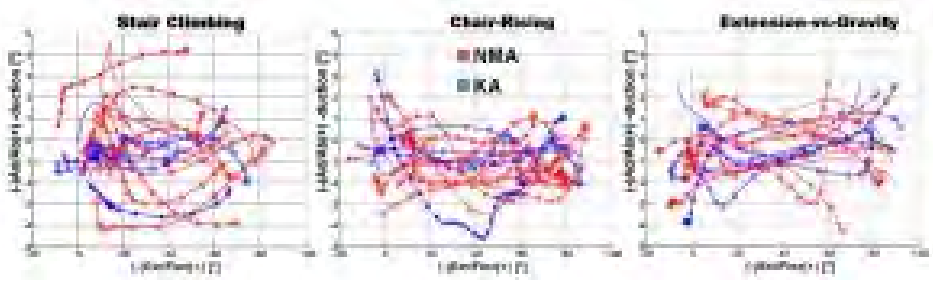
Currently, 20 patients were implanted, 11 in group A and 9 in group B. These were also assessed clinically using the Knee Society Knee Scoring System, and also biomechanically at 6 month follow-up. In the latter, knee kinematics during stair climbing, chair rising and extension-vs-gravity was evaluated via 3D mono-planar video-fluoroscopy (CAT® Medical System, Monterotondo, Italy) synchronized with electromyography analysis. Relevant prosthesis component poses were reconstructed [4] to calculate knee flexion/extension (FE), ad/ab-duction (AA), internal/external rotation (IE), together with the rotation of the contact-line (CLR) on the tibial base-plate, this being the line connecting the medial (MCP) and lateral (LCP) condyle contact points. MCP and LCP antero-posterior translations were also calculated and reported in % of the tibial baseplate length.

Results: Mean postoperative knee and functional scores in group A were 78±20 and 80±23, respectively; in group B these were better, i.e. 91±12 and 90±15.

In both groups, mean AA range (see figure) was found smaller than 3° together with normal FE and IE ranges. Particularly, IE range in the 3 motor tasks was 8.0°±3.2°, 10.1°±3.9° and 7.9°±4.0° in group A, and 6.6°±4.0°, 10.5°±2.5° and 11.0°±3.9° in group B. The extension-to-flexion MCP translations were of about 13.8±5.6% anterior, 17.0±6.6% posterior and 15.4±6.6.9% posterior in group A, and 13.0±3.4%, 16.5±5.3% and 16.6±5.6% all posterior in group B; corresponding LCP values were all posterior of about 9.5±3.6%, 11.1±4.3% and 8.5±2.6% in group A, and 102±2.1%, 13.7±8.6% and 14.6±9.7% in group B. Relevant CLR was 8.2°±3.2°, 10.2±3.7 and 8.8±5.3 in group A, and 7.3±3.5, 12.6±2.6 and 12.5±4.3 in group B.

Much more consistent patterns of motion were observed in group B than in group A. In the EMG data, prolonged activation of the medial and lateral vasti muscles was observed in group A.

Figure:



Caption: Knee ad/ab-duction during the three analyzed motor tasks in NMA and KA patients.

Conclusion: These results reveal that better biomechanical function together with clinical scores were obtained in TKA targeting KA and performed via PSI. Though irrelevant kinematic differences were observed between groups, a higher consistency in knee motion patterns was found over the KA patients. Corresponding less prolonged muscle activation suggests also a more natural stability and mobility at the knee joint, and general soft tissue balance.

These findings forecast the good biomechanical efficacy in clinics of KA via PSI, though data from of all recruited patients are necessary to establish the claimed superiority of the novel alignment approach.

ESTIMATION OF FEMORAL INTRA-NECK DRILLING CHANNEL FROM COMBINED PELVIC AND FEMORAL ANATOMICAL LANDMARKS: A CADAVER STUDY

Victor Sholukha [1,*] Jules Panda [2] Patrick Salvia [1] Benoit Beyer [1] Marcel Rooze [1] Serge Van Sint Jan [1]

[1]LABO, ULB, Brussels, Belgium, [2]Department of Surgery, University of Lubumbashi, Lubumbashi, Congo

Introduction and Objectives: Guiding information must be available when drilling a surgical pin through the femoral neck to reach the femoral head. While medical imaging (i.e., fluoroscopy) is widely available in developed countries, surgeons in less-favored countries do not have easy access to such technology. Accurate estimation of the femoral anteversion and inclination angles is of interest for surgical intervention. This paper proposes a new approach for the evaluation of the proximal femur morphology (e.g. femoral neck axis location). The first objective of this paper was the description of the pipeline allowing storage of bone morphological characteristics and the determination of regression relationships applicable for proximal femoral epiphysis shape and orientation prediction. The second goal was the approximation of a drilling pathway running within the femoral neck towards the femoral head without medical imaging support. It is based on a combination of 5 pelvic and 3 femoral anatomical landmarks (ALs) located on the subject-of-interest.

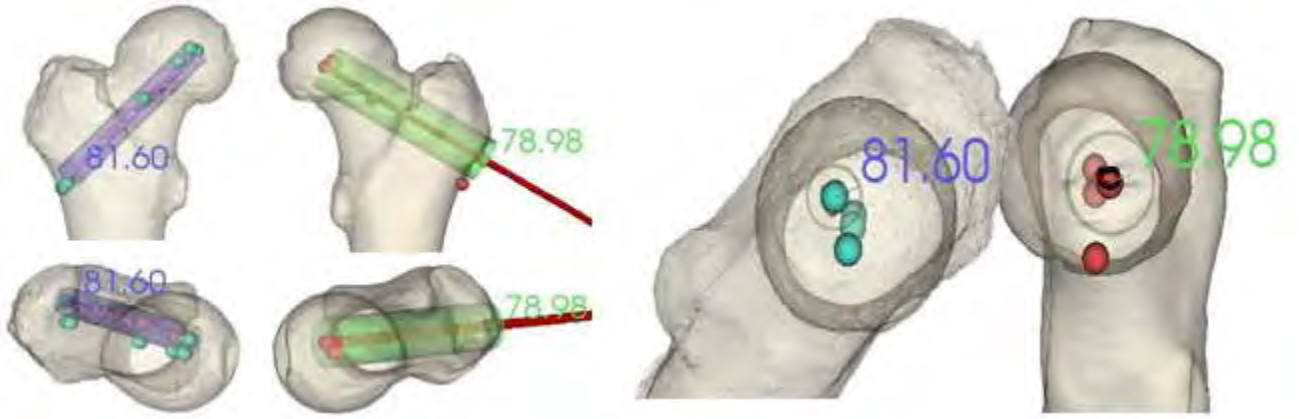
Methods: Fifty-seven bodies from donators were obtained from the Body Donation program of the University Libre de Bruxelles. X-ray control allowed to ensure the lower limbs of the donators did not show any osteosynthesis material that would lead to artifacts during CT imaging. After CT imaging segmentation, 3D models of the specimen pelvis and two femoral bones were obtained. Virtual palpation was then performed following strict definitions [1]. Supplementary ALs were virtually palpated on the surface of the acetabulum, femoral head and neck surfaces. These ALs were further used to characterize each surface-of-interest using shape approximation. The hip joint components (i.e., the pair including the pelvis and femoral bone) of one specimen in the database was used as reference assuming the hip joint as a ball-and-socket joint. The pose of the remaining database hip joints were adjusted by rigid transformation using the reference joint pair to obtain all available hip joints in the same joint orientation. For any new joint to be estimated, the above database procedure unification has been followed. Each hip orientation data available from the database were adjusted according to the orientation of the joint-of-interest using 5 pelvic and 3 femoral ALs. In order to complete the validation, the method has been integrated in a surgical ancillary prototype to perform a pin drilling on each available specimen. The drilling path prediction procedure was based on the computational method presented in our previous papers [2,3] and home made interactive software.

Results: Accuracy evaluation by “leave one out” (LOO) cross validation was performed on the 114 hip joints available from the database. The orientation of each available joint was sequentially flexed within the range [-30°, 30°] using 3° step. For each orientation step of the current hip joint, the location of femoral hip center (FHC) and drilling point (FDP) were compared with the prediction values obtained from the remaining 113 bone couples. Results of this LOO cross validation showed that the FHC and FDP mean prediction error was 5.1(2.1) mm and 9.6(4.1) mm, respectively.

Five cadavers from database were excluded by LOO method and selected for testing *in-situ* of nine femur drilling. Drilling results using the ancillary prototype on the 9 hip joints show good correspondence with the computed values:

discrepancies between the real drilled channel and the computed channel ("gold" values for drilling point and femoral hip center from CT image data reconstruction) was 8.9(3.7) mm and 7.1(3.8)° for the position and orientation, respectively. Results were obtained after the real drilling procedure and CT scan data reconstruction including inserted drilling pin. Examples of CT imaging 3D reconstruction after drilling procedure presented in Figure for right and left femur frontal, superior and neck axial views. Pin locations (red sticks) and size inside bone (in mm) demonstrate accuracy of the method.

Figure:



Conclusion: Results of this study show that proposed method can be used to predict parameters such as the femoral head center location and the most optimal entry point to insert a surgical pin or a trephine while remaining within an intraosseous pathway following the femoral neck. The obtained accuracy suggests that the method could be used as an alternative or complementary to fluoroscopy or computerized tomography used for pre-planning tasks. The novel method has therefore the advantage to solve the problem of radiation absorbed by surgeon and patient during medical imaging.

SYSTEMATIC BIOMECHANICAL ANALYSIS OF TREATMENT OPTIONS FOR TIBIAL HEAD DEPRESSION FRACTURES

Stefanie Hoelscher-Doht [1,*] Martin Jordan [1] Christina Zimmermann [1] Torsten Blunk [1] Rainer Meffert [1]

[1] Department of Trauma, Hand, Plastic and Reconstructive Surgery, University Clinics of Wuerzburg, Wuerzburg, Germany

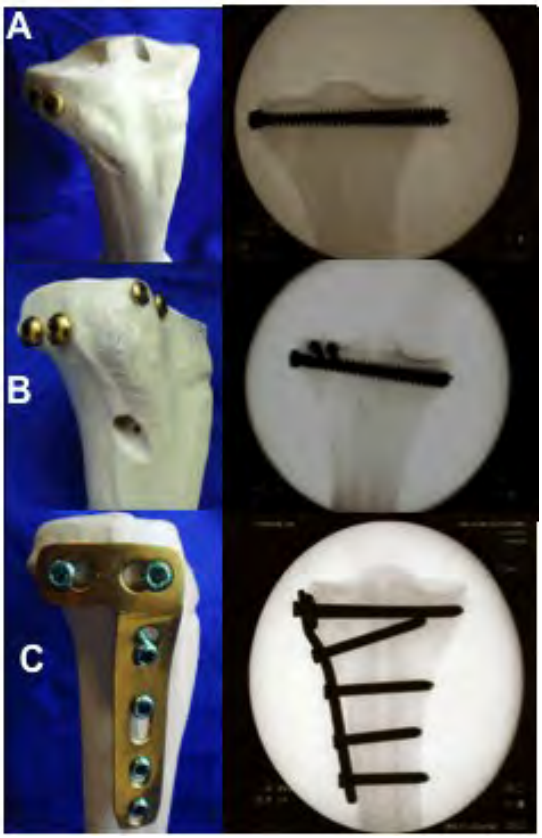
Introduction and Objectives: Tibial head fractures account for 10% of all fractures in the elderly. Due to metaphyseal bone loss, depression fractures, especially of the lateral tibial plateau, frequently occur and need to be treated operatively. After reduction of the depressed articular fracture fragment, a metaphyseal bone defect remains. Filling the defect with an autologous crest bone graft is not possible because of fatty degeneration of the crest bone. Instead, bone substitutes are used. Following operative treatment, the postoperative regime includes partial weight bearing of 15-20 kg for 3 months. Older patients, however, often do not follow this regime, resulting in a secondary subsidence of the depressed articular fracture fragment due to excessive weight bearing. A systematic biomechanical evaluation of different treatment options is needed to enable development of evidence-based recommendations for the type of bone substitute and how it is stabilized. Therefore, the aim of this study was to systematically analyse different options of osteosyntheses alone and in combination with commonly used bone substitutes for treating tibial head depression fractures.

Methods: Lateral tibial head depression fractures were created in Synbones (SYNBONE®, Switzerland) in a fracture model. After reduction, the fractures were stabilized with 8 different treatment options of an osteosynthesis alone or in combination with a bone substitute (Table 1). Two screws, 4 screws using the jail technique, and a lateral buttress plate (Figure 1) were investigated. As a bone substitute, two common clinically-used calcium phosphate cements, Norian® Drillable and ChronOS™ Inject, were applied. All specimens were X-rayed to confirm the stabilization procedures. Cyclic testing was performed using 250 N for 3000 cycles, simulating typical partial weight bearing after operative treatment of tibial head depression fractures. Displacement of the articular fracture fragment during cyclic loading (mm), the stiffness (N/mm) and the maximum load (N) in load-to-failure tests were measured.

Results: All groups with the three different types of osteosyntheses without bone substitute revealed a higher displacement compared to the control group, stabilized only with the bone substitute ChronOS™ Inject (2 Screws: 1.43±0.68 mm, 4 Screws: 1.11±0.21 mm, Plate: 3.72±3.82 mm; ChronOS: 0.53±0.20 mm; $p<0.05$). However, groups with an osteosynthesis in combination with bone substitute exhibited no significant differences compared to the control group ChronOS™ Inject only. The maximum load for the 2 screws (1957±384 N) was significantly lower compared to the jail technique with 4 screws (3067±257 N; $p=0.02$) and the buttress plate (3813±556 N; $p<0.01$). In addition, for the normalized maximum load, a significant difference was found between the jail technique (4 screws) and the buttress plate (4 screws: 231±25 %, Plate: 337±53 %; $p<0.01$). Comparing the two different bone substitutes to each other, the ChronOS™ Inject had a significantly higher stiffness than the Norian® Drillable (ChronOS: 478±149 N/mm, Norian: 307±62 N/mm; $p=0.01$). The X-rays revealed that completely filling up the defect with bone substitute depended on the

type of osteosynthesis. Using the plate, filling up was more complete compared to the 2 screws and jail technique with 4 screws.

Figure:



Caption: Figure 1: The three different osteosynthesis options: (A) 2 screws, (B) 4 screws in the jail technique, and (C) lateral buttress plate.

Conclusion: When treating tibial head depression fractures the fracture stabilization has to provide high stability under maximal loading, as well as to prevent a secondary subsidence of the depressed articular fracture fragment. Our study provides evidence about the mechanical performance of different osteosyntheses and bone substitutes. The buttress plate had the highest stability under maximum loading whereas the use of bone substitute was essential to limit the subsidence. Thus, the combination of both, osteosynthesis and bone substitute, is recommended to stabilize tibial head depression fractures. Interestingly, the specimens filled up with ChronOS™ Inject exhibited a higher stiffness than the ones with Norian® Drillable. Furthermore, the mode of failure differed between the two bone substitutes; under maximum loading Norian® Drillable was pressed out of the application channel, whereas ChronOS™ Inject formed a fixed contact to the synthetic bone spongiosa and the lateral tibial plateau broke completely away. Although the use of ChronOS™ Inject would be recommended based just on mechanical performance, knowledge of the mode of failure suggests Norian® Drillable is the preferred option.

BIOMECHANICAL COMPARISON OF THE ALL-EPIPHYSEAL AND OVER-THE-TOP TECHNIQUES FOR REPAIRING THE ANTERIOR CRUCIATE LIGAMENT USING A NOVEL ROBOTICALLY SIMULATED PIVOT SHIFT: A CADAVERIC STUDY

Tara F. Bonner [1,*] Robb W. Colbrunn [1] Joel Kolmodin [2] Paul Saluan [2]

[1]BioRobotics and Mechanical Testing Core, [2]Orthopeadic & Rheumatologic Institute, Cleveland Clinic, Cleveland, OH, United States

Introduction and Objectives:

Anterior Cruciate Ligament (ACL) injuries increasingly affect the pediatric population. The all-epiphyseal (AE) and over-the-top (OTT) are two techniques used for reconstructing the ACL in lieu of traditional techniques so as not to disrupt the epiphyseal in growing patients. Both techniques' effectiveness in restoring intact knee kinematics has been examined previously in a cadaveric study, concluding that both techniques provide anterior and rotational stability. No conclusions were made as to which technique provided more stability [1].

The robotically simulated clinical pivot shift (PS), a dynamic loading profile based on measurement of loads applied by a surgeon, was presented as a more robust test for detecting kinematic changes for evaluating ACL reconstructions [2]. This study aimed to use the simulated clinical PS to assess anterior and rotational stability provided by the AE and OTT surgical techniques.

Methods:

Six fresh-frozen, cadaveric legs were transected mid-femur and mid-tibia and mounted to the Universal Musculoskeletal Simulator capable of real-time force feedback using simVITRO™ software. Four surgical conditions were tested: Intact knee, deficient ACL, AE reconstruction and OTT reconstruction. The AE and OTT reconstruction order was randomized. For each surgical condition, three tests were performed:

1. Anterior drawer (134 N anterior, 20 N compression) at 0, 15, 30, 60, and 90° of flexion
2. Rotary loads (5 Nm internal rotation torque, 10 Nm valgus torque, 20 N compression) at 5, 15, and 30° of flexion
3. Simulated clinical PS test [2]

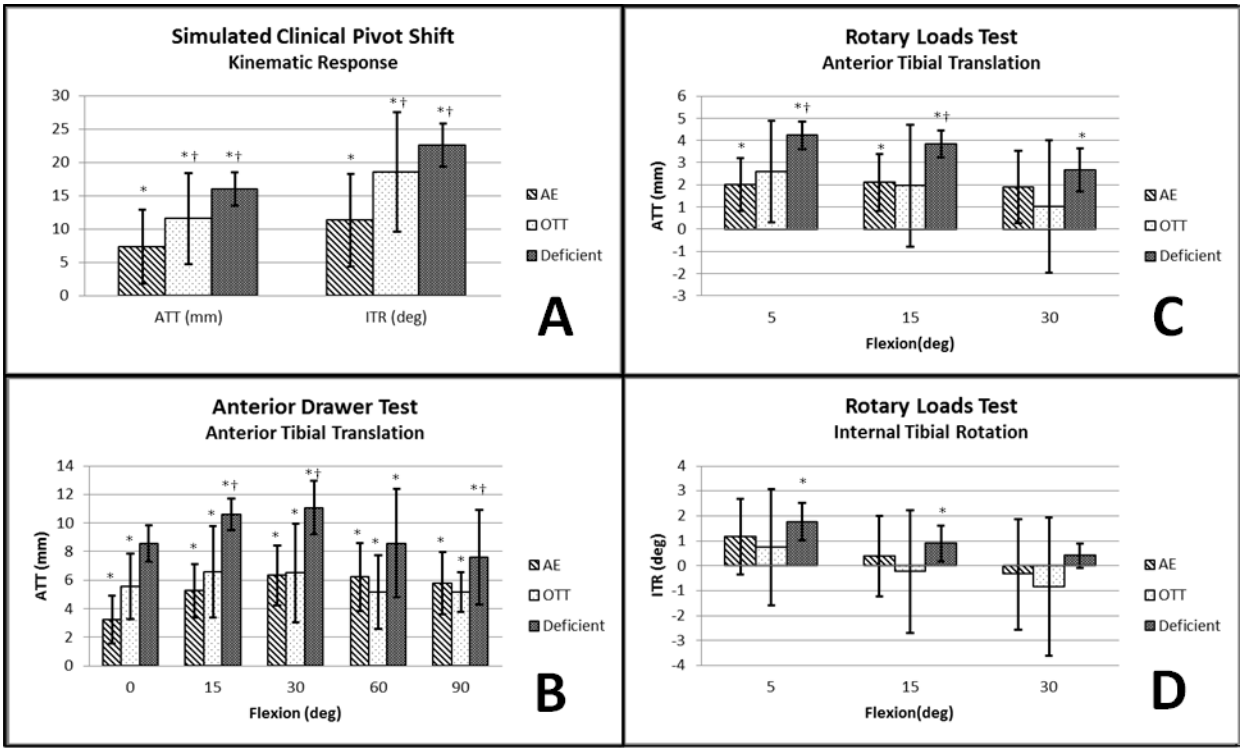
For each specimen, the kinematics from the intact knee for each respective test was subtracted from the kinematics of the three remaining surgical conditions to acquire kinematic response relative to the intact knee. Relative anterior tibial translation (ATT) and internal tibial rotation (ITR) were reported at each tested flexion angle for the Anterior Drawer and Rotary Loads tests and for the flexion angle initiating the shift in the simulated clinical PS test. This angle was at the peak ATT and corresponded to the start of the shift. Paired t-tests were used to determine significance ($p<0.05$). In one specimen the simulated clinical PS could not induce a shift, even in the deficient state, and thus was excluded from the analysis.

Results:

Figure 1A displays the ATT and ITR for the simulated clinical PS at the flexion angle initiating the shift. Neither surgery restored intact knee kinematics. OTT exhibited 4.2 mm more ATT compared to AE (p=0.021) and 7.2° more ITR (p=0.015). OTT had no significant kinematic difference compared to the deficient ACL.

Figure 1B displays the ATT for the Anterior Drawer test. Figure 1C and 1D display the ATT and ITR (respectively) for the Rotary Loads test. Neither surgery restored intact knee kinematics nor significantly reduced ATT or ITR compared to the other surgery, agreeing with previous work with similar loading conditions[1]. The AE surgery significantly reduced ATT compared to deficient at flexion angles of 0, 15 and 30° by 5.3, 5.3 and 4.7 mm respectively and there was no significant difference between OTT and deficient, though trending was seen (p<0.086). (Fig 1B).

Figure:



Caption: Figure 1: Kinematic responses relative to intact knee, *p<0.05 compared to intact, †p<0.05 compared to AE, (no significant results between OTT and deficient), A) Kinematic response induced by the simulated clinical Pivot Shift, B) Anterior tibial translation (ATT) induced by the Anterior Drawer, C) ATT induced by the Rotary Loads, D) Internal tibial rotation (ITR) induced by the Rotary Loads

Conclusion:

The all-epiphyseal technique, though unable to restore native kinematics, showed significantly improved stability (4.2 mm ATT, 7.2° ITR) compared to the over-the-top technique when tested with a robotically simulated clinical pivot shift. Analysis of the Anterior Drawer and Rotary Loads tests did not detect significant differences in these surgical techniques, and are in agreement with a previous study with similar loading conditions [1].

Limitations of our study include the small sample size, and the removal of one of the specimens. More work is needed on refining the loading profile to ensure it is able to induce a pivot shift in all specimens. While there is still room for improvement, it is currently still more effective than Rotary Loads, especially in its ability to detect rotational instabilities. The results from our study agree with previous studies [1,2] in that the Rotary Loads test does not induce large rotational changes amongst ACL surgical states. It also does not provide additional information compared to the Anterior Drawer test for measuring anterior laxity. It is our recommendation that the Rotary Loads test be replaced by one that can induce greater kinematic changes when comparing ACL surgical states. The simulated clinical PS is a solution that shows promise.

BIOMECHANICS OF COMPUTER-ASSISTED VS. CONVENTIONAL THR AFTER ONE YEAR FOLLOW-UP

T Weber [1 2,*] T Renkawitz [2] S K Bulstra [3] J Grifka [2] G J Verkerke [4 5] S Dendorfer [1]

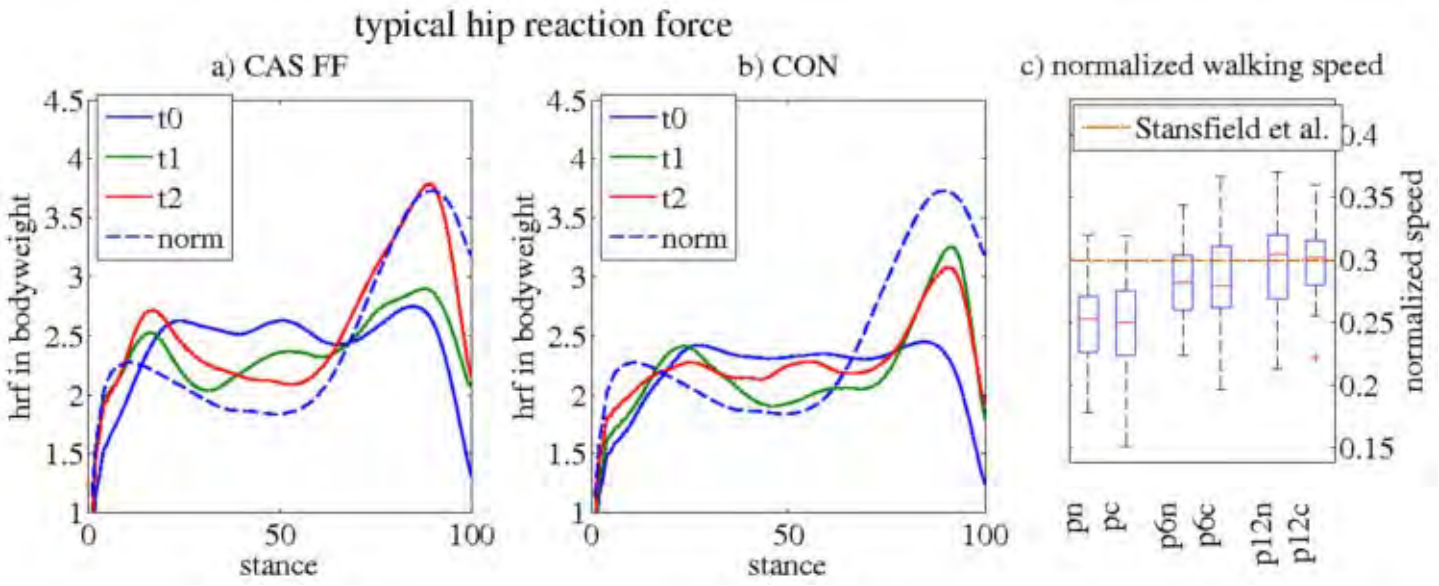
[1]Laboratory for Biomechanics, OTH Regensburg, [2]Department of Orthopaedic Surgery, Regensburg University Medical Center, Regensburg, Germany, [3]Department of Orthopaedic Surgery, [4]Department of Rehabilitation Medicine, University of Groningen, Groningen, [5]Department of Biomechanical Engineering, University of Twente, Enschede, Netherlands

Introduction and Objectives: A novel, computer-assisted Femur First (CAS FF) operation method for Total Hip Replacement (THR), which incorporates various aspects of performing a functional optimization of the cup position, and comprehensively improves range of motion (ROM) as well as cup containment and alignment parameters, has been developed. To compare CAS with conventional THR a combined workflow of experimental and computational methods was used. Novel computer simulations were used to determine biomechanical outcome in terms of hip reaction forces (hrf). We assessed on hrf: are they closer to a healthy, young normal, are they distributed more symmetrically and is the hrf orientation favorable in the CAS group?

Methods: 30 CAS and 30 conventional patients were enrolled for this prospective, randomized and patient and observer-blinded clinical trial. CT-Scans from all patients were retrieved post-op and implant position and orientation were measured by an external institute (MeVis, Germany). After given written consent patients conducted 3D video based motion-capture (SimiMotion, Germany) gait analysis (self-selected speed) at three points of time (pre-op -- t0, post-op six month -- t1, post-op twelve month -- t2), recording bony landmark based marker trajectories and ground reaction forces simultaneously (Kistler, Switzerland). The recorded data were processed using a validated and commercial musculoskeletal simulation package (AnyBody A/S, Denmark). Typical signals of the hrf for either of the groups were computed using dynamic-time-warping (dtw)1. Dtw path length as well as dtw distance were used as asymmetry measures, reflecting either phase-shift symmetry or magnitude symmetry of time-series. Force orientations are quantified in the radiographic coordinate system.

Results: Hrf of both groups are increasing during the follow-up period and are at t2 closer to a healthy normal compared to t0. Hrf for the CAS FF group increased over the follow-up period, until reaching the same hrf-magnitude as young and healthy adults at t2. Phase shift and magnitude asymmetries decrease for both groups, especially in terms of phase-shift. At t1 the force orientation of the CAS FF group was significantly closer to the center of the acetabular cup compared to the conventional group, which vanished at t2. ***Figure 1*** The typical hrf signal of the different THR-groups. a) The hrf of the CAS FF group at the different follow up points can be seen (blue: t0, green: t1, red: t2). The x-axis denotes the stance-phase in percent; the y-axis shows the hrf in multiples of bodyweight. The dashed line is the TS of the healthy group as gathered during method verification experiments. b) Results for the CON group (blue: t0, green: t1, red: t2). c) Dimensionless walking speed at different follow-up points is displayed, as well as literature data for THR patients (point-dashed, dark red line).

Figure:



Conclusion: Patients that underwent CAS FF seem to improve more than patients that underwent conventional THR in terms of hip reaction forces. The results suggest that CAS FF leads to better performance at the artificial hip joint. At t1 the orientation of the hrf is improved for the navigated group and closer to optimum suggesting that the CAS FF operation technique decreases the propensity for dislocation and impingement in an early stage. The rather big number of patients (60) that have been analyzed using a novel computational workflow and validated models is the greatest strength of this study. The model is of a mechanical nature, therefore cancelling out psychological effects. CAS FF has the potential for an improved biomechanical outcome early after surgery. A possible long-term benefit remains to be proven.

AS-0534

STRESS-STRAIN BEHAVIOUR OF NI-TI ALLOYS USED IN ENDODONTIC INSTRUMENTS BY MEANS OF TORSIONAL SIMULATED TESTS.

Leandro A. Santos [1,*] Estevam Las Casas [1] Guiomar Bahia [1] Vicente Buono [1]

[1] Universidade Federal de Minas Gerais, BELO HORIZONTE, Brazil

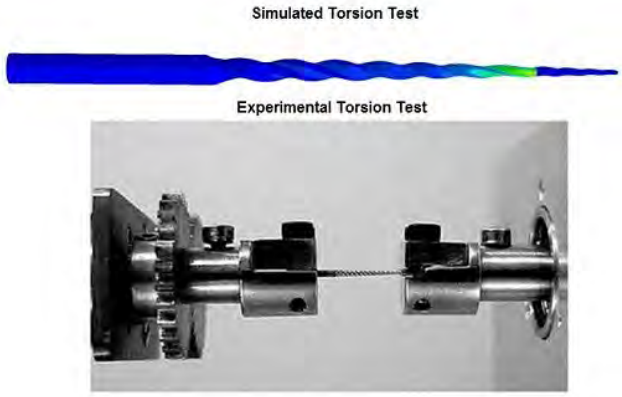
Introduction and Objectives: Endodontic treatment is a clinical intervention that aims to cure infections in the pulp of the tooth, the soft tissue inside the root canal. This treatment includes a step of shaping the root canal by means of an endodontic instrument, made of stainless steel or nickel-titanium (Ni-Ti) alloy. The Ni-Ti alloy presents a property called superelasticity (or pseudoelasticity), a nonlinear elastic behaviour that allows the material to undergo large deformation without plastic residual-strain after stress removal. This behaviour is linked to a reversible solid-state transformation from stable phase austenite to a new crystallographic structure called martensite. Due their microstructure and mechanical properties, Ni-Ti endodontic instruments present several advantages compared with the stainless steel files, such as higher flexibility and less geometrical aberrations during the treatment. Despite their advantages, the fracture of rotary Ni-Ti instruments in the root canal is still an important issue in endodontics. One of the main causes of these instruments' fracture is the torsional overloading. It occurs when the instrument has its movement stopped by friction with the canal's wall whilst the shaft continues to rotate. Thus, torsion is an important loading condition to which the instruments are subjected during use. There are standard torsion tests available to evaluate the mechanical behaviour of these instruments. To improve the fracture resistance of Ni-Ti endodontic instruments, manufacturers have introduced new conditions to heat treat the Ni-Ti alloys. The resultant improvements are easily evaluated through a stress-strain curve extracted from a tensile test performed on a Ni-Ti wire. However, these new treated alloys, in general, are applied directly to the file's geometry and performing conventional tensile tests on then can be very difficult. In this case, finite element modelling (FEM) is very helpful, once by this method it is possible to simulate torsional conditions and extract stress-strain relationships as a result. Thus, the aim of this work is to simulate torsion tests on known Ni-Ti files and correlate the results with the experimental ones. Thus, it is possible to create a map of behaviour, by which one can estipulate the stress-strain curve of a unknown alloy using experimental torsion results.

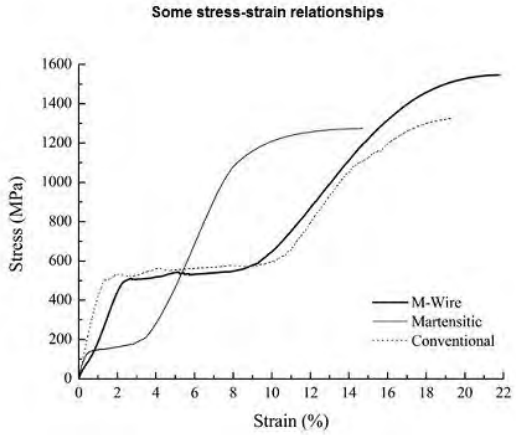
Methods: A commercially available instrument with a tip size of 25 and a 0.06 taper was selected for this study. The geometric model for finite element analysis was generated by micro-CT scanning (eXplore Locus SP, GE Healthcare, Waukesha, WI, USA). Five constitutive models, based on stress-strain curves, were selected as input data. The numerical analysis was performed in ABAQUS (SIMULIA, Providence, RI, USA) with boundary conditions that were based on the ISO 3630-1 specification for torsion tests of endodontic instruments. In these tests, the instrument is locked at 3 mm from the tip and a 3 N.mm torque is applied to its shaft. As a result, a torque-angular displacement curve is obtained. The experimental torsion test was performed on an instrument with the same geometry and unknown stress-strain behaviour.

Results: Five torque-angular displacement curves were calculated by finite element simulations. Each curve was linked to its stress-strain relationship and a map of mechanical behaviour was done. The torque-displacement curve from the

experimental test was compared to the simulated ones and it was possible to estipulate the stress-strain curve of the unknown alloy.

Figure:





Conclusion: Stress-strain relationships are very important to characterize the mechanical behaviour of materials. Through these curves, it is possible to obtain the necessary parameters to describe the behaviour of an alloy under stress, such as elastic modulus, elongation, and yield point. In this work, it was created a method to estimate these curves for an unknown Ni-Ti alloy using torsion tests and finite element modelling.

MECHANISM OF SHEAR DEFORMATION OF DEEP BRAIN DURING ROTATIONAL HEAD MOTION OBSERVED IN A THREE DIMENSIONAL PHYSICAL HEAD MODEL

Yusuke Miyazaki [1,*]

[1]Mechanical and Environmental Informatics, Tokyo Institute of Technology, Tokyo, Japan

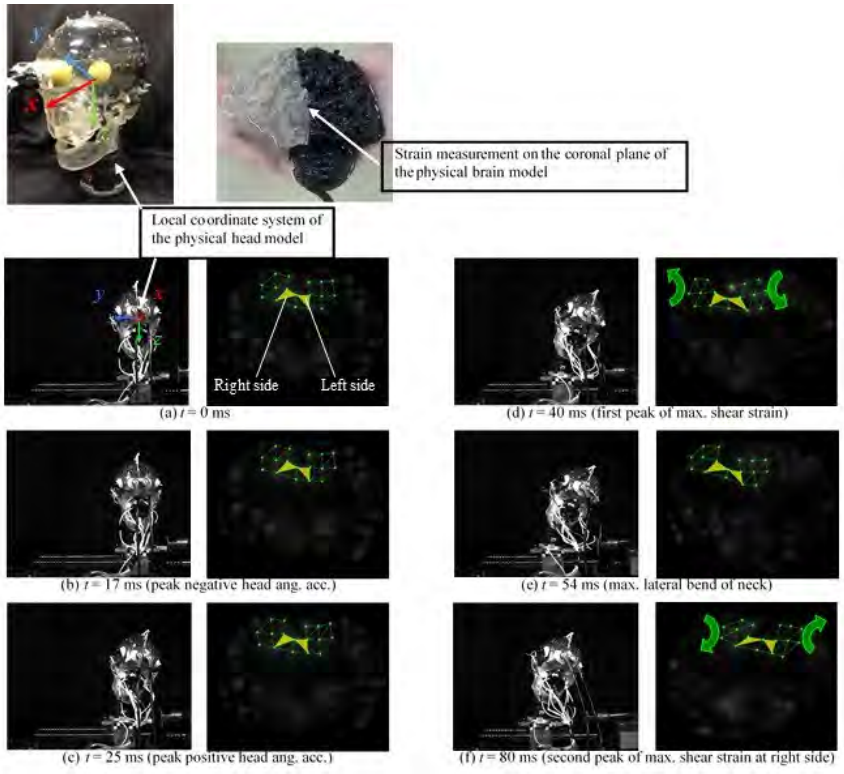
Introduction and Objectives: Traumatic Brain Injury (TBI) occurs various impact conditions such as traffic accidents, falling accidents, and sports accidents. Therefore, it is necessary to determine the mechanism by which TBIs occur and the preventive measures that can be adopted to avoid them. Especially, rotational brain injury such as concussion or Diffused Axonal Injury(DAI) can cause shear deformation of deep brain, however, the detailed mechanism is still unknown. Moreover, the head injury criterion (HIC) is calculated by linear acceleration responses of the center of gravity of the head, it is difficult to evaluate TBI due to rotational head impacts using HIC. Therefore, it is necessary to define a new injury criterion for rotational head motion in order to minimize TBIs due to rotational head impacts. So far, some injury criterion based on peak head angular acceleration and/or angular velocity have been proposed; however, the relationship between these parameters of rigid head motion and deep brain deformation is also unclear. Research using physical or computational models has been performed to clarify the mechanism. However, the shapes of the brain models were based on simplified geometries Hence, the purpose of this study is to construct a physical head model that has a three dimensional real human shape, then examine the mechanism of shear deformation during rotational head motion, and relationship between rotational head motion and brain shear deformation.

Methods: The head model consists of an accurate 3D representation of the human head, made by assembling detailed models of the skull, falx, tentorium, CSF and brain. The skull part was made of polycarbonate and was fabricated by machining based on CAD data reconstructed from CT images. The falx and tentorium part were made of polyurethane with almost the same thickness and Young's modulus as that of the dura of cadavers, and attached to the skull model[1]. A mold of the brain was fabricated using a stereo lithography system based on the CAD data of the brain reconstructed from MR images. Subsequently, a two-tone brain model, made of black and transparent silicone gel having the same dynamic viscoelasticity of human brain[1], has a detailed shape of three dimensional brain with ventricle and cerebral sulci. White markers were painted around corpus callosum on the boundary plane. Two fiber scopes attached with high speed cameras were fixed in the intracranial space. Therefore, the model can visualize shear deformation within the depth brain at corpus callosum. Finally, the gap between the skull and brain portions was filled with water to simulate cerebrospinal fluid.

Side impacts were applied on a slider attached to the lower neck under the conditions in the case that peak angular acceleration and angular velocity were controlled. The time history of rotational impacts applied to the physical head model was calculated from the acceleration time history recorded by 3-3-3 accelerometer arrays. The displacements of the white points around corpus callosum were measured. Finally, the Green-Lagrange strain around each white point was calculated from its relative displacement.

Results: The time history of the shear strain at corpus callosum showed that the there was a time delay between the peak angular acceleration and the peak shear strain(Fig.1 c and d). From the results of the experiment, shear deformation at corpus callosum occurs because of reverse torsional deformation between right and left cerebral hemisphere along with cerebral falx(Fig.1 d and f). This reverse torsional deformation was due to relative reverse rotation between skull and brain. Moreover, the peak change in angular velocity correlated highly with the peak shear strain in the brain, rather peak angular acceleration, which has been proposed as the indicator for categorizing the severity of brain injuries or injury criterion. This was because the brain deformation was quite small at the time of peak angular acceleration of the head. Thus, brain shear deformation did not correlate with the peak angular acceleration of the head.

Figure:



Caption: Time-histories of 3D physical Head-Neck model motion and deep brain deformation behavior at corpus callosum

Conclusion: Our results showed that relative reverse rotation between skull and cerebrum affects greatly on the mechanism of the deep brain, which was not correlated with the rotational acceleration of the head but the angular velocity. Thus, we propose that time duration of the rotational acceleration should be considered an important parameter for defining a new brain rotational injury criterion, rather than the peak angular acceleration

CARBON-FIBER REINFORCED PEEK PLATES – A PROMISING APPROACH TO PROXIMAL HUMERAL FRACTURE PLATING?

Christoph Katthagen [1] Michael Schwarze [2,*] Mara Warnhoff [3] Christine Voigt [1] Christof Hurschler [2] Helmut Lill [1]

[1]Trauma and Reconstructive Surgery, Diakoniekrankenhaus Friederikenstift, [2]Laboratory for Biomechanics, [3]Hanover Medical School, Hannover, Germany

Introduction and Objectives: Locking-screw plating is an established and commonly used treatment for dislocated proximal humeral fractures [1]. Despite advancement of implants and a better understanding of failure mechanisms, complication rates for proximal humeral locked plate fixation remain high at up to 30% attributed to varus loss of reduction and articular screw perforation [2, 3]. Newly developed implants are regularly introduced to the market which attempt to address these issues. Carbon-fiber reinforced polyetheretherketone CF-PEEK composite plates are less stiff than stainless steel and titanium plates, with an elastic modulus similar to bone as well as the ability to withstand prolonged fatigue strain. An approach to prevent articular screw perforation is the development large diameter screws, so called locking bolts. The main purpose of the presented study was to compare the biomechanical properties of a CF-PEEK locking plate with pre-existing data of a titanium-alloy plate when used for fixation of an unstable 2-part fracture of the surgical neck of the humerus. The secondary purpose was to compare the biomechanical behavior of locking bolts and conventional locking cancellous screws.

Methods: 7 pairs of fresh frozen human humeri (female donors, mean age 59y, range: 46y to 75y) were allocated to two equal groups. All specimens were fixed with the CF-PEEK plate (PEEK Power Humeral Fracture Plate, Arthrex). Cancellous screws (group 1) were compared to locking bolts (group 2) for humeral head fixation. Stiffness, cyclic fracture gap deflection and ultimate load were assessed in a servo-hydraulic testing machine. Stiffness was determined with a load limit of 200N in axial loading, as well as 20deg abduction and 20deg adduction. Cyclic fracture gap deflection was determined during 5000 cycles at 1Hz from 50N to 250N load. Ultimate load was determined with constant displacement speed until visual observation of failure. Results were compared between groups and with pre-existing biomechanical data of a titanium-alloy plate (PHILOS, DePuy Synthes).

Results: The CF-PEEK plate featured significantly lower stiffness in all directions and more fracture gap deflection compared to the titanium-alloy plate (all $p<0.001$, Tab. 1). In ultimate load testing, no significant differences could be detected, although 6 out of 14 CF-PEEK plates failed due to irreversible deformation and resulted in complete loss of fixation in the femoral head. No significant difference was observed between results of groups 1 and 2 in any test configuration ($p>0.05$, Tab. 1).

Conclusion: The CF-PEEK plate significantly increases movement at the fracture site of an unstable proximal humeral fracture model compared to the commonly used titanium-alloy plate. The screw design however does not affect the constructs primary mechanical behavior in the constellation tested. However, the stiffness of the CF-PEEK plate was relatively low, resulting in interfragmentary displacements of ~40% strain over the 10 mm defect. These strains are sufficiently high that they could conceivably have a significant negative impact on bone healing especially in case of large

defect zones [4, 5]. This study could not find biomechanical evidence for the use of large diameter locking bolts, although clinically there might be some advantages such as reduced screw perforation in the humeral head. The utilized setup might not be appropriate to enforce screw cut-out.

As a major limitation to our findings, the results only represent initial fixation and do not reflect biological processes of in vivo healing or the loading produced by muscle forces producing moments around the shoulder joint, although the applied forces correspond to in-vivo measurements [6]. Against this background the clinical use of CF-PEEK plates should be cautious in case of remaining large fracture gaps of more than 4-5mm after fracture reduction without additional means of fracture gap augmentation.

Table:

	CF-PEEK with cancellous screws (n=7)	CF-PEEK with locking bolts (n=7)	Significance between groups	Titanium-alloy with locking screws (n=8)	Significance between plates
Axial stiffness [N/mm]	54.7 (18.8)	57.1 (15.5)	p=0.54	183.7 (26.3)	*p<0.001*
20deg Abduction [N/mm]	44.6 (7.5)	46.1 (11.8)	p=0.8	118.4 (32.2)	*p<0.001*
20deg Adduction [N/mm]	82.2 (18.1)	96.1 (29.9)	p=0.26	505.5 (321.2)	*p<0.001*
Failure load [N]	653 (133.5)	801 (201)	p=0.32	822 (143)	p=0.69

A BIOMECHANICAL COMPARISON OF FOCAL TRAUMATIC BRAIN INJURY AND PERSISTENT-POST-CONCUSSIVE SYNDROME

Andrew Post [1,*] Marshall Kendall [2] Janie Cournoyer [2] Blaine Hoshizaki [2] Michael Gilchrist [3] Susan Brien [4] Michael Cusimano [5] Shawn Marshall [6]

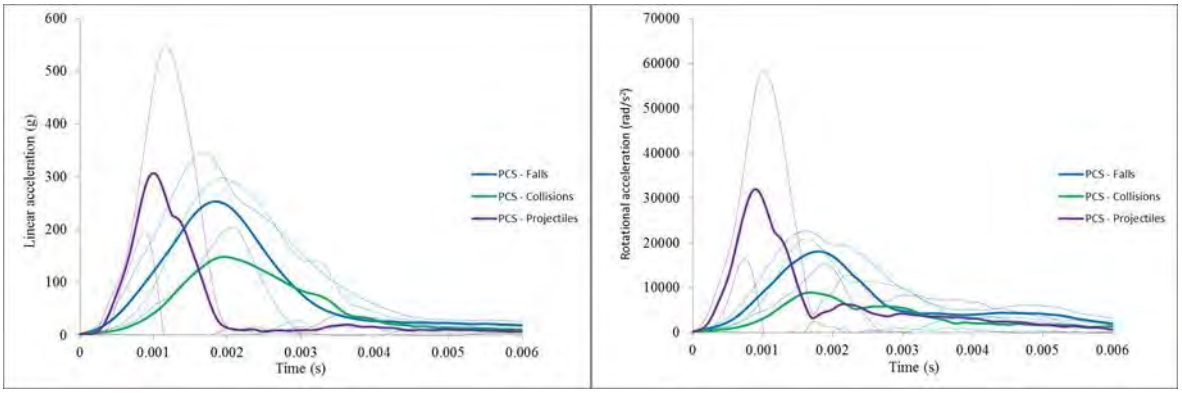
[1]Human Kinetics, [2]University of Ottawa, Ottawa, Canada, [3]University College Dublin, Dublin, Ireland, [4]Royal College, Ottawa, [5]St. Michael's Hospital, Toronto, [6]Ottawa Hospital, Ottawa, Canada

Introduction and Objectives: Every year brain injury is a leading cause of global hospitalization. Of particular concern is defining what characteristics of the brain injury event that create a high risk of focal traumatic brain injury (fTBI), and how these differ from persistent concussive syndrome (PCS). The similarities in the biomechanics of these types of injury make it difficult for clinicians and biomechanical researchers to gain an understanding of the mechanisms contributing to these injuries. This creates a unique challenge to clinicians trying to either identify the injury at the hospital clinic or ER. For biomechanists it is important to develop an understanding of the biomechanical mechanisms that differentiate between these two types of brain injury to improve protective and preventative measures. The purpose of this study was to examine the characteristics of real-life events representing fTBI and PCS to better understand differences in event characteristics and acceleration loading profiles between these two types of brain injuries.

Methods: The subjects who sustained head impact injuries were classified into two groups by neurosurgeon: fTBI and PCS. To determine the brain injury event characteristics, each subject was interviewed and a form completed that contained information for laboratory reconstruction such as: impact location, velocity, etc [1]. The dataset involved multiple mechanisms of injury (falls, collisions, and projectiles) reconstructed using a monorail, linear impactor, or ball launcher. These devices were used to impact an instrumented Hybrid III headform under conditions as described in the Neurotrauma report. The impacts were described by linear and rotational acceleration curve characteristics [2] that have been found to have a relationship with risk of brain injury. In total 20 fTBI and 20 PCS cases were reconstructed.

Results: The linear and rotational acceleration (Table 1) curves, showed that the PCS cases had significantly lower values than the fTBI cases for all descriptors ($p<0.05$) except for duration. The average impact velocity for all the PCS cases was lower than the fTBI cases ($p<0.05$). This suggests that reduction in velocity may be an important in reducing the risk from fTBI to a PCS range. There were 3 distinct mechanisms of injury within the PCS group: falls, collisions, and projectiles. When comparing these mechanisms, significant main effects were discovered for all linear and rotational curve characteristics ($p<0.05$). Considering that all mechanisms resulted in PCS there may be at least two unique loading curve types (Figure 1) that can cause injurious damage to the brain tissue. As mechanism-related unique loading curves would create unique stress and strain conditions in different regions of the brain tissue it is possible that the loci of PCS may be different for each mechanism and it could result in different symptomologies [3]. These results also suggest that mechanisms of injury should be considered when conducting brain injury analyses and research.

Figure:



Caption: Comparison of the average linear (left) and rotational (right) acceleration loading curves for different mechanisms of the PCS cases.

Conclusion: This research examined the differences in acceleration loading curves that typify PCS and fTBI in a hospital dataset. It was discovered that other than duration of curve, the PCS group had an acceleration curve parameters of lower magnitude than that of the fTBI cases, likely due to lower average head velocity for the PCS group. When isolating for mechanism of injury, PCS was characterized by lower rotational acceleration curve characteristics than TBI, suggesting that rotational acceleration loading curves may be a better variable to distinguish between these two types of injury. Further analysis was conducted within the PCS group, revealed that mechanism of injury is an important factor in predicting brain injury. This research suggests that mechanism of injury must be considered to gain an improved understanding of injury thresholds and event characteristics that could then be applied to methods of prevention. These new technologies and innovations involving improved energy absorbing materials will need to manage the conditions of velocity, mass, and compliance linked to the mechanisms of mTBI relevant to each unique sporting or societal environment.

Table:

		Rotational acceleration curve parameter				
Injury	Velocity (m/s)	Duration (s)	Peak (krad/s^2)	Time (s)	Slope (krad/s^3)	Integral
TBI	4.17 (0.75)	0.0032 (0.0018)	34.3 (14.8)	0.0017 (0.0007)	23517.2 (14836.9)	38.8 (9.31)
PCS	3.19 (1.20)	0.0037 (0.0013)	18.1 (12.2)	0.0020 (0.0006)	11291.7 (10396.5)	25.0 (13.4)

AN EXAMINATION OF TRAUMATIC MANDIBULAR FRACTURES USING DYNAMIC FINITE ELEMENT ANALYSIS

Gladstone Burke [1,*] Clive Neal-Sturgess [1 2] Robert Ashford [1]

[1]Faculty of Health, Education and Life Sciences, Birmingham City University, [2]School of Mechanical Engineering, University of Birmingham, Birmingham, United Kingdom

Introduction and Objectives: The mandible is the one of the most commonly fractured bone of the facial skeleton [1][2]. The pattern of mandibular fractures is related to the magnitude, direction and duration of impact, which are features of the mechanism of injury. The multiplicity of injury mechanisms makes it difficult to determine if an anatomical sub-site has a greater propensity to fracture.

Traditionally biomechanical investigations on bony structures have involved cadaveric mechanical testing which is expensive, labour intensive and ethically questionable. Computer trauma modelling using three-dimensional finite element analysis has the advantage of avoiding such investigations. Such computer models have use in the medico-legal and forensic field where they may aid in the determination of proximate and ultimate causation of injuries[3].

The main objectives of this study were firstly to develop a three-dimensional finite element model of the adult human mandible capable of simulating mandibular fractures as a result of impact at various sites and angulations with various objects used in interpersonal violence e.g. fist. Secondly to use the finite element model to predict the anatomical fracture sub-site and temporal occurrence of mandibular fractures in a simplified traumatic simulation.

Methods: A computed tomographic scan of the facial skeleton of an adult male was used as a data source for the production of the finite element model. The images slices were segmented to identify cortical bone, cancellous bone and teeth. Finite element meshes were generated from the 3D reconstructed image slices. The assembled mandibular model was composed of 1183976 linear tetrahedral elements and 250523 nodes. The applied material properties were derived from the literature (see table).

Finite element simulations were performed with the mandible impacted at various sites (symphysis, parasymphysis, body, angle and ramus) with varying angulations with modelled objects including a pipe and a fist. Von Mises stress was used as a failure criterion. Static and dynamic 3D-finite element analyses of simplified traumatic injuries as a result of various loading situations were undertaken with in order to predict the fracture anatomical sub-site and temporal occurrence.

Results: A 3D finite element model of a human mandible was produced which allowed the examination of mandibular fracture under experimental loading conditions. Each load produced a unique cortical stress “signature”. In these simplified trauma situations, non-linear dynamic analyses were able to give the disposition and temporal occurrence of fractures in addition to modelling patterns of fracture. The model did not simulate all patterns of mandibular fracture. Several patterns, especially those, which are encountered clinically, are due to indirect contacts with other parts of the facial skeleton, which was not modelled in this simulation. However, the modelled fracture patterns and loads were similar to those encountered in mechanical testing of cadaveric mandibles published in the literature (Figure 1).

Figure:

Caption: Simulated fist impact to right mandible. The lingual (inside) surface of the mandible is viewed. Fractures are indicated by asterisks. (Teeth are omitted in this simulation)

Conclusion: A finite element model used to study mandibular fracture without resorting to expensive mechanical cadaveric testing was developed. The model was capable of studying the effect of impact magnitude, direction and duration on the mandibular fracture pattern. Although this was a simplified model, the principles involved in modelling bony fractures on a macroscopic scale may be of use in larger models of the facial skeleton, which would be of clinical value. The mandibular model itself has the potential to provide useful biomechanical information for use in the forensic sciences.

Table:

	Element number	Node number	Young's modulus (MPa)	Poisson's ratio	Density (kg/m^3)
Cortical bone	454537	112273	13460	0.3	1740
Cancellous bone	217176	48898	7930	0.3	700

ADOLESCENT FEMORAL FRACTURE FIXATION WITH LATERAL TROCHANTERIC ENTRY RIGID HELICAL INTRAMEDULLARY NAIL - A BIOMECHANICAL EVALUATION

Darshan Angadi [1,*] Duncan Shepherd [1] Ramanan Vadivelu [2] Timothy Barrett [1]

[1]University of Birmingham, [2]University of Birmingham and Birmingham's Children's Hopsital, Birmingham, United Kingdom

Introduction and Objectives: Surgical treatment options of paediatric femur fracture include flexible or rigid intramedullary nails and submuscular plate fixation. Rigid intramedullary nailing has been suggested as a treatment option in adolescents due to the perceived advantages of stable fixation with higher union and low complication rates. However no study in the current literature has addressed the biomechanical aspects of rigid helical intramedullary nail fixation of femoral fractures in the adolescent population. Laboratory based biomechanical testing of implants is useful yet an expensive and time consuming process. Evolution of computational technology has enabled virtual testing of fracture fixation implants using finite element analysis (FEA) models of bones and implants.

Methods: 1) Development and validation of paediatric femur and helical intramedullary nail FEA models
2) Laboratory based experimental testing and FEA of femoral fracture fixation to evaluate stiffness parameters (axial/ four point bending / torsional) of common types (transverse / comminuted / segmental defect / spiral) of adolescent femoral fracture(~bodyweight of 60 kg). Methods: Experimental study involved small composite femurs implanted with helical intramedullary nail (n = 3) with (kExp Transverse, kExp Comminuted, kExp Segmental) and without (kExp Healed) fractures. Axial load (600N / 300N), four-point bending (400N / 60N), torque (4N m / 2N m) were used for healed and fractured models respectively. Femur FEA model was developed in SolidWorks using digital radiograph templates. Titanium alloy (Ti-6Al-7Nb) nail model consisted of cylinder (length 300 mm, outer diameter 11 mm-proximal, 8.2 mm-distal regions, 4.6 mm inner diameter) with helical axis. Simulation testing of fracture fixation using FEA models was performed in SolidWorks to estimate stiffness (kFEA). This validated model was subsequently used to estimate stiffness of a simulated mid-shaft spiral fracture (kFEA Spiral).

Results: Mean axial stiffness (N/mm) of femurs measured kExpTransverse = 622.84 (±36.65), kExpComminuted = 593.62 (±36.71), kExpSegmental = 562.04 (±31.51) and kExpHealed = 701.27 (±64.48). FEA model axial stiffness (N/mm) kFEATransverse = 611.97, kFEAComminuted = 602.47, kFEASegmental = 587.13, kFEAHealed = 725.46 and kFEASpiral = 576.92. Mean fourpoint bending stiffness (N/mm) of femurs was kExpTransverse = 102.53 (±16.47), kExpComminuted = 93.44 (±12.87), kExpSegmental = 88.06 (±13.76) and kExpHealed = 402.50 (±5.28) whereas FEA estimated kFEATransverse = 111.11, kFEAComminuted = 106.71, kFEASegmental = 99.01, kFEAHealed = 430.11 and kFEASpiral = 102.04. Torsional stiffness (N m/deg) (external rotation) of FEA models was kFEATransverse = 0.96, kFEAComminuted = 0.93, kFEASegmental = 0.93, kFEAHealed = 3.55 and kFEASpiral = 0.94 similar to femurs kExpTransverse = 0.96 (±0.12), kExpComminuted = 0.82 (±0.13), kExpSegmental = 0.77 (±0.14) and kExpHealed = 3.69 (±0.19). Torsional stiffness (N m/deg) (internal rotation) of FEA models was kFEATransverse = 0.96, kFEAComminuted = 0.94, kFEASegmental = 0.94, kFEAHealed = 3.56 and kFEASpiral = 0.94 comparable to experiment results kExpTransverse = 1.04 (±0.12), kExpComminuted = 0.97 (±0.20), kExpSegmental = 0.91 (±0.18) and kExpHealed =

3.86(±0.20). vonMises stress (σmax = 383.6 MPa) was noted at proximal screw in segmental fracture. Conclusions: A parametric FEA model based on simplified geometry may be used for evaluation of routine stiffness parameters of a paediatric femur. Titanium alloy rigid helical intramedullary nail used for paediatric femur fracture fixation can perform satisfactorily under physiological loading conditions experienced in the perioperative period.

MULTIPARAMETRIC ANALYSIS OF A PEDESTRIAN FEMUR DURING A CAR CRASH

Bernardo Innocenti [1,*] Matteo Bettoni [2] Walter Pascale [3] Filippo Begani [4] Silvia Pianigiani [3]

[1]BEAMS Department, Université Libre de Bruxelles, Bruxelles, Belgium, [2]Università Politecnica delle Marche, Ancona, [3]IRCCS, Istituto Ortopedico Galeazzi, Milano, [4]DIEF, Università degli Studi di Firenze, Firenze, Italy

Introduction and Objectives: The declaration of false injuries in the context of a car-pedestrian crash is a common problem with which the insurance companies have to face constantly. To provide them a valid support tool, this study through a finite element model wants to find out the risk of fracture (RF) associated to the femur by recreating the conditions of the impact in a collision between a car and a pedestrian.

Methods: A physiological bone model in contact with a car bumper model has been considered in this study. The femoral head has been considered fully encastred while the the distal part is unconstrained.

Due to the involvement of a high amount of parameters, the calculation of the risk for fracture of the femur was performed by a multiparametric study. The considered parameters are related to the physiological structure of the femur because its mechanical properties change greatly with the age, the thickness of the cortical bone and the presence of osteoporosis. Parameters related to the situation of the crash such as the type of bumper, the resulting impact force, the flection of the femur during the impact are also taken into account. in details, the considered parameters and their values are shown in the Table 1. The RF has been evaluated considering the maximum stress achieved by the femur after the impact. Subsequently the finite element analysis, through a statistical analysis was possible to trace what are the parameters that mostly affect the RF of the femur.

Results: The obtained results show that, among the several considered parameters, the RF is obviously mainly affected by the impact force and also by the height of the pedestrain. On the other hand, the bumper as well as the age of the pedastrian, are almost neglible factors (Figure 1).

Figure:

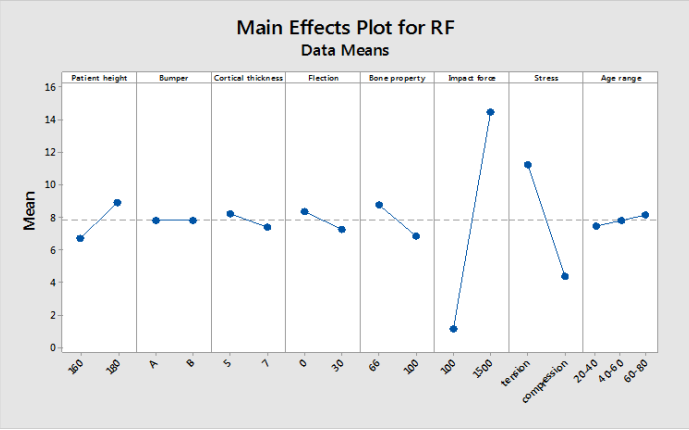

Figure 1: Influence of the analyzed parameters for the RF of the femur

Conclusion: Nowadays, insurance companies miss tools that provide help in deciding if a declaration of an injury is false after a car-pedestrian crash. This study wanted to develop a support developing a finite element model of a femur under car-pedestrian crash conditions. Several parameters have been analysed in order to consider several possible situations. The obtained results show that the features designs of a car are not decisive for the RF while the velocity of the impact is more important to be correlated with a possible femur fracture. Moreover, the age of the pedestrian, simulated as changes in the geometries and material properties of the femur bone, is not influencing the final outputs. On the other hand, the height of the patient affects the RF as the impact zone is then translated more proximally or distally. This study presents several limitations, as the complete embedment of the hip that, however, amplifies the trend of the results. Even so, the final aim of this study is not to provide a quantitative value of the induced forces and stresses during a car crash, but more to provide a tool to support decisions of insurance companies after a suspect car-pedestrian crash reimbursement request.

Table:

Parameters	**Test values**
Patient's height	160,180 [cm]
Impact position	lateral
Type of bumper	A,B
Impact force	100,1500 [N]
Cortical thickness	5,7 [mm]
Femur inclination	0°,30°
Bone material	healthy, osteoporotic
Age	20-40,40-60,60-80
Impact height	65 [cm]

FE MODEL OF FEMALE PELVIC FLOOR FOCUSED ON STRESS DISTRIBUTION IN LEVATOR ANI MUSCLE DURING VAGINAL DELIVERY

Linda Havelková [1,*] Ladislav Krofta [2] Luděk Hynčík [1] Jaroslav Feyereisl [2]

[1]New Technologies - Research Centre, University of West Bohemia, Plzeň, [2]Institute for the care of mother and child, Praha, Czech Republic

Introduction and Objectives: Female pelvis floor dysfunction such as organ prolapse, urinary and fecal incontinence is very often associated with damage of the levator ani muscle (LA) [1]. Muscle injuries and dysfunctions mostly occur during vaginal delivery when the muscle undergoes large deformation. Therefore, it is necessary to understand the anatomy and physiology of the LA during this process to be able to prevent and manage pelvic floor trauma. The objectives of this study were: (1) to measure the LA behavior by uniaxial test to find the material parameters; (2) to develop computer model of the female pelvic floor; (3) to analyze the stress distribution in the LA during the vaginal delivery respecting the optimal initial position and rotation of fetal head.

Methods: The passive biomechanical properties of the pig LA were measured to find the material parameters. Twenty LA samples extracted from eight pigs were used. The muscles were removed surgically during general anesthesia. Each sample was loaded by the uniaxial tensile test with a velocity of 6 mm/min until tissue rupture to obtain the stress-strain curve. The viscoelastic Ogden model was used to describe the passive behavior. The material parameters were determined by the least-square minimization method using the software called MATLAB [2].

The finite element method and the software called Virtual Performance Solution were used to develop new virtual model of the female pelvic floor. The model consists of the female pelvis, the LA, the obturator muscle and the fetal head. It was assumed that the other tissues are pushed without any significant reaction forces and thus they were neglected. The geometry is based on live subject MRI data. The model was reconstructed from axial 3T MR images. All slices were 2 mm thick. The asked subjects were a healthy, nulliparous, 25 years old female and three-day old child. The initial 3D geometric model was built using Slicer software. The final geometry and mesh were created in HyperMesh software. The boundary conditions were considered to simulate the real muscle attachments and supports. The fetal head trajectory was given by the pelvic shape - it followed the curvature of the sacrum and the coccyx to simulate the curve of Carus. The initial head flexion and rotation was also taken into account. Pelvis and fetal head were modeled by rigid bodies. During vaginal delivery, the LA performs extremely large deformations. Therefore the viscoelastic Ogden material was used to model both muscles [3]. The material parameters obtained from measurement were included.

The simulation of vaginal delivery was performed for optimal initial attitude of the fetal head –complete flexion, right occipitoposterior position. The distribution of stress von Mises in the LA was analyzed.

Results: The biomechanical properties of the LA were measured and its material parameters for Ogden model were calculated. The elastic parameters, μ and α, were $\mu_1 = 0.0082 \pm 0.0089$ MPa, $\mu_2 = 0.0216 \pm 0.0173$ MPa; $\alpha_1 = 0.1803 \pm 0.1299$, $\alpha_2 = 15.112 \pm 3.1704$.

The analysis of stress von Mises distribution in the LA during vaginal delivery was performed. The optimal fetal head position was considered. The results show, that the LA elongates almost 2.1 times in the inferior direction. The displacement of the upper arc top is about 54.272 mm in the posterior direction. Moreover, the length of the upper arc is 1.5 times higher by the biggest muscle elongation than in the initial resting position. The significant stresses were found in the upper arc of the LA, in the lower part in the middle and in the LA attachments. In summary, the maximal values were 0.094 GPa, 0.131 GPa and 0.481 GPa, respectively. To our knowledge based on clinical practice, right this stress pattern implies the highest risk of muscle stretch injury.

Conclusion: The new sophisticated virtual model of the female pelvic floor was developed to simulate the child birth. The model is primarily intended for analysis of stress generated in the LA. Nevertheless, it has wide range of applications in field of kinematics, dynamics as well as visualization. The model is now prepared for future applications. It will be used to analyze the stress distribution depending on various initial head position and rotation. In addition, the model will be used to develop the modern and efficient supporting tools preventing the urgent organ prolapse. In general, 3D pelvic floor models appear to be a promising for future mapping of pelvic trauma development. The project is co-financed by grants SGS-2013-26 and PRVOUK 32.

A NEUROMUSCULOSKELETAL MODEL TO SIMULATE PASSIVE WRIST EXTENSION TEST OF SPASTICITY

Ruoli Wang [1,*] Örjan Ekeberg [2] Pawel Herman [2] Johan Gäverth [3] Anders Fagergren [4] Hans Forssberg [3]

[1]Department of Mechanics, [2]Department of Computational Biology, Royal Institute of Technology, Stockholm, [3]Department of Women's and Children's Health, Karolinska Institutet, [4]AggeroMed Tech AB, Stockholm, Sweden

Introduction and Objectives: Spasticity is a motor disorder characterized by a velocity-dependent increase in tonic stretch reflexes [1], commonly seen in many neurological disorders. Clinically, spasticity is measured by an examiner rotating a joint and simultaneously estimating the resistance according to an ordinal scale. However, the limited reliability of the measurement and the impossibility to discriminate between the underlying neural (stretch reflex) and non-neural contributions have been the motivation to develop methods describing resistance joint torque quantitatively. The aim of this study is to develop a forward neuromusculoskeletal model consisting of the explicit musculotendon, muscle spindle, and motoneuron pool models, which can simulate passive wrist extension test of spasticity.

Methods: Neuromusculoskeletal model

The neuromusculoskeletal modeling includes muscle spindle modeling, motoneuron pool modeling, muscle activation dynamics and musculotendon modeling of the wrist flexors.

Muscle spindle modeling: The modified hybrid $V^{0.6}$ model was used to model the firing characteristics of the muscle spindle [2].

Motoneuron pool modeling: The motoneuron pool transformation was modeled as a sigmoid function which ranges from 0 to 1, representing the motoneuron neural excitation as a function of the muscle spindle-firing rate.

Activation dynamics: Activation dynamics can be described as the process of converting the neural excitation to muscle activation as a first order differential equation [3].

Musculotendon modeling: The musculotendon model consists of one lumped muscle actuator which represented synergistic wrist flexors and one passive plant. The passive plant can be considered as the passive viscoelastic properties of the joint. Wrist extensors were not included in the model. The Hill-type musculotendon model was used to simulate musculotendon dynamics of the lumped muscle actuator [4].

Experimental Setup and Protocol

Passive extension of the wrist at a slow (5°s-1) and a fast (236°s-1) velocity were performed using a newly developed device Neuroflexor (Aggero MedTech AB, Solna Sweden). The resistance torque induced by the passive wrist extension was measured. Range of wrist movement was set between 20° flexion and 30° extension. An example data from a chronic stroke patient (male, hand length = 0.09m, weight = 69kg) was reported.

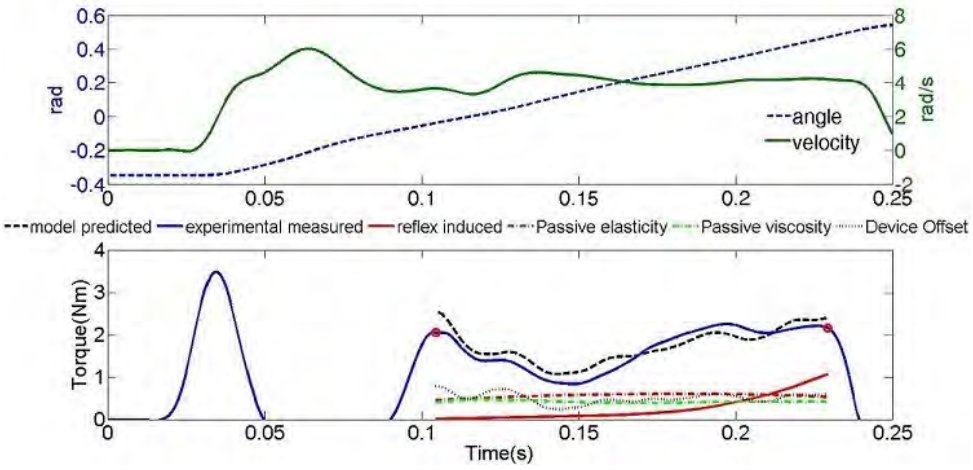
Optimization

It is assumed that no reflex induced muscle resistant torque in the slow movement; hence the resistant torque is purely caused by the passive plant. Nonlinear least squares was used to approximate four passive parameters: elasticity coefficient K_p, viscosity coefficient B_p, and non-linear expontential coefficients k_1 and k_2. Genetic algorithm (GA) was used to identify four optimal stretch related parameter: motorneural pool parameter μ and σ, dynamic and static spindle gain G_I

and G_v, so that the root-mean-square error between the measured and predicted resistant torque in part of fast movement (approximately from 0.1 to 0.23ms, Fig 1) was minimized. Previous studies have reported that the static and dynamic gains of the spindle in the pathological group did not differ significantly from the healthy controls [6]. Therefore, constraints were set to vary ±10% from the reported values (2 and 4, respectively).

Results: Simulation results from one chronic stroke patient are illustrated in the Fig 1. Four passive parameters ([K_p = 1.54, B_p = 0.1, k_1 = 0.05, k_2 = 3.2], R^2 = 0.998) were determined. Four stretch- related (neural) parameters ([μ = 157.3, σ = 10.1, G_l = 2.1, G_v = 4.1]) were found and the minimal root-mean-square error (cost function) was 5.4.

Figure:



Caption: The top: the angular velocity and position were prescribed in the simulation of the fast wrist extension. The bottom: the contributions of the torques from passive muscle properties (elasticity and viscosity) and the stretch reflex to the total resistance torque were specified. The optimization was only performed during the period marked with red circles.

Conclusion: By identifying important passive and reflex related parameters using optimization, the neuromusculoskeletal model can reliably describe non-neural and neural related contributions to the total joint resistant torque. The figures illustrate a good fit between the predicted and experimental measured resistant torque. Due to the large measurement error during the period 0.05-0.09ms and the latency of the reflex, the optimization was only performed for part of the fast movement, where the angular velocity maintained stable. Due to the fact of interdependency of the parameters and the difficulties of obtaining gradient, GA was used in the current study. In conclusion, the proposed neuromusculoskeletal model can simulate the passive wrist extension test of spasticity.

INTEGRATING ULTRASONOGRAPHY INTO A SUBJECT-SPECIFIC EMG-DRIVEN MODEL TO ESTIMATE TIBIALIS ANTERIOR MUSCLE FORCE

Stuart Miller [1 2,*] Thomas Korff [2] Anthony Blazevich [3]

[1]London Sport Institute, Middlesex University, [2]Centre for Sports Medicine and Human Performance, Brunel University, London, United Kingdom, [3]School of Exercise and Health Sciences, Edith Cowen University, Perth, Australia

Introduction and Objectives: The quantification of tibialis anterior (TA) forces *in vivo* is important in order to (i) better understand its role in human movement [1], (ii) allow a more complete analysis of pathological movement [2], and (iii) provide insight into the underlying causes of overuse injuries such as chronic anterior compartment syndrome [3]. EMG-driven musculoskeletal modelling offers an interesting approach to developing a subject-specific model for estimating muscle force *in vivo*. These models incorporate the muscle's force-length and force-velocity (FV) relationships, with a scaling factor included for activation. Of importance is that the length and velocity must refer to the contractile unit [4], rather than the whole muscle-tendon unit (MTU), as changes in tendon length are rarely synonymous with changes in muscle length. To date, joint kinematics are commonly used to model the action of the contractile components. However, this approach does not allow for the differentiation of the tendon and muscle.

The aim of this study was to develop a model that allowed for the muscle properties to be recorded *in vivo* non-evasively, resulting in a more valid approach to estimating muscle force *in vivo* than previous approaches.

Methods: A set of calibration contractions were performed by four adults (age = 26±1 yr, height = 1.79±0.05 m, mass = 75.6±12.0 kg). A second set of contractions were performed that were used as a validation tool. Isokinetic dynamometry, ultrasonography and electromyography were collected. Muscle kinematics and activation were used as the model inputs, with the ankle moment providing a means to fit the model to the individual, and to allow for the validation of the model.

The model is based on a FV sub-model that is scaled to isometric force. This uses velocity as its main input. This scaled FV sub-model was then used to calculate force across muscle lengths and activation levels. Changes in the FV relationship across muscle lengths and activation levels are removed when normalising to isometric force [5] and maximal shortening velocity has been suggested to be constant across a range of intensities and muscle lengths [6]; it was thus assumed that a single FV sub-model was appropriate.

To determine the isometric force for calculation of absolute forces from the normalised FV sub-model, a second sub-model calculated isometric force for all contraction intensities and muscle lengths. This used muscle activation and length as inputs. A force-EMG relationship was produced for each muscle length, with the slope of this relationship being modelled over the full muscle length range; isometric force for all muscle lengths and contraction intensities was determined.

Direct calculation of force during the calibration procedure is needed. The only non-invasive approach is to measure joint moment. Removal of the antagonist moment is important for valid calculation of TA force from the joint moment [7]. A moment-EMG-angle relationship for the plantar flexors (PF) was developed following investigation into the optimal approach to (i) modelling moment-EMG at individual angles (i.e. linear vs curvilinear), (ii) accounting for angle within a

single model, and (iii) modelling PF (i.e. weighting of the individual muscles), whilst optimisation procedures were incorporated to investigate the optimal EMG processing procedures. This allowed for dorsiflexor moment to be calculated. The moment arm (calculated using a modified tendon excursion method [8]) was then used to calculate tendon force.
The new muscle model was compared with a more traditional ankle model in which joint kinematics were used as the input instead of muscle kinematics. Relative root mean square error (%RMSE) was used to assess the accuracy of each modelling approach.
Results: For four of the six validation conditions, small differences were found between the two approaches to modelling the contractile components of TA. For the fast concentric condition, the angle model predicted TA force better (Cohen's *d*=2.7) whilst the length model performed better for the slow eccentric condition (*d*=0.7), although this was only a difference in %RMSE of 2.8%.
Conclusion: Under controlled conditions where the discrepancy between muscle and whole MTU (estimated from joint angle change) length change is minimal, the use of ankle angle data as input into an EMG-driven model is appropriate. However, further research is required to ascertain the validity of this simplification in more complex movements where stretch-shorten cycle actions might produce a greater discrepancy between muscle and MTU length.

AS-0544

THE EFFECT OF INTRAMUSCULAR FAT ON SKELETAL MUSCLE FORCE IN THE OBESE

Hadi Rahemi [1,*] Nilima Nigam [2] James M. Wakeling [1]

[1]Biomedical Physiology and Kinesiology, [2]Mathematics, Simon Fraser University, Burnaby, Canada

Introduction and Objectives: Obesety is a condition where excess fat accumulates in the body. While most of the excess fat is accumulated subcutaneously, some will infuse into muscle tissue. This condition affects skeletal muscle in different ways. The distribution of muscle fat can be both intra and extracellular. In addition to fat accumulation its has been shown that the proportion of type I and IIA fibre are reduced while the proportion of fatigable type IIB fibres are increased with obesity [1]. Also, a reduction in activity can lead to muscle atrophy occurring with obesity [2].

The changes to muscle structure with obesity affect its performance. This includes a reduction in both force and power output of the muscle. While experimental measurements can help us to understand the loss in the mechanical output at the level of the limb and joint, it is hard to quantify the effect of intra and extracellular fat on the performance of individual muscles. This can be done using a muscle model that allows the manipulation of intra and extracellular properties in the muscle tissue.

In this study we used variations of a 3D finite element model of human gastronemii [3] to study the effect of different intramuscular fat distribution. The effect of atrophy was also replicated by a reduction in the contractile elements (CEs).

Methods: We used a simplified geometry of unipennate muscle belly. The dimensions, boundary condition and mechanical properties of the muscle and aponeurosis were as previously described ([3], normal aponeurosis stiffness). The properties of the transversely isotropic muscle tissue were varied while the mechanical properties of the aponeuroses remained the same. Variations of the model are: [M1] Lean muscle (no fat) with 100% of CEs; [M2] muscle with a varied accumulation of X% fat (properties from [4]) in the base muscle material (BBM) and 100% CEs; [M3] lean muscle with X% reduction in CEs; [M4] muscle with X% of fat in the BBM and X% reduction in CEs; [M5] muscle with a random and sparse distribution of X% pure fat points dispersed within the lean muscle tissue; and [M6] muscle with a random and sparse distribution of X/2% pure fat points, X/2% of fat in the BBM and an X/2% reduction in CEs. M1 represented a control condition for lean muscle, M2 and M4 were models with intracellular fat, M5 represented extracellular fat, M6 contained a combination of intracellular and extracellular fat, and M3 was a lean muscle with a loss of CEs.

The concentration of intramyocellular fat for obese subjects varies between 2 to 5% depending on the fibre type [1]. In this study we have assumed that a similar amount can be accumulated extracellularly. Therefore along with an average X=10% fat level in obese people, model variants M2 to M6 were simulated in a low X=2% and an extreme X=20% fat levels.

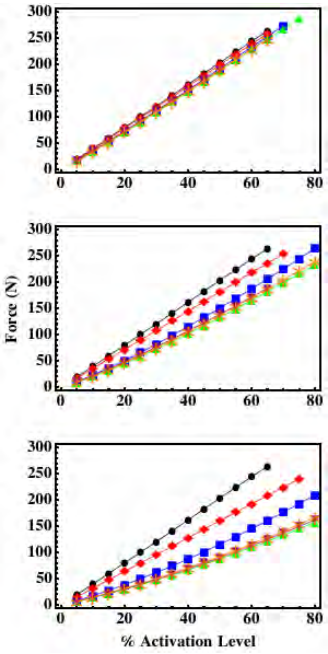
The force at the muscle-tendon junction, mean pennation angle and mean fibre length were calculated to asses structural changes and performance of the muscle in simulated scenarios.

Results: Muscle force in model variants with intramuscular fat (M2, M4-M6) was lower than lean muscle variants (M1, M3) for equivalent activation levels. There was also a substantial reduction of the muscle force with increased intramuscular fat. For example, in an extreme 20% fat scenario, forces in models M4-M6 (~90 N) were less than half of those for the M1

model at (~205 N) at 50% activation levels. Figure 1 shows the difference in force-activity profile of M1-M6 models for 2, 10 and 20% fat levels.

The pennation increased in all model variants with an increase in muscle activity; however the pennation increased to a greater extent in the in lean models M1 and M3.

Figure:



Caption: Figure 1. Force-activity plots of model variants: M1 (black), M2 (blue), M3 (red), M4 (Green), M5(purple) and M6 (orange) at 2% (top), 10% (middle) and 20% (bottom) fat levels.

Conclusion: The reduction in the fatty muscle force output compared to lean muscle may be a function of the increased stiffness of the base material properties. The stiffer tissue in the obese muscles affects the force development and transmission ability of the muscle. In addition, the results show that the loss of X% contractile elements (M3) has a smaller effect on the loss of muscle force compared to an X% intramuscular fat infusion (M2). In other words, an increase in intramuscular muscle fat is more critical to reduction in force than the decline in the contractile elements mimicking atrophy. The smaller changes in fibre pennation in the fatty muscles can affect the gearing [5] of the gastrocnemii muscles. Lowering the gearing potential of pennate muscles in general, may reduce their force and power output.

BIAXIAL COMPARISON OF AORTIC TISSUE AND CALCIFICATION BY A BUBBLE INFLATION TEST, APPLYING THE FINITE ELEMENT METHOD

Francisco Carrasco-Hernandez [1,*] Richard Brooks [1] David Richens [2] Donal McNally [1]

[1]University of Nottingham, [2]The Trent Cardiac Centre , Nottingham, United Kingdom

Introduction and Objectives: Blunt Trauma Aortic Rupture (BTAR) is a significant cause of death in automotive accidents [1], up till now the internal mechanism of this trauma has not been fully understood. To further understand this, the present work is based on the hypothesis that the arterial wall has different strength or stiffness, depending on the zone of the aorta [2]. BTAR mostly initiated at the aortic isthmus, and the aortic ductus arteriosus (DA) closes forming the ligamentum arteriosos at the isthmus zone which results in a scar in the aortic wall, with fibrosis resulting from the fusion of two materials [3]. This study test the hypothesis that the fibroses scar on the wall of the aorta formed by the DA, leads to a concentration of stress and strain, at the site of the rupture in BTAR.

Methods: This research is based on experimental bubble inflation tests done by Pearson, R. et al. [2] using aortic tissue. A Finite Element Method (FEM) bubble inflation test with a specimen of 3 layers corresponding the Intima, Media and Adventitia, and geometric boundary conditions are set to reproduce the experimental test. The model can then be validated with the experimental test.

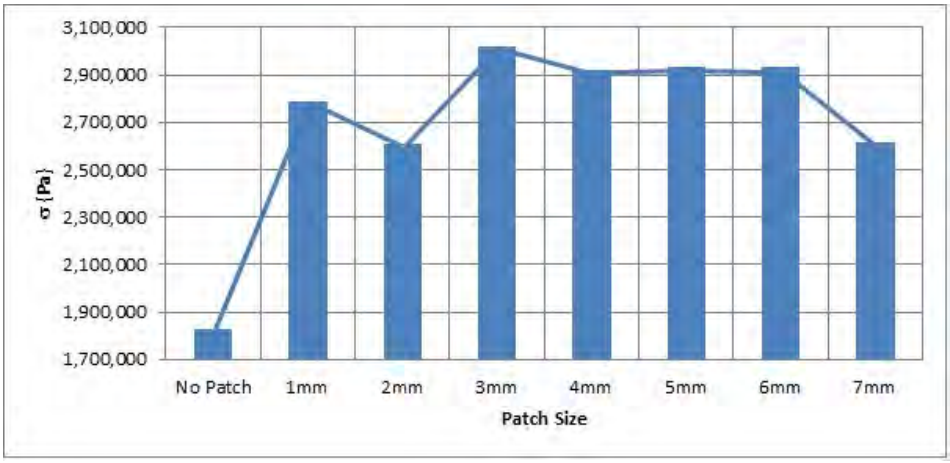
Using the verified numerical model, seven specimens were be designed with a patch of increase stiffness, with diameters of 1mm, 2mm, 3mm, 4mm, 5mm, 6mm and 7mm. In order to study the generation of stress concentration, the stiffness of the patch was also increased from the stiffness of the adventitia layer to 190%, in intervals of 10%.

Results: To understand which of the above two changes i.e. Patch size or Average of stiffness, for the greater effect, Von-Misses effective stress is compared across the inflating bubble model for varying patch sizes and stiffness. The values that are compared are in the upper element of the intima layer in the border between the patch and the aortic tissue. It is important to highlight the point that in this study there are no failure criteria.

Figure 1 with Table 1 shows the average V-M effective stress compared with the variation of patch size taking an average of stiffness across each patch. The increase in stress where a scar is introduced is considerable, on average rising to 152.7% of the stress that is given for a specimen with no patch. When the patch size is closer to the thickness of the specimen i.e. 1.03mm. After this rise is less significant

The theory of Crack Mechanics determines that a crack is the separation of material, caused by opening or sliding, with the distance of separation smaller than the length of the separation. Therefore for small diameters the concentration of strains will be bigger at certain pressure [4].

Figure:



Caption: Figure 1. Comparison of the Von Misses Effective Stress of the Average Stiffness Vs Patch Size for patch stiffness.

Conclusion: The importance of this study is that with the insertion of a scar (which simulates the DA cicatrix) in the aortic tissue are found concentrations of stress and strain between the border of the aorta and the scar, if the DA forms the isthmus, this study shows that if there is a small scar or if it presents with the dimensions comparable to the thickness of the aorta, the concentration of stress and strain are above a considerable value, this could lead to a nucleation of a crack in the border of the aorta and the scar, caused by a overpressure inside of the aorta, this could be one of the reasons why the blunt aortic trauma starts with a tear in this specific region of the aorta

Table:

Pressure MPa	No Patch MPa	1 mm MPa	2 mm MPa	3 mm MPa	4 mm MPa	5 mm MPa	6 mm MPa	7 mm MPa

AS-0546

EFFECT OF SCALED LOWER LIMB ANATOMICAL MODELS ON FORCE PREDICTIONS DURING WALKING GAIT

Ziyun Ding [1,*] Angela Kedgley [1] Anthony MJ Bull [1]

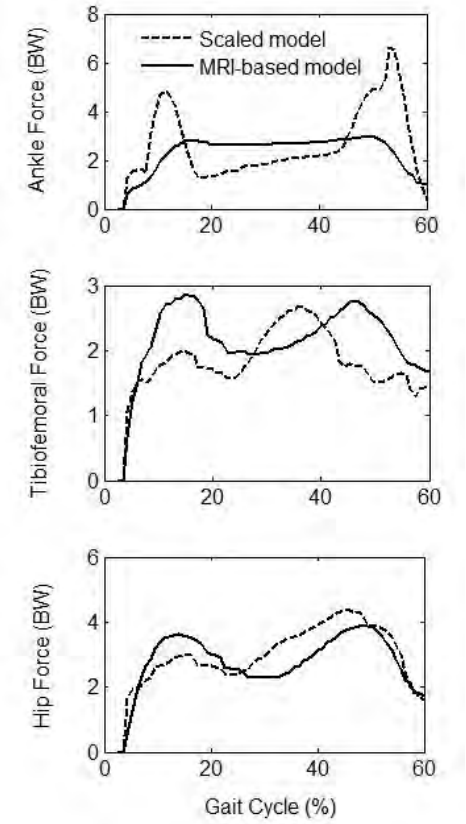
[1]Department of Bioengineering, Imperial College London, London, United Kingdom

Introduction and Objectives: Musculoskeletal modelling studies of the lower limb require detailed descriptions of lower limb anatomical geometry. Scaled implementations of generic anatomical models (e.g., Klein Horsman et al.[1]) are often used to create customised musculoskeletal models. However, the sensitivity of musculoskeletal modelling to the choice of anatomic dataset is largely unknown. This affects the validation of musculoskeletal modelling, which normally comparing the hip and knee contact forces predicted using a scaled anatomical model against the direct measurements from instrumented prostheses on a subject. This study aims to investigate the differences between using a scaled, anatomical model and a subject-specific MRI-based model in muscle and joint contact force predictions during walking gait.

Methods: Muscle and joint contact forces were calculated using a musculoskeletal model of the lower limb [2]. The model consists of 4 segments (foot, shank, thigh and pelvis), articulated by three joints at the ankle, knee and hip. Kinematic data and ground reaction force data were collected from a single subject (male, 1.83 m, 93 kg). Musculoskeletal geometry was determined in two ways: (1) by digitising an MRI scan of the whole lower limb and (2) by linearly scaling each segment of a published anatomic dataset (male, 1.74 m, 105 kg [1]). Three-dimensional scaling factors were calculated by comparing distances between bony landmarks from the calibration trial with body landmarks from the published dataset. As complete anatomical datasets, both models provided information regarding bony landmarks, joint rotation centres, and 163 muscle elements representing 38 muscle groups of lower limb. Muscle lines of action were defined by origin and insertion points. For muscles that wrapped over underlying structures, their lines of action were defined by via points or wrapping object parameters.

Results: Differences were found between muscle force predictions using two models. There were distinct differences for muscles crossing the ankle joint. Maximum difference of the peak muscle force can be as large as 400% (i.e., extensor digitorum longus, extensor halluces longus, and peroneus longus). This interpreted the significant peak value variations for the ankle joint contact forces (see Figure). The distributions of knee and hip joint contact forces were similar. Similarities include the double peaked curve and peak values during the stance phase. However, joint contact forces predicted using the MRI-based model showed better agreement with the previous research findings [3]. [3] reported that the peak tibiofemoral joint contact force occurred at contralateral toe-off (i.e., about 15% of the gait cycle) and peak values ranged from 2.3 to 2.5 BW. The contact forces predicted using the MRI-based model agreed closely to these results.

Figure:



Caption: Joint contact forces predicted during the stance phase.

Conclusion: Muscle forces and joint contact forces in a stance phase were successfully predicted employing two alternative customised models. They both described lower limb muscle geometry with 163 muscle elements hence produced similar redundancy in optimisation. However, relocated joint centres and muscle origin-insertion points from the scaled model resulted in substantial variability of force solutions relative to the MRI-based model. The use of scaled models for musculoskeletal modelling validation therefore would introduce inaccuracy. This finding suggests that it is essential to establish appropriate scaling through, for example, a lower limb anatomical database. The implementation of the lower limb anatomical database would significantly improve the accuracy of musculoskeletal modelling study.

ASSESSMENT OF THE EFFECTS OF BODY WEIGHT UNLOADING ON KINEMATICS, KINETICS, MUSCLE ACTIVITY, AND CENTER OF PRESSURE DURING OVERGROUND GAIT

Arielle Fischer [1,*] Alon Wolf [1]

[1]Mechanical Engineering, Technion- Israel Institute of Technology, Haifa, Israel

Introduction and Objectives: Body weight unloading (BWU) on treadmills is a common method of gait rehabilitation which by alleviating load on lower joints and related pain allows patients with neurological and musculoskeletal impairments to undergo treatment at the onset or right after surgery [1,2]. However, the effects of body weight reduction on the regeneration of lower joints locomotor patterns, a vital step to regain gait functioning under normal daily conditions, were hard to assess as long as research was conducted on treadmills. The walking modality-treadmill as opposed to overground- may confound the effects of BWU [3]. Once conducted overground, gait research on the effects of BWU was facing another challenge that of controlling healthy subjects' speed variability which was easily controlled on treadmills but hard to control overground [2,4]. In this research a novel mechanical device was designed to pull the BWU system at a constant speed and thus allowed healthy subjects to maintain a comfortable speed during overground walking with a BWU system. In so doing, this study could examine the unique effects of BWU on gait biomechanical parameters under conditions that approximate daily walking. We hypothesized that partial BWU during overground walking (1) will not affect lower limbs kinematic parameters, i.e., range of motion and trajectories. We furthermore assumed that BWU will result in (2) a decrease of lower joint kinetics, (3) a decrease in electromyographic (EMG) activity and (4) a shift in the center of pressure (COP).

Methods: Sample and Procedure: Fifteen healthy male subjects with no prior gait impairment, included in the sample, walked overground under various levels of body weight reduction performed with a Biodex BWU system. An electric winch pulled the system at a constant speed of 4km/h. The procedure included overground walking under a control (No vest), and three 0%, 15%, and 30% BWU experimental conditions.

Measures: Kinematic measures of the hip, knee, and ankle joints included peak angular displacement, and range of motion in the sagittal plane and joint trajectories. Kinetic measures included the peak moments and impulses in the sagittal and frontal planes of the hip, knee and ankle. The Electromyographic measures included the duration of EMG activity, peak EMG signal, and impulse of the EMG signal for the muscles examined, the tibialis anterior (TA), lateral gastrocnemius (Lat GC) and vastus lateralis (VL).

Kinematic, kinetic and EMG data were simultaneously recorded with a Vicon Nexus motion tracking system (Oxford Metrics Ltd). The foot center of pressure was calculated by using the force plate and marker data.

Results: Findings show that healthy subjects overgound gait under 0%, 15%, and 30% BWU levels did not exhibit any significant modification in flexion and extension kinematic parameters of the joints (Figure 1a). In contrast, the increase in BWU levels resulted in a significant decrease of peak moments and impulses in the sagittal and frontal planes (Figure 1b). Additionally, paired comparisons of kinetic and kinematic trajectories under three BWU levels show high correlations between trajectories ($r>0.95$; $p<0.001$). A significant inverse relationship was also observed between BWU levels and

EMG measures (Figure 1c). As the BWU level increased, the impulse of the TA, Lat GC and VL as well as the peak EMG activity of the TA and Lat GC decreased. In contrast, the BWU level did not affect the EMG signal trajectories of the muscles which remained highly correlated ($r>0.84$; $p<0.001$) under paired comparisons of BWU levels. Increasing the BWU level resulted in modifications of the foot center of pressure (COP), with a lateral shift in the coronal plane of the COP (Figure 1d) during stance.

Figure:

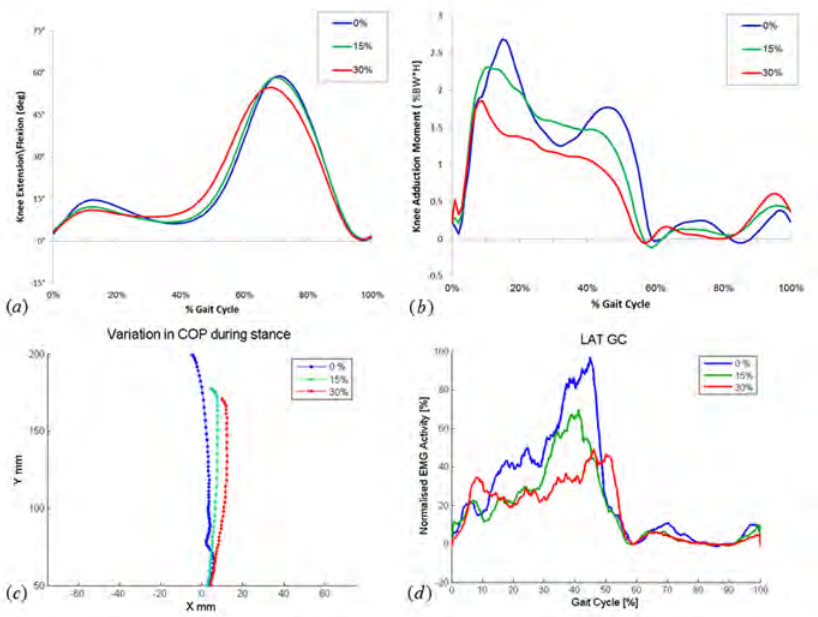

Figure 1. (a) Representative subject's Sagittal Plane Knee Flexion and Extension angle, (b) Frontal Plane Knee Adduction Moment, (c) EMG signal of the Lateral Gastrocnemius and (d) Center of Pressure under three 0% 15% and 30% BWU conditions.

Conclusion: A body weight reduction of up to 30% neither modified healthy subjects' overground gait patterns nor affected the plantarflexion needed for forward propulsion. The observed reduction in joint moments, the shift in COP and reduction in EMG activity resulting from BWU have wide implications in gait rehabilitation. These results suggest that BWU may safely be applied with clinical patients undergoing rehabilitation in situ, i.e., under conditions that replicate daily walking. This procedure is expected to reduce the load on joints and muscles without reducing the propulsive force so far observed on treadmills. As lower joints regain their functional activity with respect to balance, range of motion and locomotor patterns, patients' body weight may be gradually increased until they resume normal daily walking without any BWU. Potential applications of BWU on gait rehabilitation extend beyond clinical subjects with neurological or musculoskeletal impairments to sports injuries and/or obesity.

CAN GAIT KINEMATICS BE USED TO PREDICT RESPONSE TO STANDARDISED EXERCISE PROGRAMS IN INDIVIDUALS WITH KNEE OSTEOARTHRITIS?

Kathryn Mills [1,*] Michael Martin [2] Sean Osis [3] Blayne Hettinga [3] Reed Ferber [3]

[1]Physiotherapy, Macquarie University, Sydney, [2]Research School of Finance, Acturial Studies and Applied Statistics, Australian National University, Canberra, Australia, [3]Kinesiology, University of Calgary, Calgary, Canada

Introduction and Objectives: Three-dimensional kinematic gait analysis is often used in the assessment of individuals with medial tibiofemoral knee osteoarthritis (OA). Patients with knee OA have been reported to exhibit varus thrust and abnormal frontal plane knee mechanics, which may be associated with disease progression [1, 2]. With increasing adoption of motion capture technologies in clinical settings, an important question is which variables best guide clinical decision-making regarding patient care. Specifically, are there kinematic variables that can predict outcome to standardised conservative management? Being able to identify those who do and do not respond to a standardised exercise program has important clinical implications. Those who respond could undertake home- or group-based strategies, while those who do not may require a more tailored approach. Therefore, the aim of this study was to investigate whether and which baseline kinematic variables could be utilised to predict OA patients' outcome to a standard management strategy.

Methods: Twenty-three participants with mild-to-moderate knee OA were recruited to participate. All individuals were ≥40 years, had a BMI ≤33 kg/ m^2 and were able to walk on a treadmill without the assistance of walking aids. Participants underwent a kinematic assessment prior to participating in a 6-week lower limb strength and balance program. Gait analysis consisted of walking on a treadmill at 1.1 m/s, wearing standard laboratory shoes (Pegasus, Nike Air, OR USA). Kinematic data of the pelvis, hip, knee and ankle were collected at 120Hz using an 8-camera VICON motion capture system (Oxford Metrics, Oxford, UK) and 9 mm reflective custom marker set.

Data were analysed in Matlab (MathWorks, MA USA). An average of 20 stance phases were used to extract maximum joint angles during the first 25% of stance and joint excursions (maximum-minimum angle). The initial 25% of stance encompasses where the external knee adduction moment is greatest [3], often interpreted as when the medial tibiofemoral compartment is under the greatest load.

The 6-week home-based exercise program focused on hip muscle strengthening. Intensity was increased weekly by either increasing the number of repetitions or the resistance of elastic bands. The balance component of the program was progressed by reducing the base of support from bilateral to unilateral stance and by increasing activity duration. Program success was measured as worst pain over the previous week on a 100 mm visual analogue scale (VAS) from 0 (no pain) to 100 (worst pain imaginable). Pain ratings at the end of the intervention were subtracted from baseline measures and participants were deemed as success or non-success using the criteria of an improvement of ≥ 50% and absolute change in pain of ≥ 20 mm [4, 5].

Two classification and regression trees were fit to identify if and which baseline kinematic variables were best able to differentiate between participants who reported success and those who did not. The first tree examined the predictive ability of maximum joint angles during the first 25% of stance (25% Tree) and the second examined joint excursion (Excursion Tree). Only kinematic variables from the most affected limb were included in each model, as well as age and BMI. This analysis aims to correctly classify as many participants as possible based on a hierarchical sequence of binary splits. Each split was subjected to a penalty that balances goodness of fit against the ability to generalise the fit to the broader population.

Results: The Excursion Tree was able to classify the 9 participants who reported success and the 14 who did not using baseline kinematics, producing a single split, which successfully classified 55.55% of successful cases and all non-successful cases. The single kinematic variable found to be the best classifier was knee frontal plane excursion and all subjects who exhibited knee frontal plane excursion <8.9˚ were correctly classified as successful. The 25% Tree failed to split, meaning peak angles during the initial 25% of stance are no better than chance at directing clinical decision-making.

Conclusion: Kinematic variables observed during gait analysis were able to predict which individuals with mild-to-moderate medial knee OA will and will not respond to a standardised exercise program. Specifically, exhibiting <8.9˚ frontal plane knee excursion was found to be the best classifier. Given the sample size of the current study, our results must be interpreted with caution. However, they represent an important step towards providing clinicians with evidence-based guidance in how to integrate kinematic gait analysis in their clinical decision-making.

SHORT-TERM EFFECTS OF THORACIC SPINE MANIPULATION ON PAIN, FUNCTION AND SCAPULAR KINEMATICS IN SHOULDER IMPINGEMENT SYNDROME

Melina N. Haik [1,*] Francisco Alburquerque-Sendín [2] Paula Camargo [1]

[1]Physiotherapy, Federal University of São Carlos, São Carlos, Brazil, [2]Physiotherapy, University of Salamanca, Salamanca, Spain

Introduction and Objectives: Thoracic spine manipulation (TSM) has been proposed to treat individuals with shoulder impingement (SI) due to the regional interdependence among the shoulder and thoracic and cervical spines. Nevertheless, the effects on pain and function have been questioned recently and little evidence exists about the effects of TSM in scapular kinematics in this population. This study evaluated the short-term effects of a low-amplitude, high-velocity thrust TSM on pain, function and scapular kinematics during elevation of the arm in individuals with SI.

Methods: Fifty individuals with SI were randomly assigned to 1 of 2 interventions: TSM (n=25) or sham TSM (n=25). Both groups received the selected interventions twice with an interval of 3-4 days between them and were evaluated in 3 days. The assessor, who was blinded to group assignment, measured shoulder pain (Numerical Pain Rating Scale) and scapular kinematics (three-dimensional electromagnetic system) at day 1 (pre-intervention 1), day 2 (pre-intervention 2), and at day 3 (3-4 days follow-up after the second intervention) during 3 trials of elevation of the arm in the sagittal plane. All individuals also completed the Disabilities of the Arm, Shoulder and Hand questionnaire (DASH) at the beginning of each day of evaluation (pre-intervention 1, pre-intervention 2 and follow-up) to assess function of the upper limbs. An intention-to-treat analysis was carried using the average of multiple imputations for missing data (n=6) with SPSS software. The mean of the 3 trials was used for statistical analysis. Kinematic motion analysis involved selecting scapular data at 30°, 60°, 90° and 120° of arm elevation. A 2-factor analysis of variance (time and angle) was performed for each scapular kinematic in each group to identify differences along time and a 1-factor analysis of variance verified differences between time in each group for NPRS and DASH score.

Results: Numerical Pain Rating Scale following interventions did not change in any group ($p>0.05$) and DASH score decreased along time in both groups ($p=0.02$), but the change did not reach the minimal important difference of 10 points. No significant double interactions (time by angle) were found for any scapular rotation ($p>0.05$). However, main effects of time were found as following. In the TSM group scapular internal rotation decreased 4.1° from pre-intervention 1 to pre-intervention 2 ($p<0.001$) and increased 3.3° from pre-intervention 2 to follow-up ($p=0.001$), while in the sham TSM group it increased 2.4° from pre-intervention 1 to follow-up ($p=0.001$). Upward rotation increased 2.8° from pre-intervention 1 to pre-intervention 2 in the TSM group ($p=0.005$), while in the sham TSM group it decreased 2.4° from pre-intervention 2 to follow-up ($p=0.007$). Scapular tilt showed no differences in the TSM group while in the sham TSM group anterior tilt increased 2.2° and 1.8° from pre-intervention 1 to follow-up and pre-intervention 2 to follow-up, respectively.

Conclusion: Only one session of TSM produces a small, potentially non-clinically meaningful decrease in internal rotation and increase in upward rotation of the scapula in subjects with SI during elevation of the arm in a short-term. However,

these effects were neither cumulative nor lasting for about 4 days and do not seem to be related with relief in pain and improvement in function. More studies are necessary to conclude on the possible effects of TSM in individuals with SI.

PLAYING THE GOBLIN POST OFFICE VIRTUAL REHABILITATION GAME AT HOME

Andrew J. Murphy [1,*] Mohammad Al-Amri [2] Malcolm B. Hawken [3] Gabor J. Barton [3]

[1]Biomedical Engineering, University of Strathclyde, Glasgow, [2]School of Healthcare Sciences, Cardiff University, Cardiff, [3]Research Institute for Sport and Exercise Sciences, Liverpool John Moores University, Liverpool, United Kingdom

Introduction and Objectives: Cerebral Palsy (CP) may be considered “the most common physically disabling condition seen and managed by child health professionals” [1]. Children suffering from CP often display diminished control of trunk and pelvis movements, which can reduce their ability to achieve well controlled movement of the lower limbs and ultimately have a negative effect on activities of daily living [2,3]. Previous work has highlighted that it is possible to monitor trunk-pelvis coupling and core movement in children, and to enhance movement patterns via the use of a virtual reality gaming application (Goblin Post Office, GPO) in laboratory based training [2,3]. The primary aims of this study were to establish the feasibility and acceptability of conducting such training in CP children’s homes, and to quantify the short term effect of GPO training.

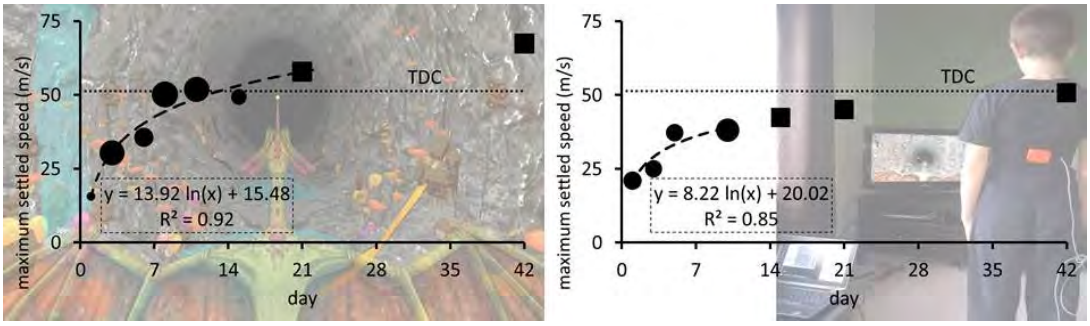
Methods: Ethical approval for this study was granted by the University of Strathclyde Ethics Committee. Two children with Cerebral Palsy (CPC1 and CPC2) volunteered (Table 1). One typically developing child (TDC) also participated by playing a single session of the game in order to provide data against which CPC performance could be compared. All children and their parents provided informed consent.

Figure 1 illustrates the setup used in children’s homes. Full detail of the adaptive algorithm that drives GPO may be found by consulting previous work [2,3], however, briefly, the aim of GPO is to use rotations of the trunk and/or pelvis to navigate a virtual dragon through a virtual cave and, using the horn protruding from the dragon’s head, to “burst”/hit targets that contain virtual letters (Figure 1). Forward speed of the dragon’s flight is continuously moderated based on a bespoke adaptive algorithm and thus over a training session it is possible to extract a “maximum settled speed” (MSS) which is representative of overall game performance.

On training days the investigators visited CPC’s home, attached a laptop to the children’s television using a VGA cable and attached a single Xsens-MTx-sensor (Xsens Technologies, The Netherlands) to CPC’s trunk using a semi elastic Velcro strap; this sensor measured trunk tilt and rotation and thus navigated the flying GPO dragon shown on the television screen. CPC conducted 1-3 training sessions per training day (Table 1).

Results: All testing was conducted safely and easily; from a technical perspective all that was required of participants’ homes was a television set with a VGA input. Anecdotal evidence suggested that all children and parents enjoyed the experience and did not find the process disruptive to their normal routine; further, as the days progressed the investigators’ notes included comments such as “showing motivation and competition”, “better controlled stance”, “less sporadic arm movements”. Figure 1 shows the results of data analysis.

Figure:



Caption: Maximum settled speed achieved by CPC1 (left) and CPC2 (right). Data is shown for the duration of the training period (circles) and as projected according to a logarithmic fit for up to six weeks of training (squares). Data points are scaled according to the duration in minutes of GPO gameplay that was conducted on each training day. The baseline data for TDC is shown by the horizontal dotted line. Semi-transparent background images show the game interface and home setup used.

Conclusion: It is acknowledged that in order to provide satisfactory evidence of the effect of GPO in the home a larger study must be carried out. However, anecdotal feedback supported the suggestion that GPO training in the home is a feasible and acceptable form of therapy for children with Cerebral Palsy and also that the investigators' subjective assessment of performance, balance and control showed improvement over the training period. Data analysis also suggested improvement in game performance; indeed CPC1 ultimately (marginally) exceeded the baseline performance of TDC. Further work is merited.

Table:

	CPC1	CPC2	TDC
age	8 years	8 years	10 years

VIRTUAL REALITY-TREADMILL COMBINED TRAINING PROGRAM TO IMPROVE GAIT IN MULTIPLE SCLEROSIS INDIVIDUALS

Agnese Peruzzi [1 2,*] Andrea Cereatti [1 2] Ignazio Roberto Zarbo [3] Anat Mirelman [4] Ugo Della Croce [1 2]

[1]POLCOMING, University of Sassari, [2]Interuniversity Centre of Bioengineering of the Human Neuromusculoskeletal System, [3]Department of Clinical and Experimental Medicine, University of Sassari, Sassari, Italy, [4]Department of Neurology, Center for the study of Movement, Cognition and Mobility, Tel Aviv Sourasky Medical Center, Tel Aviv, Israel

Introduction and Objectives: Weakness, spasticity and ataxia are common in multiple sclerosis (MS), often leading to gait abnormalities and falls [1]. Compared to healthy subjects, MS individuals show reduced stride length and walking speed, prolonged double limb support duration and greater variability in lower limb kinematics during gait [2]. Moreover, fatigue is a prevalent symptom and it can limit walking endurance. Effective gait interventions are, therefore, crucial in MS. Treadmill training (TT) has been successfully used [2]. Recently, TT has been augmented with virtual reality (VR), which allows subjects to train cognitive and motor aspects simultaneously (dual tasking), decreasing their perception of exertion and improving motivation and skill attainment [3]. The combined use of TT and VR (TT-VR) has shown promising results in neurological diseases [3, 4]. A pilot study showed that TT-VR positively affects gait of MS individuals under dual tasking [5]. The present study aims at investigating the efficacy of a six-weeks TT-VR on gait of MS subjects under single and dual task conditions and to compare its effects to TT alone. We hypothesize that both interventions will improve gait in single task, but that TT-VR will improve gait in dual task.

Methods: A parallel group controlled trial with three months follow-up is employed. The study includes 40 subjects with relapsing remitting MS (EDSS:3-5.5,MMSE≥26) with stable medical and clinical conditions in the six months prior to the study. The study is in progress: so far, 17 participants have been recruited from the Neurology Unit at Sassari University Hospital (10f, age:40±8), have been randomly assigned to the TT-VR or to the TT and are currently participating in the training. The set-up includes a treadmill with a harness, an LCD screen used to deliver the VR, two magneto-inertial sensors, attached to the subject's shoes and used to reproduce real-time feet motion in the VR, and an additional unit, placed on the subject's head and used to move the VR accordingly [6] (Figure). In the TT-VR the participants walk on the treadmill while watching a virtual tree-lined trail and are asked to pass the obstacles appearing on the trail. Successful and unsuccessful passes, as determined by the inertial measurements, are rendered to the subject with visual/acoustic feedback. Cognitive concurrent tasks are added to the VR to challenge their attention. The obstacles properties are modified according to the severity of the motor limitations and adapted during the training to increase task complexity. Trainings is provided three days/week for six weeks. Progression is based on a study of individualized TT for neurological subjects [4]. To assess training effects, a gait analysis is performed before, immediately, one and three months after the intervention with and without a concurrent cognitive task (dual and single task, respectively). Selected gait, joint kinematics and kinetics parameters are estimated using a six-cameras stereophotogrammetric system (Vicon B10, 100 frames/s), two force platforms (AMTI, 1000 frames/s) and the Vicon Plug-in Gait marker set. Five trials are evaluated for

each condition. Only data at baseline for 17 subjects are reported. Mean and standard deviation are computed across patients and a paired t-test (a=0.05) is used to compare single and dual task conditions.

Results: Lower limb joint kinematics did not show any difference between single and dual task. Both gait speed, cadence and maximum ankle muscular moment and power, significantly decreased in dual task (Table).

Figure:

Caption: Experimental set-up

Conclusion: Dual tasking is typical in everyday life and increases the burden of gait of MS subjects. The TT-VR is an intensive individualized gait intervention which trains MS individuals to better manage cognitive processes, such as reasoning, planning and problem solving during walking. We are conducting a controlled trial to assess efficacy of a six-weeks TT-VR training for patients with MS. Patients are expected to significantly improve gait in dual task, decreasing fall risk and increasing quality of life.

Table:

parameter	measurement unit	single task	dual task
ankle PF(loading response)	deg	-8(4)	-7(3)
ankle DF		12(4)	12(4)

EFFECT AND SUSTAINABILITY OF A HIPPOTHERAPIE-K-INTERVENTION IN ADULTS WITH CEREBRAL PALSY WHILE STAIR CLIMBING.

Martina Binzen [1,*]Carmen Gempp [1]Eveline Rich [1]Julia Ruf [1]Lukas Stammler [2]Philippe Merz [2]Ruth Obrist [3]Beat Göpfert [4 5]

[1]Physiotherapy, Health Division, Bern University of Applied Sciences, Bern, [2]BZG, Bildungszentrum Gesundheit Basel-Stadt, Münchenstein, [3]Hippotherapie Obrist, Kaiseraugst, [4]Center of Biomechanics, CMBE, University of Basel, [5]Laboratory for Movement Analysis , Children's University Hospital Basel (UKBB) Basel, Basel, Switzerland

Introduction and Objectives: Stair climbing is a simple daily task for a healthy person but for someone with cerebral palsy (CP) it needs often an extra effort, additional force [1], coordination [2], and balance requirements. This is often visible in an arrhythmic and asymmetrical movement pattern with a longer stance phase [3]. The goal of this Time-Series-Study was to analyze the effect and sustainability of an 18 week Hippotherapy-K intervention in hemiplegic adult CP-patients while stair climbing and compare it before and after the intervention, and 18 weeks post intervention within each subject and with a healthy control-group. Further, during the intervention only Hippotherapy-K (once a week, 30 – 40 min, outdoor) was done, all other physical therapies were stopped.

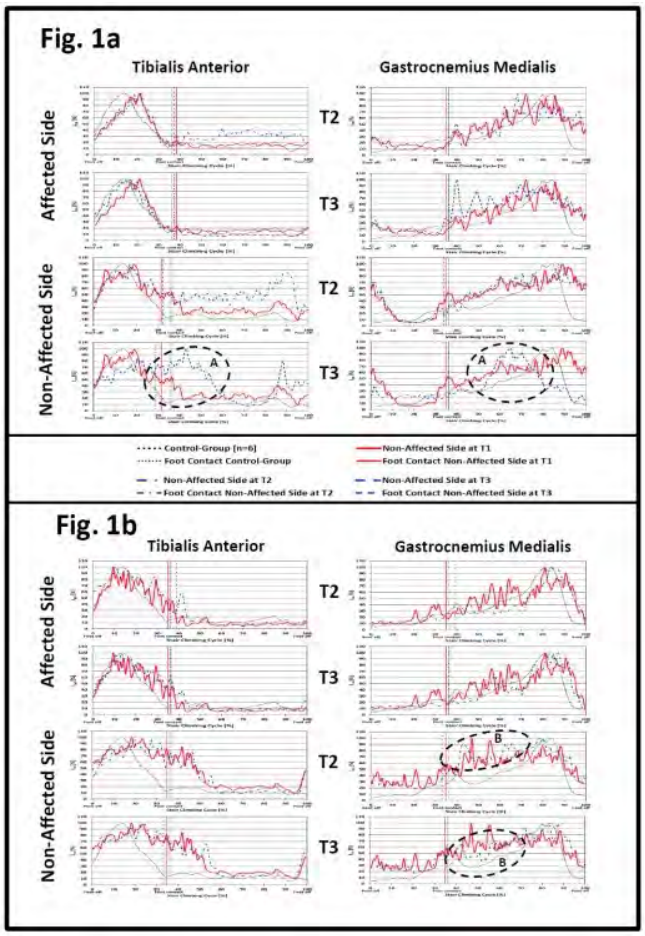
Methods: 6 subjects with a hemiplegic CP (22-46 y, 5m, 1f, 3 to 6 trials) were performing an instrumented 3-D gait analyses (Vicon, 12 cameras T20, 200Hz) and surface EMG (Biovison, 2400Hz.), while climbing a 4 step stair at a self-selected speed and style at defined time points. The measurements were done before the intervention (T1), as a baseline, after the 18 weeks of Hippotherapy-K (T2) and 18 weeks post intervention (T3). The kinematic data of the lower body and normalized Wavelet transformed EMG-Total-Intensity (I_{tot}) of the muscles: Tibialis anterior (TA), and Gastrocnemius medialis (GM) were time normalised and averaged over a Stair Climbing Cycle (SCC) starting at the foot-off of the lower step (0%) and finishing at foot-off for the same leg at the next following step (100%). The changes were compared to T1 and with the healthy control-group.

Results: The results show individual changes between T1, T2 and T3 for the 6 CP-subjects. The changes form the measurements at T1 to T2 show that 3 subjects are climbing the stairs faster but with a less symmetrical duration of the stance phase. This is seen in the bigger difference between the duration of the stance phase for the affected and non-affected side. Further 2 other subjects are slower ascending the stairs and 1 does it at the same speed. The changes at T3 have even more variability, 2 subjects are slower than at T1 and T2, 2 are faster than at T1, but slower compared to T2, however become more symmetrical in the stance phase duration. Finally the last 2 ones climb faster than at T1 and T2, and show a more asymmetrical duration of the stance-phase.

The I_{tot} pattern changes for all subjects between the 3 measurements. An example of a subject is shown in Fig. 1a, where an increased asymmetrical stance phase duration leads to longer and higher I_{tot}-level in the other leg. This subject has the same speed at T1 and T2, and increases it at T3 by 8%, but gets less symmetrical, visible in TA-I_{tot} and GM-I_{tot}-pattern of the non-affected side at T2 and T3 (A). Further bigger angular variations occur at foot contact in the knee- and ankle joint as well as in the angle between the foot and the surface of the stairs. The effects of the changes in the gait symmetry during stair climbing are seen in another subject in Fig 1b. This one climbs at T2 and T3 slower compared to T1, further it

decreases the gait symmetry within the duration of the stance phase at T2, but increases it at T3. The result of the more symmetrical stance phase is seen in the GM- I_{tot} –pattern (B), as it gets closer to the pattern of the control group.

Figure:



Discussion

The results of the study showed a delectable effect of the Hippotherapy-K intervention within CP-patients while stair climbing, although we could recruit a small number of subjects in our area. The varying results in stair climbing like changes in speed and duration of the stance phase between T1 and T2, indicates an individual, but measurable effect of the Hippotherapy-K intervention. This individual effect might be linked to the “differential learning strategy” stated by Schöllhorn [4], because during a 30 to 40 min. Hippotherapy-K session a high number of similar but varying 3D-movement, some may even demand fine motor skills, have to be performed by the patients and may allow them to learn new movement patterns and also use these variations.

The changes between T2 and T3 show some sustainability of a Hippotherapy-K intervention, which are again subject individual and might be related to their daily activity and therapy program.

Conclusion

The results of the study showed that Hippotherapy-K intervention had an effect on the stair climbing, which each subject used its own way. Therefore we think Hippotherapy-K should be seen as a complementary therapy to the regular program towards a holistic approach.

RELATION BETWEEN RIB KINEMATICS AND LUNG VOLUMES: COMPARISON BETWEEN NORMAL SUBJETCS AND CYSTIC FIBROSIS PATIENTS

Benoit Beyer[*1,2], Véronique Feipel[1], Victor Sholukha[2], Laurence Chèze[3], Serge Van Sint Jan[2]

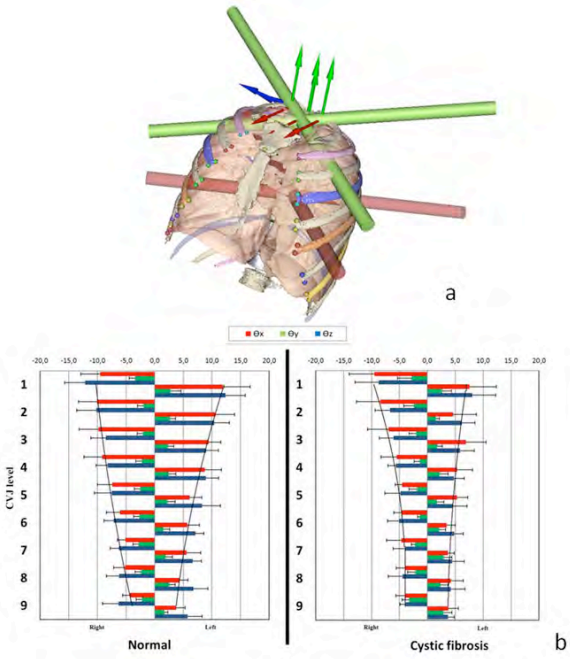
[1]Laboratory of functional anatomy, [2]Laboratory of Anatomy Biomechanics and Organogenesis, Université Libre de Bruxelles ULB, Brussels, Belgium, [3]Laboratoire de biomécanique des chocs LBMC, UMR_T 9406, Université Lyon1, Lyon, France

Introduction and Objectives: Relation between rib kinematics and thorax global shape variations is described in the literature but data and analysis of segmental costovertebral joint complexes (CVJ) kinematics are lacking. A thorax 3D model of breathing motion was previously obtained and rib kinematics relative to vertebra was analyzed for upper thoracic levels in a sample of asymptomatic subjects (1). This study proposes an extended description in normal subjects from thoracic levels 1 to 9 and attempts to analyse the relation between inspiratory capacity and rib kinematics. The full method is then applied to a sample of patients with cystic fibrosis.

Methods: *In vivo* computed tomography (CT) imaging was obtained at three different lung volumes (total lung capacity, middle of inspiratory capacity and functional residual capacity) calibrated according to plethysmography. Data from 9 patients with cystic fibrosis and 10 asymptomatic subjects were processed using a previously described method (1). 3D models of ribs and vertebrae were reconstructed for thoracic levels 1 to 9. Custom made software was used for virtual palpation (2) aiming to define 5 anatomical landmarks (ALs) on each vertebra and rib. Local anatomical coordinate systems were constructed following anatomical planes (figure 1a). Kinematics was processed using orientation vector and mean helical axis parameters (MHA) at each level to obtain angular displacements around each reference axis. A fusion method (2) of ALs with 3D models was used to obtain visualisation of both motion and kinematic parameters. Non parametric statistical test for independent samples was used to analyse the influence of pathological conditions on kinematics parameters. Pearson's correlation coefficient was used to analyse the link between kinematics and anthropometrical parameters in both groups.

Results: An advanced 3D model of continuous motion and kinematic parameters visualisation was achieved. Rib angular displacements occurred around dorso-ventral (i.e. pump handle motion) and medio-lateral (i.e. bucket handle motion) axes similarly at each CVJ level and MHA orientations were similar. Mean ranges of motion around both axes decreased with rib number (figure 1b) in both groups (around lateral axis: [from 12.2° to 5.7°] from level 1 to 9 in normal subjects; [from 8.7° to 3.6°] in cystic fibrosis group; around medio lateral axis: [from 9.5° to 3.8°] in normal subjects; [from 9.5 to 3.7°] in cystic fibrosis group). A correlation was found between rib kinematics around the medio-lateral axis and inspiratory capacity only in the cystic fibrosis group ($r > 0.7$). Significant differences in rib kinematics around the medio-lateral axis were found between groups ($p < 0.05$) at almost all thoracic levels.

Figure:



Caption: Figure 1: (a) 3D model of full thorax with mean helical axes CVJ levels 1 (green) and 7 (red). (b) Mean ranges of motion Θ in degree around x,y and z axes at CVJ levels [1-9] in both groups.

Conclusion: The 3D model of the costovertebral joint during breathing allows visualisation and quantification of segmental kinematics parameter. The influence of a clinical condition was tested and it appeared that kinematics parameters were reduced in patients with cystic fibrosis. Correlation between segmental kinematics and inspiratory capacity was demonstrated only in the cystic fibrosis group but not in normal subjects. These results suggest the hypothesis of an influence of external parameters on volume displacement such as an increase of respiratory muscle activity in patients with cystic fibrosis (3).

'BIG DATA' MOTION ANALYSIS

at Strathclyde's 'ISB EXPERIMENT'

2012

Motekforce Link introduced the **GRAIL**, which stands for Gait Real-time Analysis Interactive Lab. This total package solution for gait analysis and training uses dual-belt instrumented treadmill with fast pitch and sway and motion capturing in an interactive and dynamic Virtual Reality environment.

NOW

Motekforce Link proudly introduces the **M-Gait** system: An instrumented dual-belt treadmill and the **D-Flow** software, as a start of your lab. The **M-Gait** is a modular approach, enabling various system enhancements to improve the functionality of your set-up, with options to include:

- Treadmill with fast pitch and sway
- 3D motion capturing
- Real-time biomechanical Human Body Model
- EMG, accelerometers, etc.
- Interactive Virtual Reality system (VR)
- Body Weight Support

VISIT US!

At Booth 21 or see the **M-Gait** during the University of Strathclyde's "ISB Experiment" in the exhibition hall.

DIFFERENCES IN ANATOMICAL PARAMETERS BETWEEN THE AFFECTED AND UNAFFECTED HIP IN PATIENTS WITH BILATERAL CAM-TYPE DEFORMITIES

K.C. Geoffrey Ng [1,*] Mario Lamontagne [1,2] Paul E. Beaulé [3]

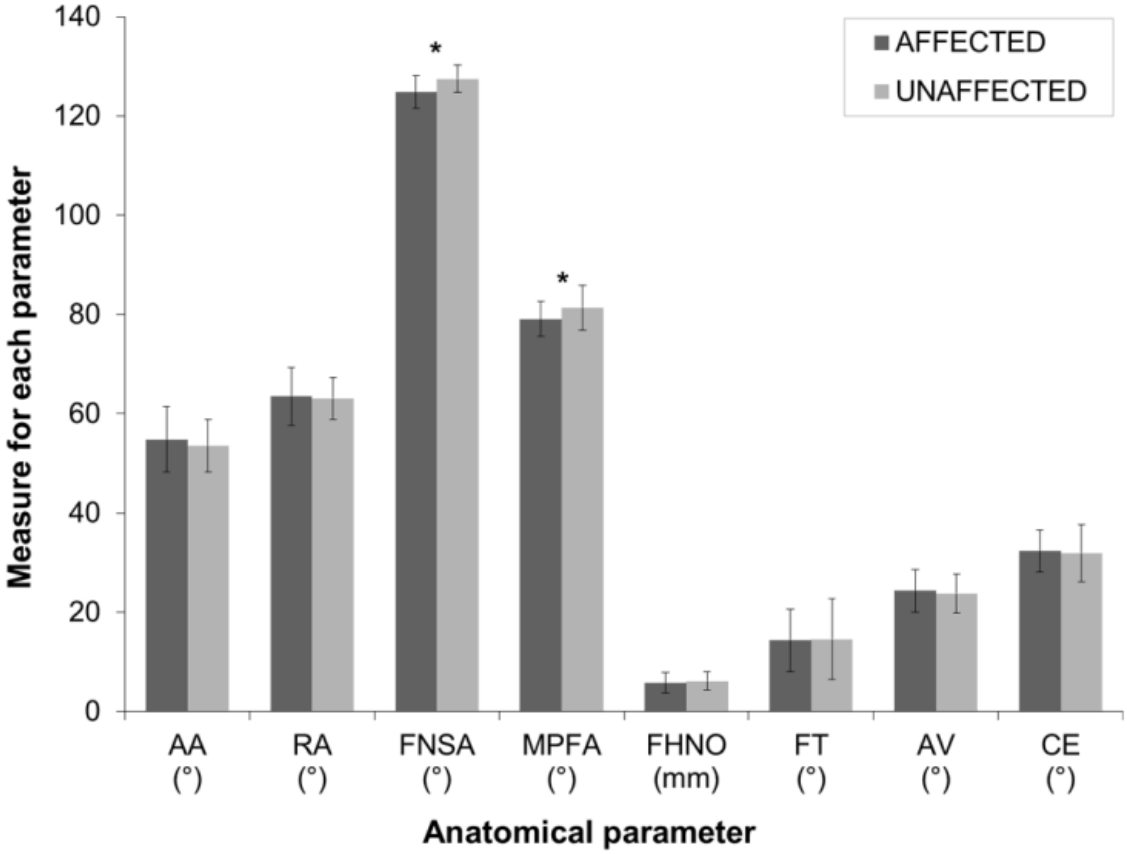
[1]Department of Mechanical Engineering, [2]School of Human Kinetics, [3]Division of Orthopaedic Surgery, University of Ottawa, Ottawa, Canada

Introduction and Objectives: Cam-type femoroacetabular impingement (FAI), characterized by an enlarged, aspherical femoral head deformity, results in adverse hip joint loading and eventual osteoarthritis [1]. It is still unclear why many individuals with bilateral cam deformities demonstrate only unilateral symptoms. The presence of a large cam deformity, indicated by elevated alpha angles, may not be sufficient to explain symptomatology [2], thus FAI may be attributed to additional anatomical parameters [3]. The purpose was to examine patients with bilateral cam-type deformities, who demonstrate unilateral FAI symptoms, and compare the anatomical hip joint parameters between their affected (symptomatic) and contralateral, unaffected (asymptomatic) hips.

Methods: Twenty-two patients initially presented themselves with primary unilateral hip pain, clinical signs, and were confirmed to have a cam deformity on imaging data, with an axial or radial alpha angle higher than 50.5° or 60°, respectively [4]. Patients underwent pelvic and knee computed tomography (CT) imaging as well as a physical examination, evaluating their affected hip and their contralateral, unaffected hip's flexion, straight-leg raises, internal and external rotations. Patient-specific CT data were blinded and evaluated for multiple anatomical parameters associated with FAI symptoms [3, 5, 6], including: axial (AA) and radial alpha (RA) angles, femoral neck-shaft angle (FNSA), medial proximal femoral angle (MPFA), femoral head-neck offset (FHNO), femoral torsion (FT), acetabular version (AV), and centre-edge (CE) angle; for both hips, using Onis 2.4 (DigitalCore, Japan). CT measurements were performed by two readers, each performing two readings. Twenty patients (n = 20; age = 37 ± 8 years; BMI = 26 ± 5 kg/m^2) indicated elevated alpha angles for both affected (AA = 55 ± 7°; RA = 64 ± 6°) and unaffected hips (AA = 54 ± 5°; RA = 63 ± 4°), confirming bilateral cam deformities; whereas two patients were excluded for unilateral-only deformities. A paired sample t-test was computed, using SPSS Statistics v.20 (IBM Corporation, USA), to compare differences in anatomical parameters and physical examination measurements, between the patients' affected and unaffected hips (CI = 95%).

Results: Intra- and inter-reader anatomical observations were in strong to near-perfect agreement (ICC > 0.75). The affected hip demonstrated substantially reduced hip flexion, leg raise, internal and external rotations, in comparison with the unaffected hip (Table 1). There were no differences in cam deformity parameters (AA angle, RA angle, FHNO) as well as FT, AV, and CE angle, between affected and unaffected hips (Figure 1). Many patients (40%) actually had higher alpha angles on their unaffected hips. There was a significant difference in FNSA, between affected (124.8 ± 3.3°) and unaffected hips (127.5 ± 2.8°; t(19) = -4.2, p = 0.001); as well as a difference in MPFA, between affected (79.1 ± 3.5°) and unaffected hips (81.4 ± 4.5°; t(19) = -2.8, p = 0.01).

Figure:



Caption: Figure 1. Patient-specific anatomical parameters, comparing the affected and contralateral, unaffected hip (*significant difference, $p < 0.05$)

Conclusion: To our knowledge, no study has incorporated a patient cohort with bilateral cam deformities, to examine differences in anatomical parameters. The physical examinations confirmed that the affected hip had restricted ranges of motion, indicative of FAI, which could be attributed to a combination of elevated alpha angles and decreased neck angles. Interestingly, several patients had larger cam deformities in their unaffected hip. This further supports that large cam deformity, alone, cannot explain symptomatology and does not lead to FAI [3]. The femoral neck angles (FNSA, MPFA) were the significant parameters [3, 5, 6], which can potentially predict which hip experiences early symptoms, in individuals with bilateral cam deformities. The coxa vara structure, seating the femoral head further into the acetabulum and, thus, altering the abductor moment and bringing the cam deformity closer to the anterosuperior labrum, can further explain differences in clinical signs, and as to why the asymptomatic hip does not experience early symptoms. The ongoing study will examine asymmetry and if compensatory load is applied onto the contralateral hip due to neuromuscular compensation.

Table:

Physical Examination	Affected Hip	Unaffected Hip
Hip Flexion (°)	123 ± 14	130 ± 20
Straight-Leg Raise (°)	90 ± 17	97 ± 16
Internal Rotation (°)	31 ± 15	38 ± 12
External Rotation (°)	32 ± 21	42 ± 19

Caption: Table 1. Summary of patient physical examinations, comparing the affected and contralateral, unaffected hip

MRI-BASED GEOMETRICAL DETAIL AFFECTS HIP CONTACT FORCES MORE THAN COST FUNCTION FORMULATION

Mariska Wesseling [1,*] Friedl de Groote [2] Lode Bosmans [1] Ward Bartels [2 3] Christophe Meyer [4] Kaat Desloovere [4] Ilse Jonkers [1]

[1]Department of Kinesiology, [2]Department of Mechenical Engineering, KU Leuven, Leuven, [3]Mobelife NV, Heverlee, [4]Department of Rehalibation Sciences, KU Leuven, Leuven, Belgium

Introduction and Objectives: Modeling choices, e.g. the level of subject-specific detail included in the model, as well as cost function formulation affect calculated hip contact force (HCF). The goal of this study was to assess the relative importance of introducing subject-specific detail in bone and muscle geometry, derived from magnetic resonance imaging (MRI), in the musculoskeletal model compared to introducing minimization of hip contact forces in the optimization criterion on calculated hip contact forces during gait. Additionally, the effect of accounting for muscle wrapping around the hip joint capsule was evaluated.

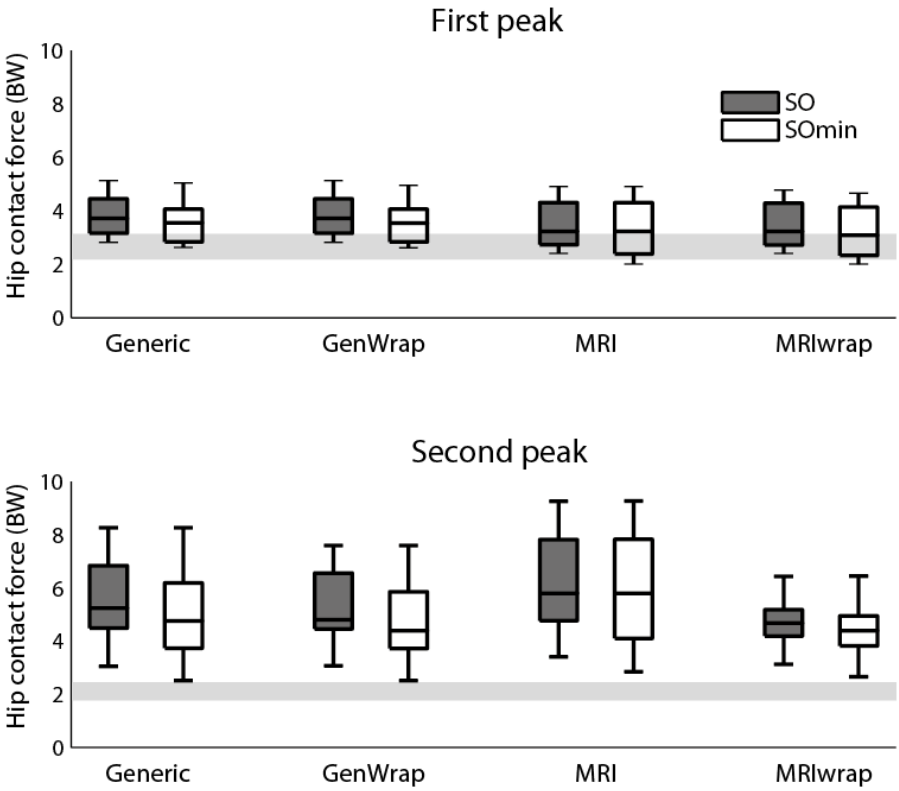
Methods: Five subjects (54±6 yrs.) walked at self-selected speed (1.29±0.23 m/s). 3D marker trajectories were captured using Vicon (Oxford Metrics, UK) and force data was measured using two AMTI force platforms (Watertown, MA). MR-images were acquired (Philips Ingenia 3.0T) of all subjects while lying supine.

A musculoskeletal model consisting of 14 segments, 19 degrees of freedom and 88 musculotendon actuators was used [1] and all analyses were performed in OpenSim 3.1 [2]. Firstly, the generic model was scaled using the marker positions of a static pose. Secondly, a MRI-model was created using in house developed software and contained the subject-specific bone structures and muscle paths of all hip and upper leg muscles [3]. Thirdly, wrapping surfaces for the hip flexor muscles were added to the MRI-model, to reflect the effect of the hip joint capsule (MRIwrap). The trajectory of iliacus and psoas major around the hip joint was described using nine points in the MR-images. Two circles were fitted through these points, one defining a wrapping sphere for iliacus, rectus femoris and sartorius and one defining a wrapping surface for the psoas major. Finally, two average wrapping surfaces were created based on the five subjects and were added to the generic model (GenWrap). This model was scaled to the dimensions of each subject, resulting in a total of four models. For all models, an inverse kinematics procedure was used to calculate joint angles. Muscle forces were calculated using static optimization by minimizing squared muscle activity (SO), as well as by minimizing the weighted sum of squared muscle activity and magnitude of HCF (SOmin). Next, HCFs were calculated and first and second peak HCF, normalized to body weight (BW), were compared to contact forces measured using instrumented hip prostheses (HIP98) [4].

Results: Results show that by including MRI-based geometrical detail into the model, HCFs decrease and are more comparable to contact forces measured using instrumented prostheses (figure 1; table 1). Including MRI-based geometrical detail and wrapping surfaces have the largest effect on the magnitude of HCFs, by decreasing HCF up to 0.72 BW for the MRIwrap compared to generic model. Including wrapping surfaces results only in decreased contact forces at the second peak as at this time instant the muscles wrap over the surfaces, thereby increasing the muscle

moment arm. Including minimization of the hip contact forces in the optimization criterion also decreases HCFs, up to 0.48 BW.

Figure:



Caption: Figure 1. The magnitude of hip contact force at the first and second peak for the different musculoskeletal models using SO (dark gray) and SOmin (white). The light gray zones indicate the range of measured hip contact forces [4].

Conclusion: Inclusion of MRI-based subject-specific information in the musculoskeletal model results in HCFs that are more comparable to contact forces measured using instrumented prostheses. Including wrapping surfaces for the hip flexor muscles in the MRI model has a large effect on the contact forces. Including a minimization of HCFs in the optimization criterion also decreases contact forces, however to a lesser extent than including subject-specific wrapping surfaces. Also, when wrapping surfaces are included in the generic model (GenWrap), contact forces decreased and are closer to forces measured using instrumented prostheses (table 1). Therefore, our findings suggest that inclusion of subject-specific geometrical detail in the MRI-based musculoskeletal model is more important than altering the optimization criterion.

Table:

		Δ HCF (BW) with HIP98		Δ HCF (BW) with Generic	
		First peak	Second peak	First peak	Second peak
SO	Generic	1.17	3.01	0.00	0.00
	GenWrap	1.17	2.76	0.00	-0.25
	MRI	0.83	3.63	-0.34	0.62
	MRIwrap	0.82	2.29	-0.35	-0.72
SOmin	Generic	0.92	2.43	-0.25	-0.58
	GenWrap	0.91	2.21	-0.26	-0.8
	MRI	0.69	3.38	-0.48	0.37
	MRIwrap	0.55	2.07	-0.62	-0.94

Caption: Table 1. Average of differences in resultant hip contact force (normalized to body weight (BW)) with the contact forces measured using instrumented prostheses (HIP98) as well as with contact forces calculated for the generic model at the first and second peak hip contact force.

SIMULATION OF IMPINGEMENT AND MICRO-SEPARATION FOR TOTAL HIP REPLACEMENTS DURING STAIR CLIMBING

Amir A. Al-Munajjed [1,*] Michael Damsgaard [1] John Rasmussen [2]

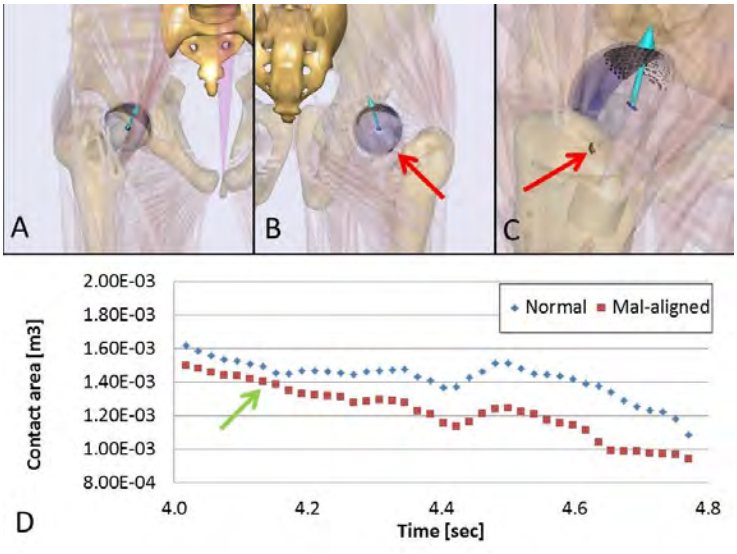
[1]R & D, AnyBody Technology, [2]Department of Mechanical and Manufacturing Engineering, Aalborg University, Aalborg, Denmark

Introduction and Objectives: The total number of total hip replacements (THR) is rising in the past years particularly in younger patients. These patients have different expectations from the elderly in terms of range-of-motion and possible activities, like sports. These activities can lead to complication like impingement, separation and micro separation in the THR. The objective of this study was to analyze such complication in the THR due to the variation of the cup inclination using a musculoskeletal simulation approach for stair climbing.

Methods: A male subject was recorded climbing stairs using a motion capture system (SIMI, Munich, Germany). This data was used to build a musculoskeletal model in the AnyBody Modeling System v6.1 (AnyBody Technology, Aalborg, Denmark). The standard anatomical hip joint was replaced by a generic hip implant comprising a simple stem with ball and a cup. Different cup alignments in terms of anteversion and abduction angle of the acetabular cup have been analyzed. A mal-alignment was introduced to enforce impingement. The force dependent kinematic solver was used instead of the standard inverse dynamics solution to detect and simulate the kinetic effect of the impingement. The contact area between femoral ball and acetabular cup were computed.

Results: The contact area is shown in figure 1 during the stair climbing activity for two different cup inclinations, one normal and the other mal-aligned. This leads to impingement between stem and ball (figure 1A-C), the contact area is reduced and concentrated to the rim area, figure 1D. Additionally, micro separation could be seen in the model between ball and cup.

Figure:



Caption: Screenshot of a mal-aligned THR during stair climbing in [A] anterior, [B] posterior and [C] magnified lateral view showing impingement (red arrow,) and [D] contact area graph for normal and mal-aligned cup with time of impingement (green arrow).

Conclusion: This study shows that complications like impingement and separation can be seen during stair climbing with a mal-aligned cup position. The mal-alignment shows even before impingement a reduced contact area, however, after impingement, a high concentration of forces at the rim area can lead to increase in wear in the THR. Even though, the mal-alignment in this subject was severe, these results can be very useful to understand clinical complication with THR. Future work will focus on including other daily activities and to include the results in wear tests simulation.

WEAR OF CROSS-LINKED UHMWPE HIP REPLACEMENTS USING AN ELECTROMECHANICAL HIP JOINT SIMULATOR UNDER TWO-AXIS AND THREE-AXIS OF ROTATION CONDITIONS

Murat Ali [1,*] Mazen Al-Hajjar [1] John Fisher [1] Louise M. Jennings [1]

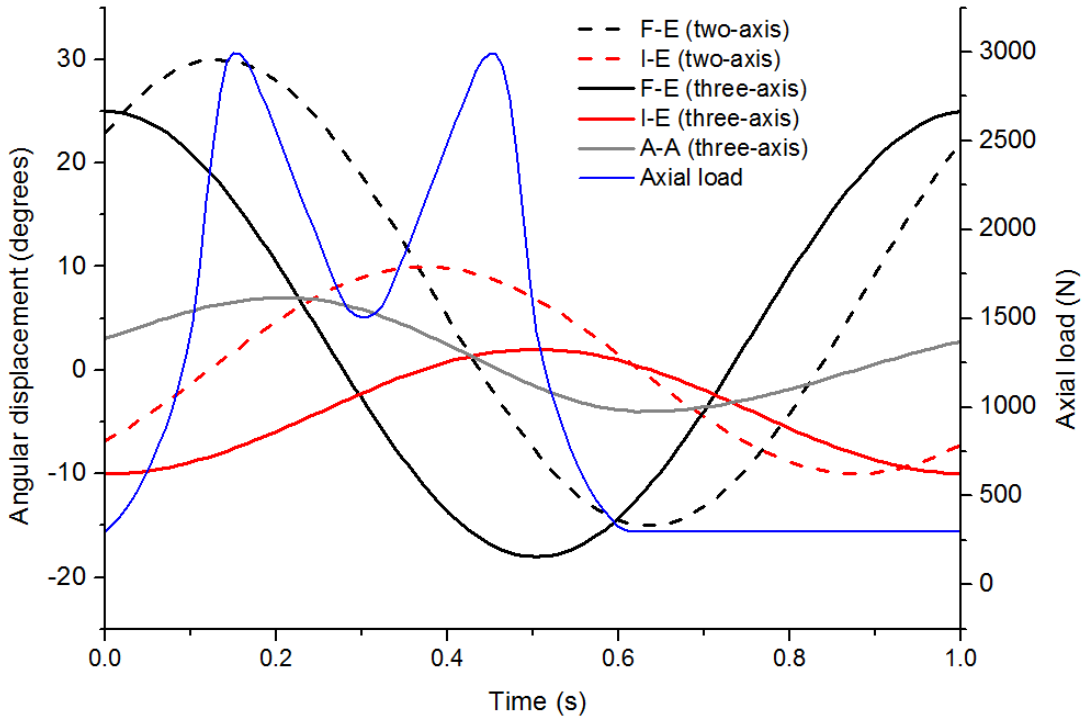
[1]School of Mechanical Engineering, Institute of Medical and Biological Engineering, University of Leeds, Leeds, United Kingdom

Introduction and Objectives: Hip joint simulators provide a laboratory based *in-vitro* test method to study the tribology of hip implants. This has been achieved through applying a combination of loading and articulating motions using single axis or multiple axes of rotation. Although applying up to three-axis of rotation increases the complexity of the testing method, advances in technology has made the development of multi-station machines with three-axis of rotation a viable option, providing the complete anatomical range of motion during gait to be simulated. The aim of this study was to compare the wear rates of cross-linked UHMWPE (Ultra High Molecular Weight Polyethylene) under two-axis and three-axis of rotation conditions using the same hip simulator.

Methods: A ProSim Electromechanical Hip Joint Simulator (ProSim EM13, Simulation Solutions, Stockport, UK) was set up with 36 mm diameter metal-on-polyethylene (Marathon™, DePuy Synthes Joint Reconstruction, Leeds, UK) hip replacements (n = 6). The same components were used throughout this study and were lubricated with 25% new-born calf serum. For the two-axis of rotation condition, flexion-extension (F-E) and internal-external rotation (I-E) were applied, with abduction-adduction (A-A) included for the three-axis simulation as shown in Figure 1. The rotation angles and phasing under the two-axis of rotation test condition was defined to compensate for operating under biaxial rotation only, and to obtain elliptical wear paths which are physiologically relevant [1]. The same twin peak input load profile was applied during both conditions. The wear rates were compared over three million cycles for each test with gravimetric measurements carried out approximately every one million cycles (Mettler Toledo XP205, Greifensee, Switzerland). The surface roughness (R_a) was measured before testing and at the end of each test (Form Talysurf, Taylor Hobson, Leicester, UK). The mean wear rates per million cycles were calculated with 95% confidence limits and statistical analysis was carried out (one-way ANOVA) with significance levels taken at $p \leq 0.05$.

Results: The wear rates over three million cycles of testing under the two-axis and three-axis of rotation conditions were 13.1 ± 1.4 mm^3/million cycles and 12.2 ± 1.4 mm^3/million cycles respectively. There was no statistically significant difference ($p = 0.29$) between the wear rates of the metal-on-polyethylene bearings through two-axis and three-axis rotation simulation. The mean pre-test surface roughness (R_a) of the polyethylene liners was 0.614 ± 0.070 µm. At the end of the two-axis and three-axis rotation tests, the roughness of the liners decreased to 0.057 ± 0.018 µm and 0.070 ± 0.024 µm respectively. There was no significant difference ($p = 0.30$) in surface roughness of the polyethylene liners under both conditions at the end of each test.

Figure:



Caption: Figure 1. Angular displacements, loading profile and phasing for the standard gait cycle under two-axis and three-axis of rotation conditions. F-E: flexion-extension, I-E: internal-external rotation, A-A: Abduction-Adduction.

Conclusion: Applying three-axis of rotation during hip joint *in-vitro* testing provided the full range of motion and cross-shear to be implemented as expected to occur *in-vivo*, however, with appropriate phasing and angular displacements the cross-shear effects were also simulated using two-axis of rotation. These conditions are understood to be a contributor to the increased wear of cross-linked UHMWPE. By using a newly developed electromechanical hip joint simulator, this unique study has shown that applying angular displacements using two-axis of rotation can provide wear rates which are comparable to the volumetric wear rates when three-axis of rotation is applied.

Motion Analysis

SS-0005

GENDER DIFFERENCES IN 3D PELVIS, HIP AND KNEE KINEMATICS DURING HUMAN GAIT

Gabriel G. Zeitoune [1,*] Gustavo Leporace [1] Leonardo Metsavaht [2] Luiz Alberto Batista [3] Jurandir Nadal [1]

[1]Federal University of Rio de Janeiro, Brazil, [2]Institute Brazil of Health Technologies, [3]State University of Rio de Janeiro, Rio de Janeiro, Brazil

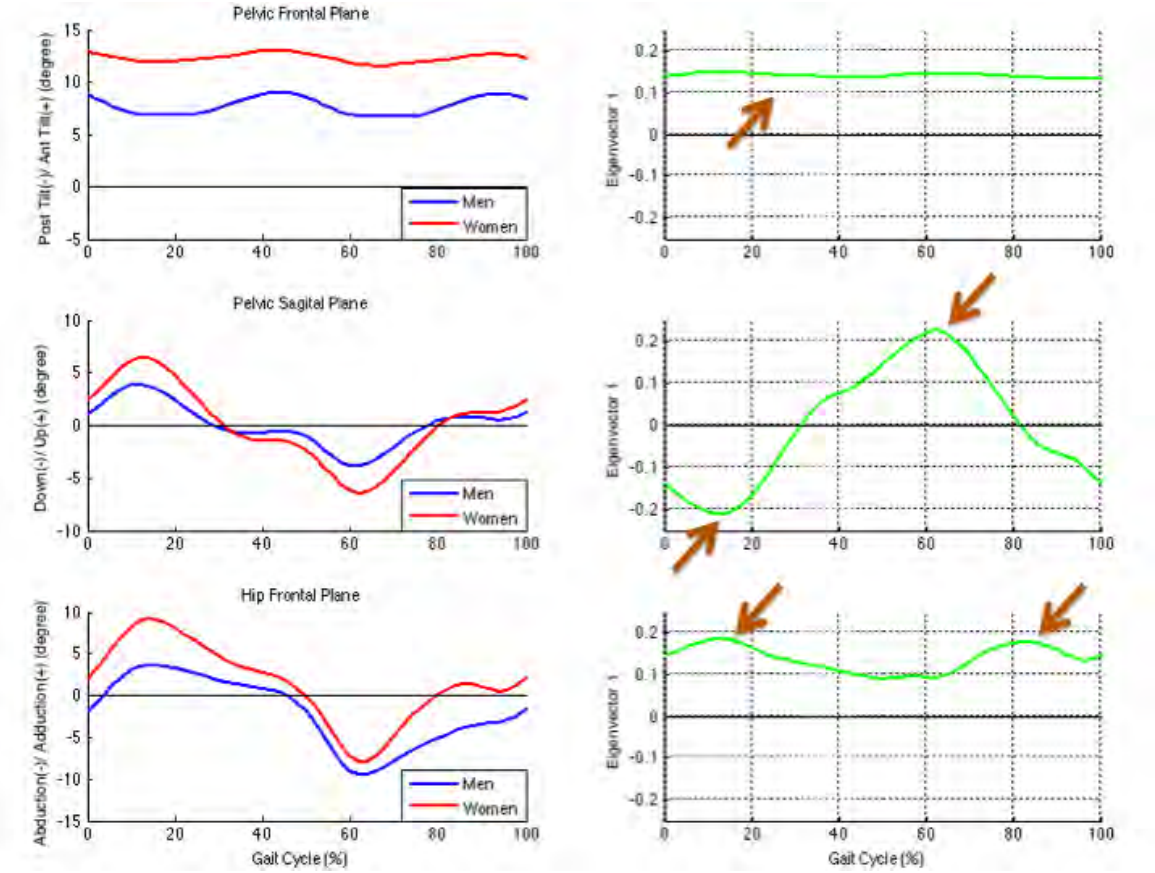
Introduction and Objectives: The hip range of motion in frontal plane and spatio temporal parameters differences in normal gait between women and men has been found [1-3]. Due the lower limb (LL) work as a kinematics chain, other joints can also behave in a different way, affecting the distribution of mechanical loads deriving from the initial contact. However, these papers chosen subjective parameters of gait cycle as dependent variables, which has been described as a study limitation of biomechanical signals [4]. Principal component analysis (PCA) has the advantage of allowing the whole gait cycle analysis without using subjective variables. In this perspective, the objective of this study was to compare the kinematics of the pelvis, hip and knee joints during gait between men and women.

Methods: Ten men (80,9 7,9 kg, 1,75 0,04 m) and seven women (62,9 11,4 kg, 1,62 0,07 m) composed the sample. All of participants had no recent history of low back pain and limb injuries. Subjects were oriented to walk along an eight meters long walkway. Three gait cycles for each LL were captured. The kinematic data were collected using eight cameras and a three-dimensional (3D) motion analysis system (VICON, Oxford Metrics, UK) at 100 Hz. Reflective markers were placed on the skin in trunk, pelvis and both LLs. The raw three dimensional (3D) coordinates of each marker were filtered by a low pass 2nd order Butterworth filter, applied in the forward and reverse directions, to avoid phase distortions, with a cut-off frequency of 8 Hz. After that, the pelvis, hip and knee kinematics was calculated according to [5]. To determine the beginning and final of each cycle, the Foot Velocity Algorithm [6] was used and the three joints data for the three planes of each cycle were interpolated to 51 values, representing 0% to 100% with a cubic spline algorithm. The mean of 6 cycles (three for each side) for each individual were calculated. For PCA the pelvis, hip and knee 3D kinematics of 17 subjects were inserted in nine matrices E [17 x 51] where each row corresponded to subjects and each column corresponded to the interpolated signals. The number of PC retained in the analysis from each joint 3D kinematic data were those that the cumulative sum accounted approximately 80% of the original data variance. Each PC score was compared by a non parametric Mann Whitney test ($\alpha = 0.05$). The correspondent eigenvectors of the retained PCs were analyzed in temporal correspondence to the original signals of both groups to identify the location where the variance between them could be explained [4]. The locations where eigenvectors deviate from zero indicate increased differences between groups (Figure 1).

Results: It was found significant differences between men and women for the first eigenvector of the pelvis in the sagittal plane ($p = 0.02$) and the first eigenvector of the hip and pelvis in the frontal plane ($p < 0.01$). There were no significant differences for any knee plane of motion. These findings corroborate the literature [1-3], wherein women walk with greater hip adduction. However, the first eigenvector of the hip showed that this difference is not only in load response, but also throughout the gait cycle. Additionally, during the whole cycle the pelvis remains with higher anterior tilt and pelvic contralateral drop in load response, which may explain why the hip presents increased adduction. The combination of the

pelvic and hip angular behavior generate pseudo knee valgus at this phase, visually looking like an abduction of the knee, however this does not happen indeed.

Figure:



Caption: On the left there are the graphs of gait cycle kinematic of the pelvis, hip and knee joint, with red lines for the females and blue lines for the males. The plotted values are the averaged data from each gender group. On the right, with green lines there are the eigenvectors graphs that were statistically significant for each joint. The brown arrows show the largest variance of the data.

Conclusion: It was concluded that due to the observed angular behavior of the three joints in question, women appears to be more susceptible to injuries and their consequences, such as anterior knee pain, which is one of the risk factors the excessive medial collapse of knees.

UPPER LIMB KINEMATICS AND INERTIAL SENSORS: WHICH CALIBRATION FOR THE BEST ACCURACY?

Brice Bouvier [1 2 3 4,*] Adriana Savescu [1] Sonia Duprey [2 3 4] Raphaël Dumas [2 3 4]

[1]Institut National de Recherche et de Sécurité, Vandoeuvre-lès-Nancy, [2]Université de Lyon, Lyon, [3]Université Claude Bernard Lyon 1, Villeurbanne, [4]Laboratoire de Biomécanique et Mécanique des Chocs, IFSTTAR, Bron, France

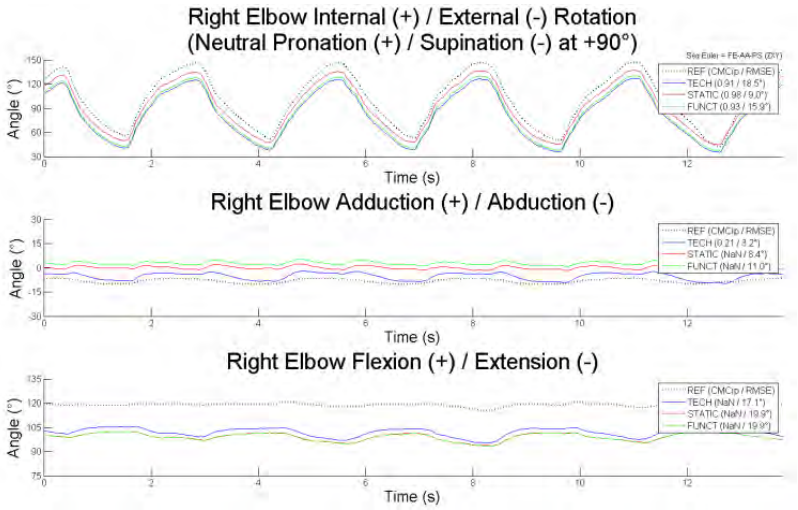
Introduction and Objectives: Magneto-Inertial Measurement Unit sensors (MIMU) are increasingly used in motion analysis as they allow monitoring ambulatory measurements. Sensor 3D orientation can be estimated by combining information from a 3D accelerometer, a 3D gyroscope and a 3D magnetometer. When focusing on joint kinematics, the definition of segment coordinate systems must be associated with MIMU [1]. International standards [2] do not provide a usable method due to the absence of position information delivered by MIMU. In the literature, three main classes of MIMU calibrations can be distinguished: segment axes equal to technical MIMU axes (TECH), and segment axes generated during a static pose (STATIC) or during functional movements (FUNCT). Despite much interest from the scientific community in this topic, two aspects of research deserve more investigation regarding MIMU-based upper limb kinematics. First, few studies have investigated the comparison of MIMU calibrations, being either focused on segment axes and not joint angles [1] or performed on an artificial arm [3]. Second, evaluations of the performance of MIMU-based upper limb kinematics often appear incomplete and disparate in terms of the protocol and validity criteria used [1,4,5]. The present study compares TECH, STATIC and FUNCT classes of calibration in terms of accuracy for the generation of wrist, elbow and shoulder (humero-thoracic) joint angles during maximal amplitude movements.

Methods: Ten subjects were equipped with four wireless MIMUs (MTw, Xsens, Netherlands) on the thorax, and right upper arm, right forearm and right hand segments. The three classes of MIMU calibration, TECH, STATIC and FUNCT were compared. STATIC consists in maintaining a standing pose with the upper arm along the body, elbow flexed at 90°, in neutral forearm pronation-supination (PS). FUNCT uses the combination of STATIC and functional movements of wrist extension, elbow flexion/extension (FE) and shoulder internal/external rotation (IER). An optoelectronic system (Eagle 4, Motion Analysis C., USA) was used as the reference measurement system for the kinematics (REF), according to the ISB standard [2]. Joint angles were compared during six separate movements of maximal amplitude (max): wrist FE, wrist abduction/adduction (AA), elbow FE, forearm PS, shoulder FE and shoulder AA (in the scapular plane). In addition, a seventh test movement consisted of a circular movement in the transverse plane (wheel) that mainly relied on elbow and shoulder DoFs. The experiment was repeated five times per subject, involving a total of fifty experimental sessions (N=50). For the seven test movements, the accuracy of the three MIMU calibrations was assessed using the mean Coefficient of Multiple Correlation inter-protocol (CMCip) [6] and the mean RMSE values calculated over the whole experiment (N=50) and compared with the REF data. Four mean CMCip thresholds were considered: very good (≥0.85), good (0.75-0.85), moderate (0.65-0.75) and bad (<0.55).

Results: The accuracy of the three MIMU calibrations was very good and equivalent (0.85≤CMCip≤0.99) for all the principal FE angles during max wrist FE, elbow FE, shoulder FE and AA, and wheel movements. The same observation

was made for the coupled PS during max forearm PS (0.93≤CMCip≤0.97) (figure 1). Lower accuracy and disparities between calibrations could be observed for the principal AA angle during max wrist AA (0.66≤CMCip≤0.86) and for the coupled AA and IER shoulder angles during max shoulder FE and AA, and wheel movements (0.53≤CMCip≤0.86), without any constant predominance of a particular calibration. Regarding RMSE values, no significant difference could be observed between MIMU calibrations for any of the movements performed (8.0°≤RMSE≤26.2°).

Figure:



Caption: Figure 1. Elbow joint angles over time from REF (black-dotted), TECH (blue), STATIC (red), FUNCT (green) during max forearm PS

Conclusion: This study highlights that the three classes of calibration (TECH, STATIC, FUNCT) provide good level of accuracy considering CMCip, without any significant difference between them. However, it should be mentioned that the accuracy is only one aspect of the MIMU calibration performance. Indeed, differences between MIMU-based and REF joint angle always exist due to the different definition of the segment axes and the dissimilar effect of soft tissue artifact [1]. RMSE values are comparable to previous results of 20° and 10°-20° reported in the literature [1,7]. For a complete evaluation of MIMU-based upper limb kinematics, reproducibility [1] and interpretation [5,8] of joint angle should also be considered key criteria.

BIOMECHANICAL DOSAGE EFFECT OF KNEE BRACES ON INTERNAL JOINT MOMENT AS MEASURED BY THE E-TIBIA

Howard J. Hillstrom [1,*] Jim Tse [1] Lilly Tran [1] Darryl D'Lima [2] Shantanu Patil [2] Sherry Backus [1] Andrew Kraszewski [1] Benjamin Fregly [3] Glenn Garrison [1] Andreas Kontaxis [1] Mark Lenhoff [1]

[1]Rehabilitation - Leon Root, MD Motion Analysis Lab, Hospital for Special Surgery, New York, [2]Shiley Center for Orthopaedic Research and Education, Scripps Clinic, La Jolla, [3]Mechanical and Aerospace Engineering, University of Florida, Gainesville, United States

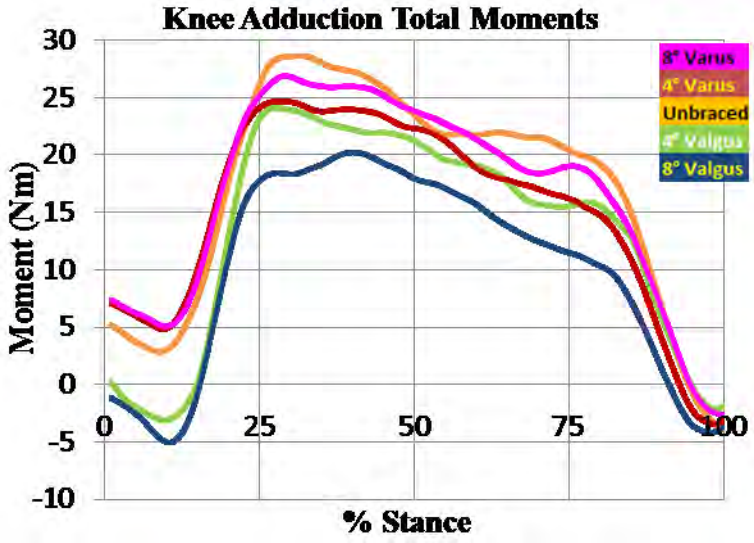
Introduction and Objectives: High body mass index, soft tissue injuries, and malalignment have all been associated with knee osteoarthritis (OA). Varus malalignment overloads the medial compartment of the joint and is the most common deformity in these patients. Pollo et. al. fit a strain gauge upon the hinge of an Unloader Select knee brace in a previous study and found that a portion of the load was shared with the knee via the hinge.[1] The effect of knee brace alignment upon compressive loading within the joint for treating OA is unknown. *Purpose*: Total knee moment and contact forces were measured on an individual wearing a knee brace that was adjusted for various alignments to determine the 'biomechanical dosage' effect. The test subject has been fitted with an instrumented total knee replacement (e-tibia) that can measure total knee moments and contact forces *in vivo*. Inverse dynamics and e-tibia data were simultaneously collected from the subject while wearing an Ossur Unloader Select knee brace adjusted to -8°, -4°, 0°, 4°, 8° of alignment (valgus (+) and varus (-)). Our hypotheses are: (**H1**) increasingly valgus brace alignments will more effectively decrease internal joint moment while varus brace alignments will also decrease internal joint moment and (**H2**) that the treatment mechanisms of knee bracing employs both load sharing and shifting.

Methods: A single-subject study was conducted on a female (69 years old, 81 kg) who had an e-tibia. Composed of a polyethylene insert, tibial tray, and telemetry system, the e-tibia measured three forces (F_x, F_y, F_z) and three moments (M_x, M_y, M_z) using 12 load cell strain gages that are integrated within the e-tibia.[2] The subject walked at her self-selected speed on a level walkway while simultaneously measuring e-tibia contact loading and 3D inverse dynamics (12 Eagle cameras, Motion Analysis Corp, Santa Rosa, CA; 2 Bertec, Columbus, Ohio; and 2 AMTI, Bilarica, MA force plates). The test subject walked with a knee brace (Unloader Select, Ossur Americas, Foothill Ranch, CA) adjusted to four different alignments (dosage) and an unbraced condition representing baseline (control). Each brace condition corresponded to a different frontal plane alignment (-8°, -4°, unbraced, +4°, +8°) of varus to valgus correction. Data collection was performed for five trials per condition. Total internal moment and contact forces were measured directly by the e-tibia.

Results: The unbraced condition (orange) had the largest peak moments at approximately 25% and 80% of stance phase (Figure 1). While employing 4° (light green) and 8° (dark blue) valgus brace correction, the first peak reduced by 15.8% and 29.3% respectively while the second peak reduced by 8.9% and 22.9% respectively. Increasingly valgus brace alignments more effectively decreased joint moment as measured by the e-tibia. Interestingly, 4° and 8° varus brace correction also reduced peak moments but not as much as valgus bracing. Taken together this data supports acceptance of **H1**. Since all four brace alignments reduced internal knee moment compared with the unbraced condition this data

supports the theory that the brace shares load with the knee. One plausible explanation is the load path through the hinge as described by Polo et al.[1] In the case of increasing amounts of valgus brace correction for genu varum (i.e. 4° and 8°) the internal moment progressively reduced which supports the theory that knee braces are offloading the involved compartment by reducing the total internal (varus) moment through application of a larger valgus brace moment. This load shifting in conjunction with the load sharing supports acceptance of **H2**. Since braces can provide different amounts of offloading of the involved knee compartment the treatment effect is analogous to a 'biomechanical dosage'.

Figure:



Caption: Figure 1: Knee Adduction Moments as Measured by the e-tibia

Conclusion: This study employed a test subject with an e-tibia, an electronic total knee replacement that measures internal moments and contact forces during functional tasks in vivo. Increasingly valgus brace alignments more effectively decreased internal joint moment while varus brace alignments also decreased internal joint moment. The data supports both a load sharing and shifting mechanism for treatment of knee OA knee with braces.

A COMPARATIVE BIOMECHANICAL STUDY ON THE FUNCTIONALITY OF DIFFERENT ORTHOTIC CONCEPTS IN PATIENTS WITH CARPOMETACARPAL OSTEOARTHRITIS.

Timo Schmeltzpfenning [1,*] Jennifer Grunden [1] Birgit Scheib [2] Joachim Bauer [1] Jörn Heidemann [3] Kai Heinrich [4] Han Wu [4] Judith Bleuel [4] Christiane Gonska [4] Gert-Peter Brüggemann [4] Nina Hamann [4]

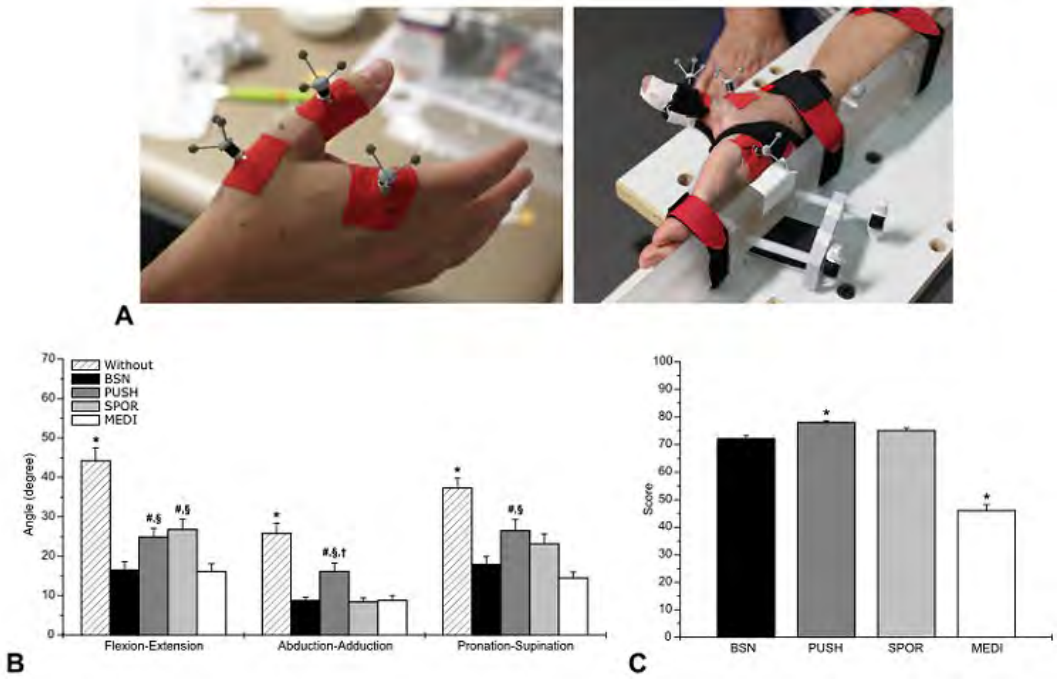
[1]R&D Department, [2]SA , BSN medical, Hamburg, [3]Joint Centre, Brühl, [4]Institute of Biomechanics and Orthopaedics, German Sport University Cologne, Köln, Germany

Introduction and Objectives: Osteoarthritis (OA) of the carpometacarpal (CMC) joint is a painful chronic disease, which limits the degree of thumb motion. Key element in treatment is pain reduction by stabilizing the affected joint. Patients' compliance, however, depends on daily functionality. The aim of this study was to compare orthotic concepts regarding their combination of stabilization effectiveness and functionality in daily activities.

Methods: Eighteen female subjects (mean age 63 ±3 y) diagnosed thumb CMC OA (stage II/III) were included in the study. Four orthotic concepts, differing in material and mechanical construction have been tested and compared (Rhizo Forte , BSNmedical (BSN); OrthoCMC, Push (PUSH); Rhizo-Hit, Sporlastic (SPOR); Rhizomed, Medi (MEDI)). Stabilization effectiveness was analyzed by a three-dimensional thumb kinematic model using a 6 infrared camera system at 100 Hz and retro-reflective marker arrays. Range of motion (ROM) of the thumb CMC joint was determined while hands were fixed in a custom made test bench. Sollerman test was used to examine hand functionality scoring 20 activities of daily living [1].

Results: All orthoses significantly restricted the ROM in flexion-extension, adduction-abduction and pronation-supination compared to the ROM of the thumb without external support. Significant inter-conceptual differences could be measured for all analyzed movements and for the performance of daily activities. Mean flexion-extension ROM was significantly smallest using the orthotic construction of Medi and BSN compared to the concepts of Push and Sporlastic. Mean adduction-abduction ROM was significantly largest with the minimalistic design of the Push thumb brace compared to all other orthotic concepts. The stabilization in pronation-supination direction was significantly higher with BSN and Medi compared to Push, but similar to Sporlastic. Contrary to the kinematic results, the performance of daily tasks could be managed best with Push (78 out of 80), whereas the Medi concept hindered the patients most during the execution (46 out of 80). Both differed from the other orthoses. Mean sum scores with BSN (72) and Sporlastic (75) were between the values of Push and Medi and showed no statistical differences to each other.

Figure:



Caption: Fig. 1. (A) Hand fixed in custom made test bench during maximum active opposition-reposition with marker arrays positioned on thumb and index finger. (B) Ranges of motion of thumb CMC joint during opposition-reposition with and without orthoses. Mean ± SE. *significantly different from all orthoses p<0.05, #significantly different from BSN p < 0.05, §significantly different from MEDI p< 0.05, † significantly different from SPOR p < 0.05 (C) Mean Sollerman sum score of hand function while using the orthoses. Mean ± SE. *significantly different from all other orthoses p < 0.05.

Conclusion: The right combination of maximum functionality in daily activities and stabilization of the thumb is essential for the ideal treatment and compliance of CMC OA patients. However, our results show a negative effect on functionality by increasing the thumb stabilization. This correlation can be influenced by the conceptual design of the thumb orthotic. Best compromise of both product properties can be provided by the orthotic concept of BSN, whereas Medi and Push either lack on the functionality or stability.

Computer Simulation

SS-0009

EVALUATING THE EFFECT OF THE STIFFNESS OF AN AFO ON GAIT IN A HEALTHY TEST SUBJECT: EXPERIMENTS VS. PREDICTIVE SIMULATIONS.

Veerle Creylman [1,*] Luiza Muraru [1] Jos Vander Sloten [2] Ilse Jonkers [3] Louis Peeraer [1 4]

[1]Mobilab, Thomas More, Geel, [2]Mechanical Engineering, Biomechanics Section, [3]Department of Kinesiology, Human Movement Biomechanics, [4]Department of Kinesiology, Musculoskeletal Rehabilitation, KU Leuven, Leuven, Belgium

Introduction and Objectives: An Ankle Foot Orthosis (AFO) is commonly used in clinical practice to assist gait of patients with different pathologies. In the past years, musculoskeletal simulations have been used to quantify the effect of AFO-stiffness on gait [1]. However, to our knowledge none of the results of these simulations were compared to experimental results.

This study quantified the effect of a varying AFO-stiffness on the gait pattern of a healthy test subject using (1) experimental gait measurements while walking with AFOs with different stiffnesses and (2) predictive simulations of the effect of varying AFO-stiffness on the kinematics and dynamics of the test subject.

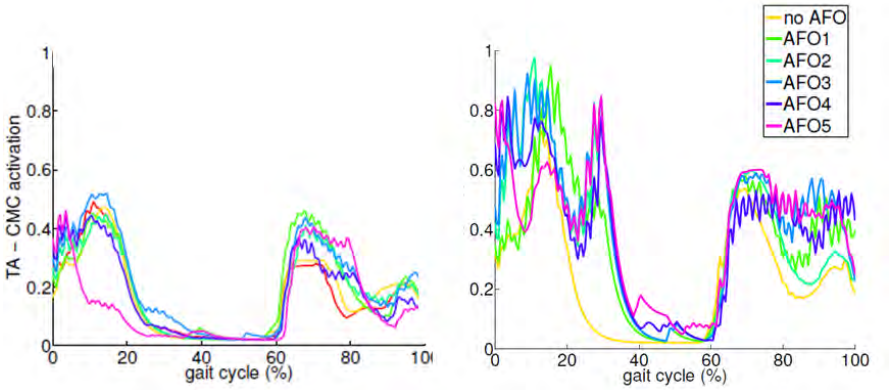
The main goals of loading response are weight acceptance, shock absorption and advancing the body over the heel rocker. Therefore, the ankle plantar flexes while the knee flexes. In this study, it is hypothesized that with increasing AFO-stiffness during loading response, the ankle plantar flexion will decrease, the maximum knee flexion angle during will increase and the activation of the m. tibialis anterior will decrease.

Methods: A healthy female of 27y, mass 53 kg, is test subject for this study. Based on the scan of her lower leg, 5 patient-specific AFOs with different stiffnesses are fabricated using the SLS-method [2]. AFO-stiffness is calculated in a FE-simulation. Gait measurements are performed in six conditions: while wearing shoes and while wearing the five different custom-made AFOs combined with the same shoes. Kinematic data are collected using the CODAMOTION system. AMTI force plates are used to collect ground reaction forces. A generic musculoskeletal model of the lower limbs with 23 degrees of freedom and 92 muscles is scaled in OpenSim to match the test subject's anthropometric data [3]. The torque supplied by the AFOs is simulated as a rotational spring around the ankle joint with a constant stiffness based on the FE-analyses. The kinematic data of the person walking with the AFO with average stiffness are used as an input to the simulations to calculate the effect of varying AFO-stiffness on muscle activations using Computed Muscle Control (CMC). The muscle activations of the person walking with the AFO with average stiffness are used as an input to the simulations to calculate the effect of varying AFO-stiffness on kinematics in a forward dynamic (FD) simulation.

Results: The hypothesis is that with increasing AFO-stiffness the maximum ankle plantar flexion during loading response decreases and the maximum knee angle increases. This is not confirmed by the experimental results (table: mean results and standard deviation between brackets) where for increasing AFO-stiffness no trend in the plantar flexion is observed. In contrast, when evaluating the results of the FD-simulation, the hypothesis is confirmed.

Similar results as in the kinematics are observed for the calculated activation of the m. tibialis anterior (figure, left experimental results, mean over trials and right simulations): the hypothesis is not confirmed by the experimental results, but confirmed by the simulations.

Figure:



Caption: Calculated activation of the m. tibialis anterior for both the experiments (left, mean over trials) and simulations (right) for AFOs with variable stiffness.

Conclusion: The musculoskeletal simulations used here are based on a ``mechanical'' approach and from this point of view the hypotheses are confirmed: e.g., a stiffer AFO will limit plantar flexion during loading response and therefore push the knee into flexion. However, the results from the experiments do not confirm the hypotheses: it is possible that the healthy test subject attempts to maintain normal gait kinematics and therefore changes muscle activation patterns. Hence, during experiments, both the muscle activations and the kinematics of gait may be changed simultaneously while during the predictive simulations either the muscle activations or the kinematic data are varied. A further evaluation of the influence of AFO-stiffness on gait requires an elimination of the discrepancy between the experiments and the simulations by incorporation of compensating mechanisms observed.

Table:

Applied AFO-stiffness	No AFO	AFO 1 45 Nm/rad	AFO 2 69 Nm/rad	AFO 3 87 Nm/rad	AFO 4 131 Nm/rad	AFO 5 199 Nm/rad
Experimental ankle plantar flexion (°)	3.95 (0.87)	2.07 §0.83)	1.27 (0.89)	2.14 (0.36)	1.58 (0.87)	0.76 (0.51)
Experimental knee angle (°)	18.38 (2.18)	20.53 (2.69)	21.21 (1.51)	18.24 (1.96)	19.81 (2.20)	20.47 (1.90)
Simulations: ankle plantar flexion (°)	5.4	4.9	4.7	4.4	3.9	3.3
Simulations: knee angle (°)	14.0	14.0	14.0	14.1	14.2	14.5

APPLICATION OF PERSONALISED FOOT ORTHOTICS FOR THE TREATMENT OF MEDIAL KNEE OSTEOARTHRITIS (MKOA)

Richard Allan [1,*] James Woodburn [1] Scott Telfer [1] Mandy Abbott [1] Martijn Steultjens [1]

[1] School of Health and Life Sciences, Glasgow Caledonian University, Glasgow, United Kingdom

Introduction and Objectives: Increased knee joint load plays play a crucial role in the pathogenesis of knee osteoarthritis. The external knee adduction moment (KAM) is commonly accepted as an indirect measure of loading of the medial compartment such that a reduction in the KAM reflects a reduction in the loading of the medial compartment. Orthotic interventions such as lateral wedged insoles are routinely prescribed to the KOA population. These are designed to reduce the KAM, effectively redistributing load, thus addressing the inadequate knee joint load patterns. Research has demonstrated a heterogeneous response to this orthotic intervention, with 23-30% of cases exhibiting an increase in the KAM [1].

Some debate remains as to whether a fully customised approach to orthotic design can provide additional benefit over prefabricated orthoses. Recently, a novel approach to 3D printing of orthotics via Computer Aided Design and Fused Deposition Modelling (FDM) has received increased attention in this area[2], providing the opportunity to allow a more personalised intervention To date these techniques have not been applied to a KOA population.

The purpose of this study is to explore a personalised approach for patients with medial KOA and assess differences in biomechanical response to alterations in two key orthotic design variables: the degree of lateral wedging (posting) and orthotic length.

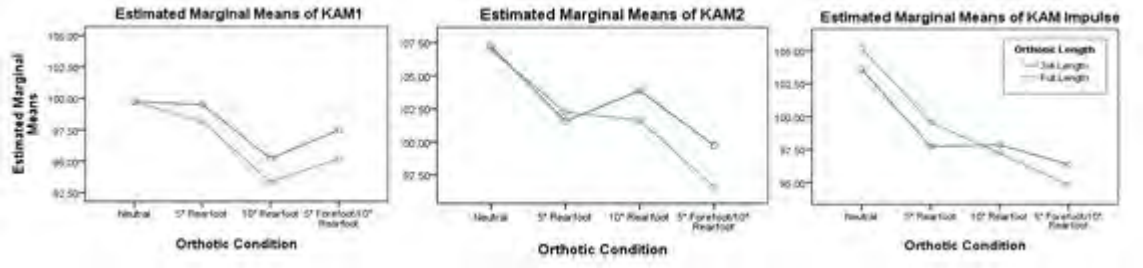
Methods: Personalised foot orthotics (PFOs) were created for 9 females with symptomatic medial knee osteoarthritis (62.0±7.2yrs; 1.64±0.05m; 73.6±7.5 kg). Computer aided design (CAD) software was used to design 8 PFOs (4 full length and 4 ¾ length each with: 0° rearfoot posting; 5° rearfoot posting; 10° rearfoot posting and a combination of 5° forefoot 10° rearfoot posting) per participant based on a 3D surface scan of their feet. All PFOs were manufactured in-house using FDM methods. 14 camera motion analysis system was used to track retroflective markers at a frequency of 120Hz, and an embedded force plate measured ground reaction forces at 2400Hz. Markers were attached to the patients test leg and pelvis to define a unilateral marker model which included the pelvis, thigh, shank and full foot segments.

Quantification of the orthotic effect focused on a core set of clinically meaningful kinetic variables targeted for FO interventions. This included; Peak knee adduction moment in the 1st and 2nd half of stance (1KAM, 2KAM), KAM Impulse (KAMI) and peak knee flexion moment in the 1st half of stance (1KFM). All kinetic variables were normalised to %BW*h and defined relative to a shod test condition. Two-way mixed effect ANOVAs were performed to determine if the PFO type, PFO length and any interactions were significant at $\alpha < 0.05$ level.

Results: Significant main effects were found for posting level for 1KAM ($p = 0.01$), 2KAM ($p=0.002$) and KAMI ($p=0.000$). Mean effect of conditions are presented in figure 1. No significant effects were found for PFO length or for group interactions. No significant effects were found for the KFM. Large between subject differences were found across all FO conditions. A mean reduction in 1KAM occurred after the introduction of lateral posting, with the greatest level of effect

occurring with a 10° level of posting (-5.7(-0.2, -11.2) %). Within subject effect of posting level was consistent suggesting that this is the most significant factor for the reduction of medial compartment loading irrespective of PFO length. Neutral PFOs increased 2KAM above shod; indicating greater medial compartment loads and was only counteracted once lateral posting was increased. As lateral posting increased, 2KAM reduced, remaining above the shod, with only the 5° forefoot 10° rearfoot PFO demonstrating an mean overall reduction, (-1.8(-8.0, 4.3)%) . Largest reductions in KAMI were found for the 5° forefoot 10° rearfoot (-4.4 (-9.2, 0.3)%) suggesting that lateral posting, irrespective of PFO length is crucial for the reduction in the cumulative loading of the medial compartment.

Figure:



Caption: Figure 1 Estimated marginal means of selected kinetic variables relative to shod

Conclusion: Increased levels of posting provide greater reductions in KAM variables for patients with mKOA, however consistent with previous studies large between subject variability further demonstrates the responsive/non-responsive nature of the KOA population to orthotic intervention. It remains unclear whether our elevated findings related to 2KAM and to an extent KAMI are the result of the true biomechanical adaptations or could potentially be the result of systematic measurement error; however the reductions in 1KAM are consistent with previously reported findings, suggesting our results are valid. Our research further demonstrates the existing debate as to whether a personalised approach provides any additional benefits over standard orthotic interventions and requires a more in depth assessment.

Assistive Technology

SS-0011

DEVELOPMENT OF AN ORTHOTIC GLOVE WITH EMG FEEDBACK FOR ASSISTIVE AND REHABILITATIVE PURPOSES

Oluwalogbon O. Akinnola [1,*] David Branson [2] Sue Cobb [2] Paul Smith [3]

[1]Mechanical Engineering, [2]Faculty of Engineering, [3] Faculty of Medicine and Health Sciences, University of Nottingham, Nottingham, United Kingdom

Introduction and Objectives: Hand rehabilitation is a priority in medical research in the UK with an estimated 550,000 people suffering from illnesses that affect the muscles, reducing grip and coordination [1]. However, current commercially available devices designed to provide assistive and/or rehabilitative solutions offer limited physical utility, such as a splint used to hold a utensil in a single grip, or they were generally cumbersome thus limiting use of some systems to fixed locations [2,3].

In response to this deficit an Orthotic Glove was designed and built to be lightweight and simple to use. It featured wrist-mounted servo motors acting as muscles that pulled on fishing line tendons attached to the front and back of the index, fore, and middle fingers. This enabled antagonistic pairings to open and close fingers for power and precision griping. The design used flex sensors to achieve amplified motion based on small finger movements and was predominantly assistive. This study investigatess the use of Electromyographic sensors as control feedback sources to improve rehabilitation quality and fidelity in the Glove.

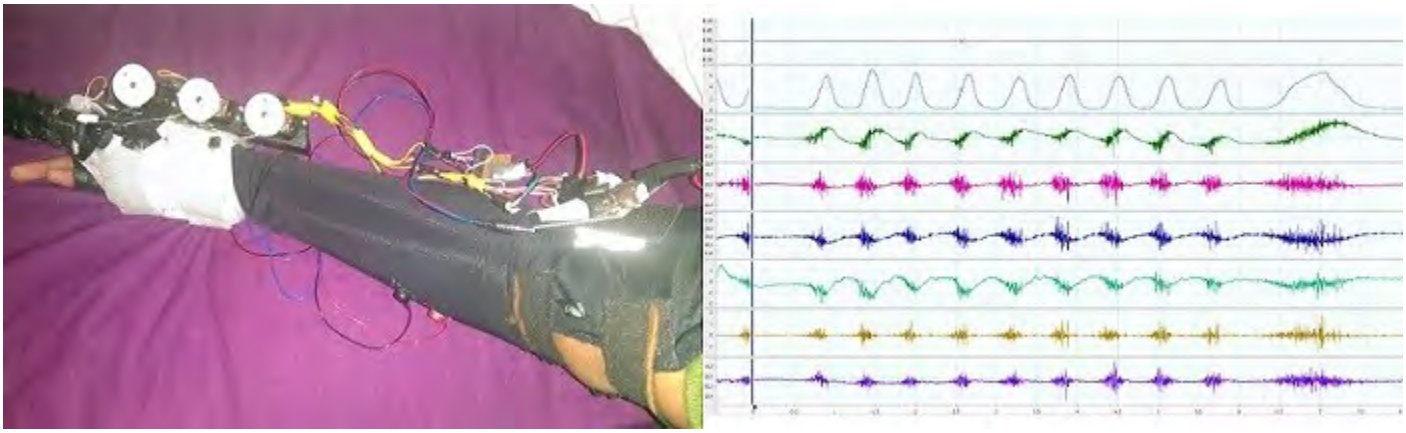
Methods: Ten experiments, with three repeats each, were carried out to determine signal behaviour and reliability of muscle activation during normal hand motions with the glove off. There was one subject in the series of investigative trials, the author. The subject was a healthy right handed male, 23 years old, weight: 88kg, height: 186cm. Each experiment began by cleaning the arm, roughening the skin surface to encourage sensor adhesion, and placing passive 3M Red Dot 2560 electrodes on the left arm of the subject. Muscles monitored were the Extensor Indicis, Abductor Pollicis Brevis, Flecor Pollicis Longus, Flexor Digitorum Superficialis, Flexor Digitorum Profundus, and Extensor Digitorum. Muscle activity was recorded as oscilloscope plots using three Powerlab 26T data acquisition devices and LabChart 8 from ADIstruments. The plots have Time (s) on the x-axis and Voltage (mV) on the y-axis. Extra instruments, such as a dynamometer and pressure pad, were connected as needed.

Results: The experiments provided good insight into how muscle signals changed with various finger movements. It was found that signal amplitude was proportional to the force being applied by the finger irrespective of the duration of the application (Fig 1). Force and acceleration are intrinsically linked so greater acceleration meant larger signal amplitude. Results also suggested that when closing the hand flexor muscles are much more active than extensors, yet when opening the hand both muscle groups create signals similar in magnitude and nearly in phase, thus flexor activity alone cannot indicate a closing hand.

The main sources of error in the experiments were sensor noise and crosstalk – the activation of other muscles in the arm when moving a finger. Noise greatly harms the fidelity of the glove response as it can be mistaken for muscle activity resulting in unwanted motion. Action was taken to limit this, however experimental limitaions prevented complete

elimination. Thus results are only estimations of signal behaviour. The effects of crosstalk were proportional to the size of the motion; e.g. when moving the middle finger, the one most affected by crosstalk, a signal of 0.030mV in the forefinger flexion muscles accompanied a signal of 0.079mV in the middle finger flexion muscles. When the signal increased to a 0.124mV signal from the middle finger, the forefinger signal increased to 0.121mV. Whilst this does not negatively affect practical use of the Glove as natural movement is still achievable, it was experimentally difficult to determine what level of signal change was attributed to individual muscles.

Figure:



Caption: Fig1: a) Orthotic Glove MkII b) Trial 6 oscilloscope plot . Activity in muscles as force increases

Conclusion: The research produced a working prototype of a portable assistive and rehabilitative device.The results support the implementation of EMG signals as a means to initiate motion. Using these signals the rehabilitative benefits of the device will improve as the neural pathways involved in moving the fingers are also trained along with the muscles [4]. More work is needed to minimise noise and to optimise sensor location to improve the fidelity between the Glove response and the user's intention.

Feet and Footwear

SS-0012

A BIOMECHANICAL STUDY ON EFFECTS OF FUNCTIONAL ORTHOTICS IN IMPROVING THE SWING STABILITY AND SWING PERFORMANCE

Chun-Ju Chang [1,*] Sai-Wei Yang [1] Keh-Tao Liu [2] Ching-Wei Chang [1] Siou-Ting Hsu [1] Yen-Ling Lin [1]

[1]National Yang-Ming University, Taipei, Taiwan, Department of Biomedical Engineering, [2]Global Action Inc, Taipei, Taiwan, Republic of China

Introduction and Objectives: With technology changing at such a rapid pace, there are lots of foot orthosis design in the world. An outstanding golf player not only practicing diligently, but also needs an effectively foot orthosis to help acquiring good postural control in the golf competitions [1]. In golf swinging, feet and ankles require highly static stability to give assistance for the player. Providing the functional insole may be an important intervention, it can improve the player's foot stability, increase the hitting speed and decrease clubface hitting angle variability, but the efficacy of arch support is still lack of scientific data. There are two objectives in this study, which included: (1)A golfing motion analysis will be conducted to understand effects of different foot type and lower limb alignment in golf swing; (2)The foot orthosis based on foot arch and lower limb alignment will be prescribed to evaluate the effect of new designed orthotics being able to improve performance.

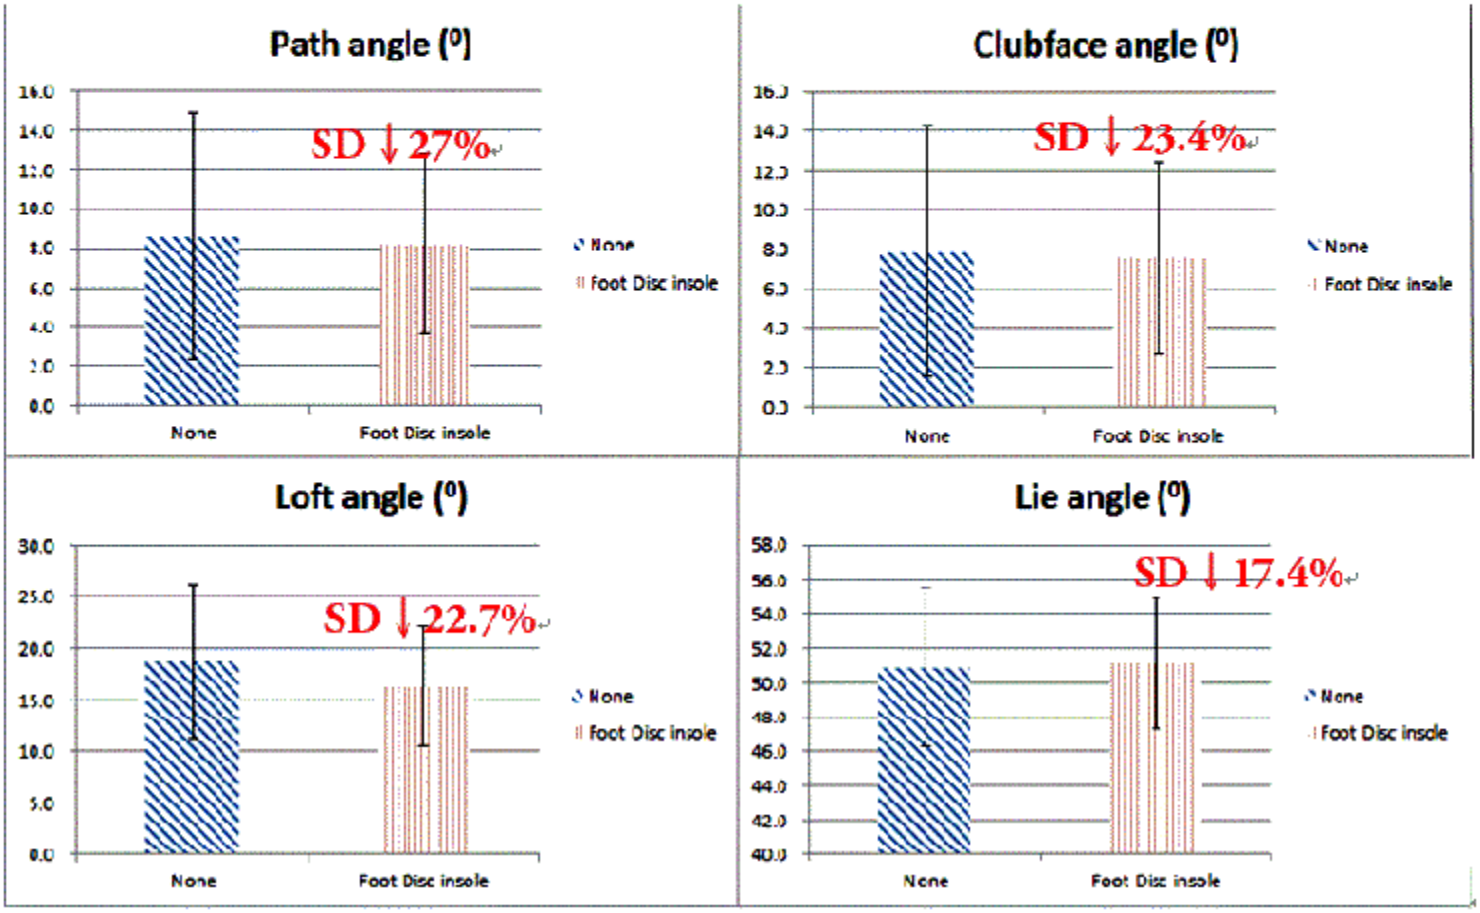
Methods: Nineteen young golf players were recruited into our study, fourteen male and five female, the mean age was 17.1±8.9 years old, the height was 168.6±10.6 cm, and the weight was 61.5±16.1 kg. Considering the foot type and lower limb alignment for the foot insole, there were 11 subjects with flat arch, 8 normal arch, and no one with high arch; and 12 subjects with genu valgum, 4 straight leg, and 3 with genu varum. All of the subjects volunteered joining the foot orthosis study, and were informed the details of the study processes and singed the informed consent provided by Institutional Review Board (Taipei Veterans General Hospital, IRB No.2012-07-008ACY).

The subjects had to wear familiar golf shoes during the tests, and we recorded the swinging performance with and without foot orthosis randomly. Each of them was asked to hit the maximum distance with 5 iron club [2]. The golf foot insoles was designed by the Foot Disc (Global Action Inc, Footdisc®, Taiwan), which consist of three layers decompressed materials, arch support and adequate heel stability. mySwing Golf Swing Analyzer (Noitom Technology Ltd, China) was used to measure the hitting speed, swing ratio, path angle, and clubface angle (Fig 1). A independent t-test was used to discriminate the effect of insole.

Results: The statistic results of mean and standard deviation data (Table 1) showed there were no significant difference between the variable of hitting speed, timing of upswing and downswing phase, and the angle parameters. But in the raw data of standard deviation, we found out that the deviation decreased after wearing the foot insole in each variable. The deviation of hitting speed decreased 2.6%, downswing time decreased 4.2%, and especially at the angle of path angle, clubface angle, loft angle and lie angle, the decreased deviation was 27%, 23.4%, 22.7%, and 17.4% (Fig 2~5). Although the performance of kinematics did not change significantly, the standard deviation of angle showed the change of swinging pattern while giving the foot insole intervention.

The statistic results of coefficient of variation (CV) data (Table 2) showed there were significant difference between the variable of downing timing (3.241±2.574 vs. 2.354±0.944, p=0.034) and path angle (60.67±45.32 vs. 42.87±29.65, p=0.027). By wearing the foot insole, the subjects had less coefficient of variation compare with the no insole condition.

Figure:



Caption: Fig 1: mySwing Golf detect device; Fig 2: Angle compare between no insole vs. Foot Disc insole

Conclusion: This study suggests the golf players wearing proper foot insole with decompressed materials, arch support and fitting lower limb alignment will improve their swinging performance and decrease the swing variability. A sports foot

insole may provide the player adequate postural stability, release foot pressure, and reduce the risk of musculoskeletal injury which results from muscle and joint motion overused [3].

Table:

Variable (unit)	no insole	Foot Disc insole	*p*	SD changed
Speed (mph)	82.3±7.8	82.3±7.6	0.923	-2.6 %

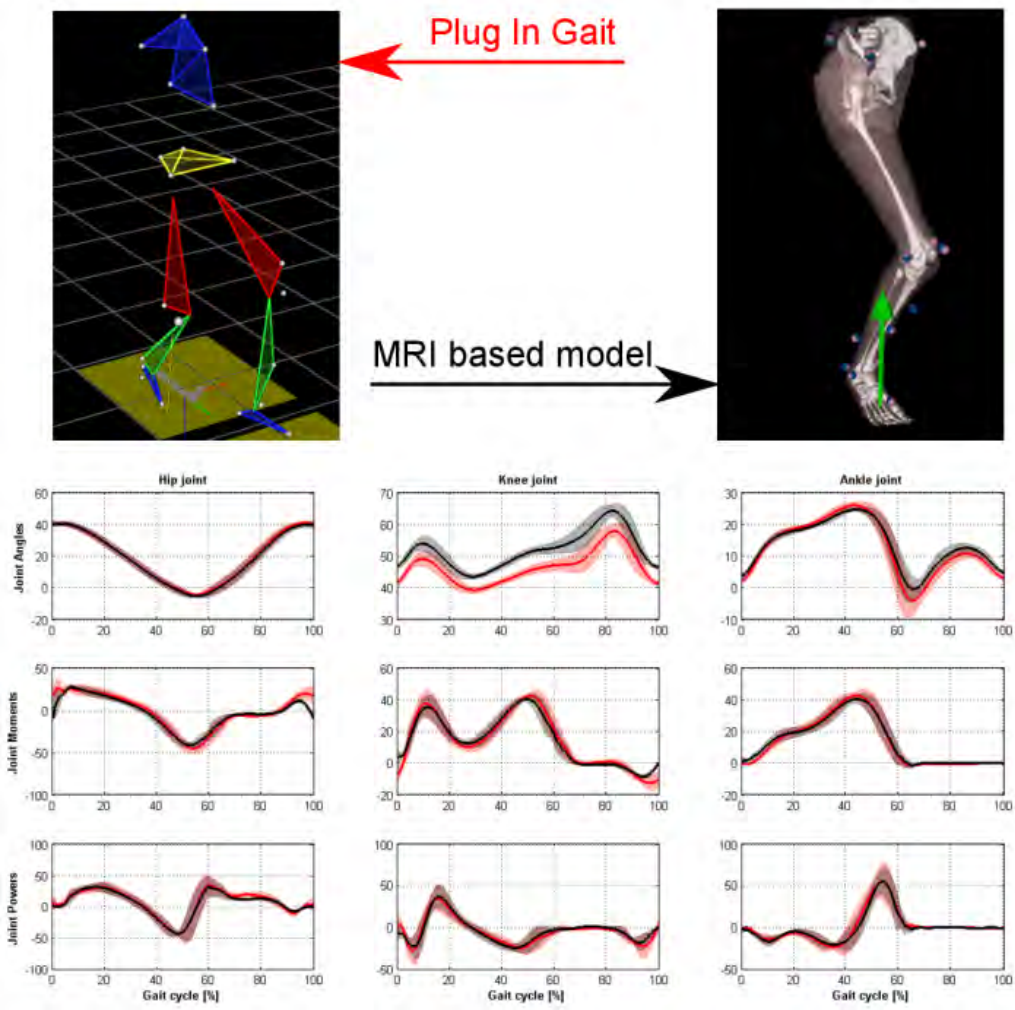
DO SUBJECT SPECIFIC SIMULATIONS MODIFY GAIT ASSESSMENT OUTPUTS COMPARED TO THOSE FROM TRADITIONAL GAIT ANALYSIS?

Luca Modenese [1,*] Hans Kainz [1] John Walsh [2] Lee Barber [3] David Lloyd [1] Christopher Carty [1]

[1]Griffith Health, Centre for Musculoskeletal Research, Southport, [2]Queensland Children's Gait Laboratory, [3]Queensland Cerebral Palsy and Rehabilitation Research Centre, Brisbane, Australia

Introduction and Objectives: Gait analysis is a valuable tool for clinical assessment of pediatric populations with movement disorders, in particular children affected by cerebral palsy, as it provides the therapist and the surgeon with parameters (joint angles, moments and powers) that provide insight into patient's dysfunctional walking mechanics and joint energy exchange. These parameters are typically calculated in clinical practice using a marker-based model developed more than two decades ago [1], while the current musculoskeletal (MSK) modeling tools, which could now be implemented, allow the use of personalized models from medical images, e.g. magnetic resonance imaging (MRI).
The aim of this investigation was to compare the joint angles, moments and powers derived from traditional gait analysis methods against corresponding outputs obtained by using a state-of-the-art personalized model in order to determine whether a more anatomically accurate model alters typical parameters used in clinical gait assessments.
Methods: MRIs for the entire lower limb were collected on three children with cerebral palsy with mean (SD) age: 10.7 (2.3) years, height: 1.41 (0.18) m, mass: 31.3 (6.15) kg. Three dimensional bone geometries and external skin surface were obtained through segmentation and used to generate unilateral subject specific MSK models usable in OpenSim [2] using NMSBuilder [3]. In these models, joint centres and axes were defined by fitting analytical shapes to the bone structures, e.g. a sphere to the femoral head. The external skin shell volume and bones were assigned appropriate densities [4] in order to calculate the inertial properties of each body segment. Virtual markers were located on the MSK model using MRI visible markers as reference. The resulting models and experimental marker and force plate data were finally used to run simulations to calculate joint angles (via inverse kinematics), joint moment (via inverse dynamic analysis) and joint power. Alternatively, the same marker trajectory and force plate data were processed using the Plug In Gait model [5] available through Vicon (Oxford). Shapes of the curves were compared using a correlation coefficient.
Results: The joint angles, moment and power obtained from the subject-specific models showed very good agreement with the output of the standard gait analysis in the sagittal plane (Figure and Table) The variables outside the sagittal plane of motion showed moderate agreement with a minimum for hip rotation for kinematics (R = 0.68, SD: 0.04) and knee adduction for kinetics (R = 0.59, SD: 0.33).

Figure:



Caption: Comparison between the typical joint angles, moments and powers obtained from Plug in Gait and a musculoskeletal model generated from MRI scans in the sagittal plane. The models are visible in the upper part of the Figure.

Conclusion: We found general good agreement in clinical gait assessment outputs resulting from the current traditional model adopted in clinical practice against state of the art subject specific MSK models. The results suggest that it might not be necessary to build a personalized MSK model for the aim of a standard clinical gait assessment, as it generally produces similar outputs to the traditional gait model. However, these results also prove that there is no impediment in adopting the new subject specific MSK gait analysis methods. Importantly, developing and using these personalized MSK models is of paramount importance for introducing innovations into clinical gait analyses, such as quantitative analyses of muscle function (moment arms, muscle-tendon lengths, contributions of muscle-tendon forces to movement). Furthermore, these MSK models may enable the development of future applications like computer aided surgery and/or predictions of treatment outcome. These innovations have the potential to provide greater insight into the mechanisms causing dysfunctional walking mechanics in patient populations, thereby optimising treatments.

Table:

Considered parameters (sagittal plane)	Hip	Knee	Ankle
Joint angles	0.99 (0.001)	0.99 (0.003)	0.98(0.015)
Joint moments	0.80 (0.08)	0.89 (0.04)	0.99(0.008)
Power	0.61 (0.17)	0.80 (0.08)	0.96 (0.01)

BIOMECHANICAL-BASED CLASSIFICATION OF FLATFOOT: EFFECTIVENESS OF DYNAMIC ANGLES AND INDEXES FROM 3D KINEMATICS AND BAROPODOMETRY

Claudia Giacomozzi [1,*] Paolo Caravaggi [2] Giada Lullini [2] Lisa Berti [2] Alberto Leardini [2]

[1]Technology and Health, Istituto Superiore di Sanità, Rome, [2]Movement Analysis Laboratory, Istituto Ortopedico Rizzoli, Bologna, Italy

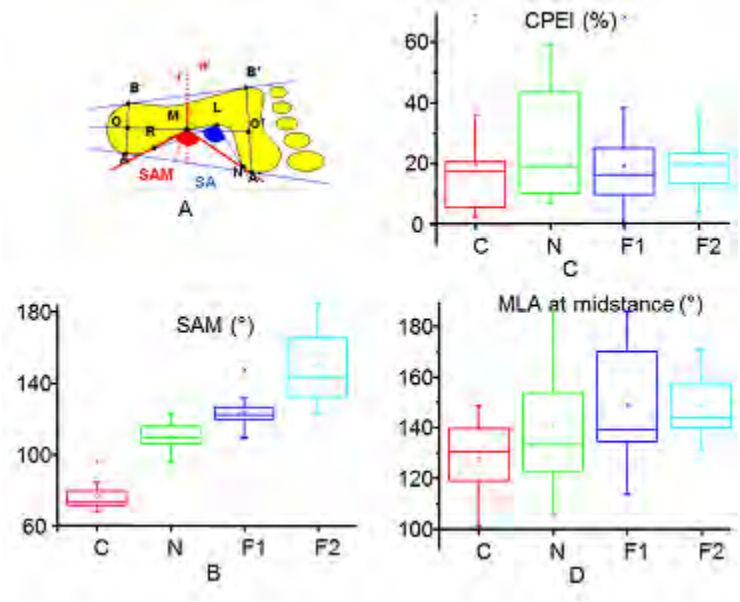
Introduction and Objectives: Clinical classification of flatfoot, based on morphology and function, may be effectively supported by objective measurements of footprints and joint motion during locomotion [1]. Motion analysis systems integrating 3D kinematics and baropodometry allow the detection of relevant functional parameters frequently used in the clinics to classify flatfeet: foot joints rotation, dynamic foot angles, footprint angles and morphometry, arch index, centre of pressure excursion index, etc. This study focusses on the analysis of these and ad-hoc defined parameters, their possible correlations and intra-subject variability. Main aim of the study is to identify the most appropriate and reliable subset of indicators which, in agreement with relevant clinical classifications, may deliver a deeper insight into the flatfoot functional classification.

Methods: 53 volunteers (25F/28M) were clinically screened and enrolled in the study. 3-5 consistent trials of level barefoot walking were acquired for each subject/foot – 358 trials in total - by using an integrated pressure-kinematics technique based on a VICON motion system, a NOVEL baropodometer, and the IORfoot model [2]; the model allowed the spatial registration between the two instruments [3]. 80 out of these 106 feet were clinically assessed by two expert physicians and classified as Cavus (C, high-arched, 9 feet), Normal (N, normal-arched, 25 feet), Level 1 Flatfoot (F1, 22 feet), or Level 2 Flatfoot (F2, more severe than F1, 24 feet). Preliminary analyses proved that most foot joint rotations during gait do not discriminate among the foot types; thus only range of motion of medial longitudinal arch (MLA) and its value at midstance were taken into account. The following baropodometric dynamic variables were calculated (Fig. 1A): Subarch Angle (SA); Modified Subarch Angle (SAM); Arch Index (AI); midfoot width w; Midfoot/Forefoot Ratio (RMFW), i.e. the ratio between w and A'B'; Centre of Pressure Excursion Index (CPEI). Median values and coefficients of variation (CV) were calculated for each foot over the available trials; ANOVA with Bonferroni correction was performed and correlation coefficients R^2 calculated over all median values and variables.

Results: The groups were found homogeneous with respect to age (31±15years); BMI of F2 (24.9±3.8kg/m^2) only differed from BMI in C (21.4±2.58kg/m^2). SA failed to be calculated in 19% of footprints, mostly in the C group where it remained undefined for all feet, and only discriminated F2 from the other groups. SAM (Fig 1B), AI, w and RMFW well discriminated the 4 groups, all statistically different one from the others (Table 1); SAM showed the lowest CVs (C: 0.11±0.08; N: 0.07±0.06; F1: 0.04±0.02; F2: 0.04±0.03). CPEI (Fig. 1C; Table 1) did not differ among the groups, and showed high variability within each group and high CV within each subject's trials (C: 0.72±0.52; N: 0.41±0.22; F1: 0.58±0.38; F2: 0.30±0.20). MLA range and MLA at midstance did not discriminate between F1 and F2, even though MLA at midstance had very low CV (C: 0.01±0.00; N: 0.01±0.01; F1: 0.02±0.01; F2: 0.01±0.01); they resulted statistically higher in F1 and F2 than in N and C, but with wide overlapping among the groups (Fig. 1D; Table 1). Interestingly, cluster analysis of MLA

range within each group revealed two well separated clusters, whose centroids (k1,k2) were comparable among the groups (C: 35.8, 15.3; N: 29.6, 14.6; F1: 30.5, 16.9; F2: 32.9, 16.9). Finally, SAM showed very high correlation coefficients (R^2) with AI (0.82), w (0.89), and RMFW (0.92), while CPEI, MLA range and MLA at midstance did not correlate with any variable.

Figure:



Caption: Figure 1. A: Novel dynamic footprint measures, plus ad-hoc definitions: M is the intersection point between medial midfoot and line r perpendicular to OO' through its midpoint; w is the midfoot width over r. B: SAM box chart. C: CPEI box chart. D: box chart of MLA at midstance (Legend: C: cavus foot; N: normal foot; F1: Level 1 Flatfoot; F2: Level 2 Flatfoot)

Conclusion: SAM, AI, w and RMFW seem to be the most appropriate dynamic footprint indexes for classifying flatfeet; SAM might be selected due to the lowest intra-subject CV. Within each group, MLA range seems to have high relevance to characterize the foot flexibility under load during walking.

Table: Table 1. Mean values ± standard deviations of the calculated parameters within each group

	SAM (°)	AI	w (cm)	RMFW	CPEI (%)	MLA range (°)	MLA at midstance (°)

QUANTIFICATION OF HEAD AND TRUNK ACCELERATIONS DURING GAIT AS A PROXY MEASURE OF POSTURAL CONTROL DEFICITS IN PARKINSON'S DISEASE.

Christopher J. Buckley [1 2,*] Brook Galna [3] Lynn Rochester [3] Claudia Mazzà [2 4]

[1]MRC-Arthritis Research UK Centre for Integrated Research into Musculoskeletal ageing (CIMA), [2]Mechanical engineering, University of Sheffield, Sheffield, [3]Institute of Neuroscience / Newcastle University Institute for Ageing, Newcastle University, Newcastle, [4]INSIGNEO Institute for in silico Medicine, University of Sheffield, Sheffield, United Kingdom

Introduction and Objectives: As a result of poor postural control when walking, people with Parkinson's disease (PD) are susceptible to falls [1]. Currently few measures exist that can quantify postural control during gait in people with PD. Lately, a selection of upper body variables have shown promise when used as sensitive measures of impaired postural control [2]. In particular, acceleration of the head relative to trunk acceleration is sensitive to the ageing process [3]. However, no investigations of gait in PD have examined head accelerations relative to trunk accelerations to quantify postural control. The objective of the current investigation was to explore whether accelerations of the head and trunk can provide a sensitive proxy measure of postural control in people with PD.

Methods: Thirteen people diagnosed with PD (70±11 years, 18 to 54 months since diagnosis) and nineteen age-matched controls (70±6 years) walked continuously for two minutes around a 25m circuit. Three inertial sensors (OPAL, ADPM Inc) were located on their pelvis (P), at their shoulder level (S) and on their head (H). Each sensor measured movement in the anteroposterior (AP), mediolateral (ML) and vertical (V) directions and were used to calculate: i) the magnitude of acceleration (root mean square); ii) step-to-step symmetry within a stride (Harmonic ratios normalised to gait speed) [2]; and iii) the ability to attenuate acceleration from inferior to superior located anatomical segments [3]. The ability to attenuate acceleration was measured using three coefficients designed to quantify the amount of acceleration attenuated from the P to the H (CPH), the P to the S (CPS) and the S to the H (CSH) [3]. A series of two-tailed paired *t*-tests was used to test the difference between groups and the level of significance was set at $p = 0.05$.

Results: No significant differences were found between the two groups in terms of anthropometric characteristics or spatiotemporal gait values. The magnitude of acceleration results showed no significant differences between the PD and control group with the exception of the head in the ML direction (PD 1.08±0.29g vs Control 0.86±0.21g, $p = 0.024$). For all sensor locations and directions, the Harmonic ratios did not show any significant differences between the two groups. In contrast, the coefficients of attenuation showed that people with PD typically did not attenuate accelerations through the trunk and neck as well as control participants (see table 1). This was most evident in the ML direction where significant differences were observed in all three coefficients (CPH: $p = 0.003$; CPS: $p = 0.009$; CSH: $p = 0.031$). In addition, a significant difference was also observed in the AP direction for CPS ($p = 0.002$).

Conclusion: People with PD walked with greater magnitude of ML head accelerations and demonstrated impaired attenuation of accelerations from the pelvis and the neck to the head. The magnitude of acceleration results must be interpreted with caution due to being gait speed and stride length dependent [4], which are both commonly effected by PD

[1]. Being speed dependent weakens the method in regards to clinical application, however, this weakness is not shared by the coefficient of attenuation [3]. Currently clinicians require objective quantifiable measures of postural control to supplement standard clinical assessments and conventional rating scales [4]. Between the three analysis techniques we present here, the coefficients of attenuation were the most sensitive to PD (particularly in the ML direction). Our findings indicate that when using inertial sensors, the inclusion of measuring the movement of the head provides unique information regarding postural control for those with PD. This information is simple to measure and is proposed to benefit clinicians seeking objective measures that are sensitive to early symptoms of PD.

Table:

	CPH %			CPS %			CSH %		
	PD	Control	*p*	PD	Control	*p*	PD	Control	*p*

IN VIVO ACHILLES TENDON FORCES DURING CYCLING DERIVED FROM 3D ULTRASOUND-BASED MEASURES OF TENDON STRAIN

Taylor Dick [1,*] Allison Arnold [2] James Wakeling [1]

[1]Department of Biomedical Physiology and Kinesiology, Simon Fraser University, Burnaby, Canada, [2]Department of Organismic and Evolutionary Biology, Harvard University, Boston, United States

Introduction and Objectives: Traditional motion analysis provides limited insight into muscle and tendon forces during movement. This study used B-mode ultrasound, in combination with measured joint angles and scaled musculoskeletal models, to provide subject-specific estimates of *in vivo* Achilles tendon (AT) force. Previous studies have used ultrasound images, tracked in 3D space, to estimate AT strains during walking, running, and jumping [1,2]. Our approach extends this work in one novel way. Specifically, we characterized AT stiffness on a subject-specific basis by recording subjects' ankle moments and AT strains during a series of isometric tests. We then used these data to estimate AT force during movement from *in vivo* measurements of tendon strain.

To demonstrate this approach, we report AT forces measured during cycling. Cycling offers a unique paradigm for studying AT mechanics. First, because the crank trajectory is constrained, joint angles and muscle-tendon unit (MTU) lengths of the gastrocnemius (MG, LG) and soleus (SOL) are also constrained. By varying crank load, subjects' ankle moments can be altered without imposing changes in MTU lengths. For this study, 10 competitive cyclists were tested at 4 different crank loads while pedaling at 80 rpm. Based on published EMG recordings (e.g., [3]) and on *in vivo* tendon force buckle data from one subject [4], we hypothesized that the cyclists' AT forces would increase systematically with crank load.

Methods: We coupled B-mode ultrasound with motion capture to estimate *in vivo* AT forces non-invasively during cycling and during a series of isometric ankle plantarflexion tests. Marker trajectories were tracked using an optical motion capture system. Joint angles and MTU lengths were calculated based on scaled musculoskeletal models [5] using *OpenSim* [6]. A 50 mm linear-array B-mode ultrasound probe was secured over the distal muscle-tendon junction (MTJ) of the MG and was tracked using rigid-body clusters of LEDs. AT lengths were calculated as the distance from a calcaneus marker to the 3D coordinates of the MG MTJ. Subject-specific AT force-strain curves were obtained from isometric tests using ultrasound to track the MTJ, markers to track both the ultrasound probe and the AT insertion, and a strain gauge to measure the net ankle torques generated by each of the subjects at ankle angles of -10° dorsiflexion, 0°, +10° plantarflexion, and +20° plantarflexion. AT strain during cycling was converted to AT force using each subject's force-strain relation. Subject-specific tendon slack lengths were calculated as the mean tendon length at 310° over all pedal cycles, based on examination of the AT length changes and on published data showing that this position in the pedal cycle precedes tendon loading across multiple pedalling conditions [4].

Results: Peak AT forces during cycling ranged from 1320 to 2160 N ± 400 N (mean± SD) and increased systematically with load (p<0.001; Fig. 1A/B). At the highest load, the peak AT forces represented, on average, 50 to 70 % of the

combined MG, LG, and SOL muscles' maximum isometric force-generating capacity, as estimated from the muscles' scaled volumes [7], the muscles' scaled optimal fiber lengths [5], and a specific tension of 20-30 N/cm^2. Peak AT forces occurred midway through the pedaling downstroke, at about 80°, which is consistent with the AT forces directly measured from one subject [4] and with patterns of EMG during cycling [3]. Peak AT strains during cycling were uncoupled from the MG MTU strains and ranged from 3 to 5 % across the different loads examined, measured at the MG MTJ.

Figure:

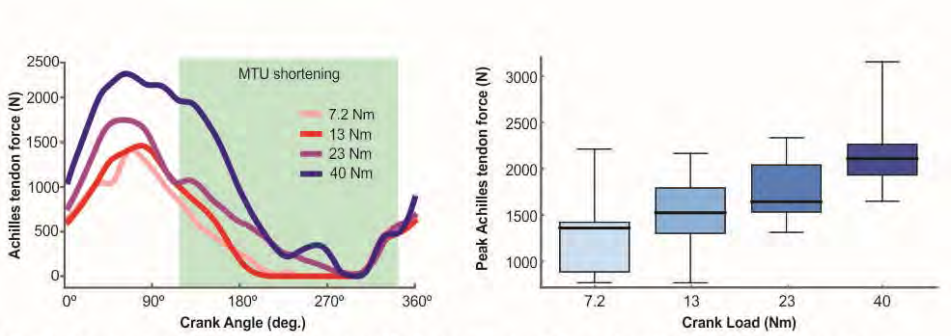

Fig 1. Evaluation of cyclists' *in vivo* AT forces using B-mode ultrasound and motion capture confirms that AT force increases with load. (A) Average AT force and MG MTU length over the pedal cycle for a representative subject cycling at 80 r.p.m and increasing crank loads. (B) Boxplots showing peak AT force for n=10 subjects cycling at

Conclusion: Our results are consistent with published data from a single subject in which AT force was measured using an implanted tendon buckle [8]; however, our results were obtained non-invasively using ultrasound and motion capture. These methods substantially augment the experimental tools available to study muscle-tendon dynamics during movement.

SS-0017

WALKING WITH INCREASED TRUNK SWAY TO DECREASE AMBULATORY LOAD ON THE KNEE JOINT: IMPLICATIONS FOR THE LOWER BACK

Corina Nüesch [1,*] Dominik Laffer [1] Annegret Mündermann [1]

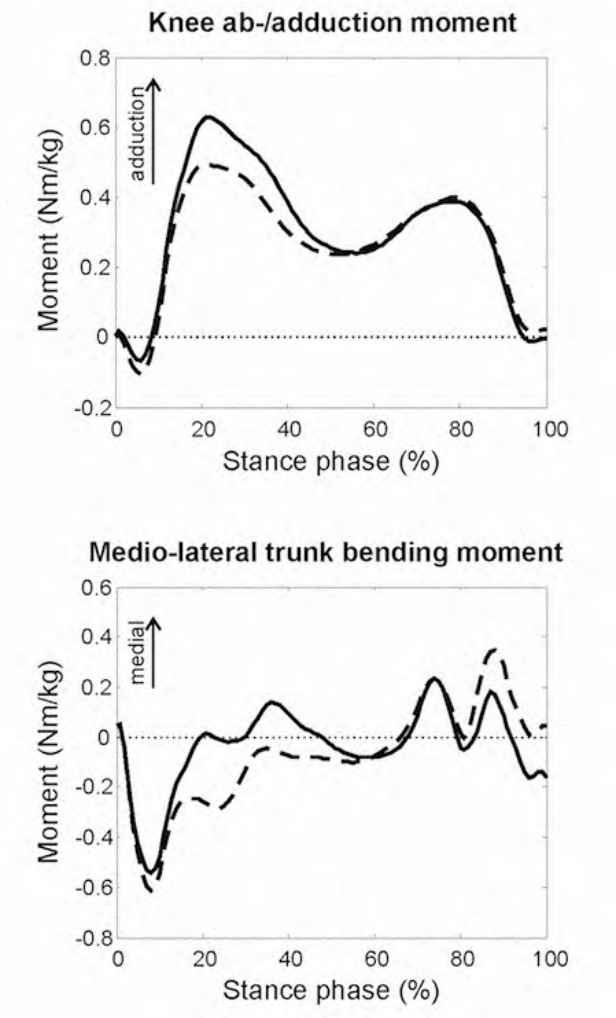
[1] Osteoarthritis Research Center, University Hospital Basel, Basel, Switzerland

Introduction and Objectives: The external knee adduction moment has been associated with the presence, severity and rate of progression of medial compartment knee osteoarthritis (OA) [1-3]. Different interventions to alter the load distribution at the knee joint during walking have been proposed. One such method – walking with increased medio-lateral trunk sway – has been shown to reduce the knee adduction moment in healthy subjects and in patients with knee OA [4,5]. However, it is unclear whether walking with an increased trunk sway alters and potentially increases the load at the lower back. Therefore, the objective of this study was to test the hypothesis that walking with increased trunk sway is associated with a reduction in the first peak knee adduction moment and an increase in the lateral bending moment at the lower back in healthy subjects.

Methods: Fifteen healthy subjects (seven males, eight females; age: 30.0 ± 8.7 years; weight: 70.5 ± 11.7 kg; height: 1.77 ± 0.08 m) participated in this study after providing informed consent. Exclusion criteria were knee pain and/or lower back pain. Three-dimensional full body kinematics and kinetics were measured using a 12-camera motion analysis system (Vicon, Oxford, UK) and two force plates (Kistler, Winterthur, Switzerland) with the full body PlugIn-Gait model [6,7]. For each subject, we collected six walking trials with normal trunk sway and six walking trials with increased medio-lateral trunk sway. Subjects walked with shoes and at their self-selected speed. For walking with increased trunk sway, subjects were instructed to increase the side-to-side motion of the upper body (with self-selected trunk-sway amplitude). For each waveform, we calculated the amplitude of the medio-lateral trunk sway, the first peak knee adduction moment, and the trunk bending moment at the time of the first peak knee adduction moment. Differences between the two walking conditions were analyzed using paired t-tests. Moreover, associations among these parameters within subjects were detected using linear regression analyses.

Results: When walking with increased trunk sway, medio-lateral trunk sway amplitude was increased six fold and the first peak knee adduction moment was reduced by 20% (Table 1). Furthermore, the mean waveform of the lateral trunk bending moment showed a prolonged greater moment that was twice as high at the time of the peak knee adduction moment than during normal walking (Figure 1). The coefficients of determination between the trunk sway amplitude and the peak knee adduction moment or the trunk bending moment respectively, were greater than 0.5 in more than two thirds of the subjects.

Figure:



Caption: Figure 1: Mean waveforms of the knee adduction moment and the lateral trunk bending moment of the stance phase for normal walking (solid line) and walking with increased trunk sway (dashed line)

Conclusion: Similar to previous studies [4,5], walking with increased medio-lateral trunk sway decreased the first peak of the knee adduction moment compared to normal walking. At the same time however, the external trunk bending moment increased in magnitude and was still higher at the time of the first peak knee adduction moment. The altered load pattern in the first part of the stance phase together with the prolonged occurrence of the medial trunk bending moment (negative) could indicate a higher load of the lower back. To counteract these greater resultant moments, greater activation of trunk stabilizing muscles might be required and fatigue of these muscles might occur earlier. These changes might contribute to the development of low back pain or increase already existing low back pain and should be monitored in gait retraining programs with increased medio-lateral trunk sway to reduce the load on the knee joint.

Table:

	Walking	Trunk Sway	*P* Value
Medio-lateral trunk sway amplitude (°)	1.7 (0.7)	10.4 (3.2)	<0.001
First peak knee adduction moment (Nm/kg)	0.68 (0.15)	0.55 (0.13)	<0.001
Trunk bending moment at time of first peak knee adduction moment (Nm/kg)	0.08 (0.16)	-0.14 (0.11)	<0.001

SS-0018

INTERPRETATION OF TIBIO-FEMORAL KINEMATICS CRITICALLY DEPENDS UPON THE KINEMATIC ANALYSIS APPROACH

Maryam Hajizadeh [1,2,*] Pascal Schütz [2] Renate List [2] Heide Boeth [3] Rainald Ehrig [4] Michael Freeman [5] William R Taylor [2]

[1]Mechanical Engineering Department, Sahand University of Technology, Tabriz, Iran, Islamic Republic Of, [2]Institute for Biomechanics, ETH Zurich, Zurich, Switzerland, [3]Julius Wolff Institute, Charité – Universitätsmedizin Berlin, [4]Zuse Institute Berlin (ZIB), Berlin, Germany, [5]ETH Zurich, Zurich, Switzerland

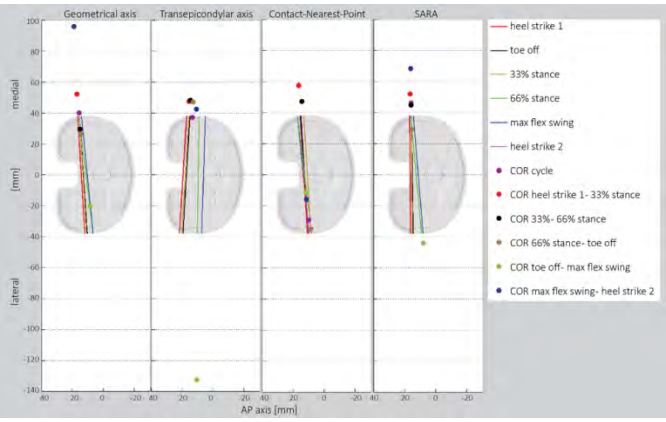
Introduction and Objectives: The analysis of tibio-femoral kinematics is important for understanding the functionality of the knee after total knee arthroplasty (TKA) [1] and the calculation of internal knee joint loading [2]. The most commonly used approaches for kinematic analysis of the knee joint are the geometrical knee axis [3-5], contact nearest point axis [3], and functional axis [1]. Controversial results on femoral anterio-posterior translation (APT) as well as the location of the center of rotation (CoR) in the transverse plane might be explained by the usage of different approaches for the kinematic analyses. Here, any lever arm of the analysis points around the actual “real” axis of rotation would result in an artificial APT and CoR, and therefore in an error in the interpretation of the joint kinematics. The objective of this study was therefore to assess the sensitivity of different kinematic analysis techniques used in the literature on the calculation of femoral APT as well as on the location of the CoR in the transverse plane.

Methods: A subject-independent set of tibiofemoral kinematic data was generated based on the pose data of the tibial and the femoral components of a TKA during a complete gait cycle of level walking. The original data was assessed *in vivo* using moving video fluoroscopy and simultaneous skin marker measurements [4], and then filtered with a moving average approach. Four different approaches were used to assess the joint kinematics: geometric center axis (GCA)[4], transepicondylar axis (TEA)[5], contact nearest point axis (CNPA)[3], and symmetrical axis of rotation approach (SARA) [6]. All these axes were calculated for the complete gait cycle of level walking. The GCA was defined by the position and orientation of the connecting line between the centers of spheres fitted to the medial and lateral femoral condyles. The TEA was approximated by the connecting line between the medial and lateral femoral epicondylar skin markers of a standing trial. The CNPA was created based on finding two points with the least femoro-tibial distance for each of the condyles for each frame for the entire gait cycle. Finally, the SARA local femoral axis was defined by a combination of chair-sit-to-stand and chair-stand-to-sit as a basic motion task for knee flexion/extension movement (SARA). Among all these definitions, only CNPA was an instantaneous axis, while all the others were fixed femoral component axes, being transformed to the tibial coordinate system during each frame. The two points defined by the intersection of the respective axes with the sagittal planes on the medial and lateral extremes of the tibial component were used for comparing the outcomes of analysis using the different techniques. Furthermore, CoRs were calculated as the linear least squared intersection of all axes in the transverse plane [7].

Results: The choice of the kinematic analysis technique used to assess the tibio-femoral motion showed a strong influence on the APT parameters, as well as the CoRs determined for the different time phases of the gait cycle (Figure

1). Furthermore, the ranges of motion (RoM) for APT were higher on the lateral sides for the GCA, TEA and SARA approaches, while CNPA produced a higher RoM on the medial side (Table 1).

Figure:



Caption: Figure 1: Knee AoR and CoR for all kinematic analysis techniques. Axes are shown at different time points within the gait cycle, while CoRs are presented for phases of cycle.

Conclusion: Even though only one single cycle of gait has been assessed, clear differences between kinematic analysis techniques in both APT and CoR were observed, demonstrating that interpretation of joint kinematics is critically dependent upon the analysis technique used. Importantly, the location of the CoR in the transverse plane shows large variance within the gait cycle for most approaches. Furthermore, not only the representation of each phase of the cycle were different between approaches, but also the average CoR for the whole gait cycle differed, possibly explaining the acute differences in tibio-femoral kinematics presented in the literature. For consistent interpretation of knee kinematics, and therefore the ability to compare the results of different studies, a clear consensus is required in the field on how to standardise analyses of tibio-femoral kinematics.

Table:

	RoM-Medial APT [mm]	RoM-Lateral APT [mm]
GCA	3.35	5.73
TEA	12.58	14.76
CNPA	5.90	3.20
SARA	3.27	8.45

COMPUTATIONAL SIMULATIONS AND STRESS DISTRIBUTIONS OF LANDING DURING BAREFOOT RUNNING USING FOREFOOT STRIKE PATTERN

Yu Hua Li [1 2,*] Kah Fai Leong [1 2] Yao Dong Gu [3]

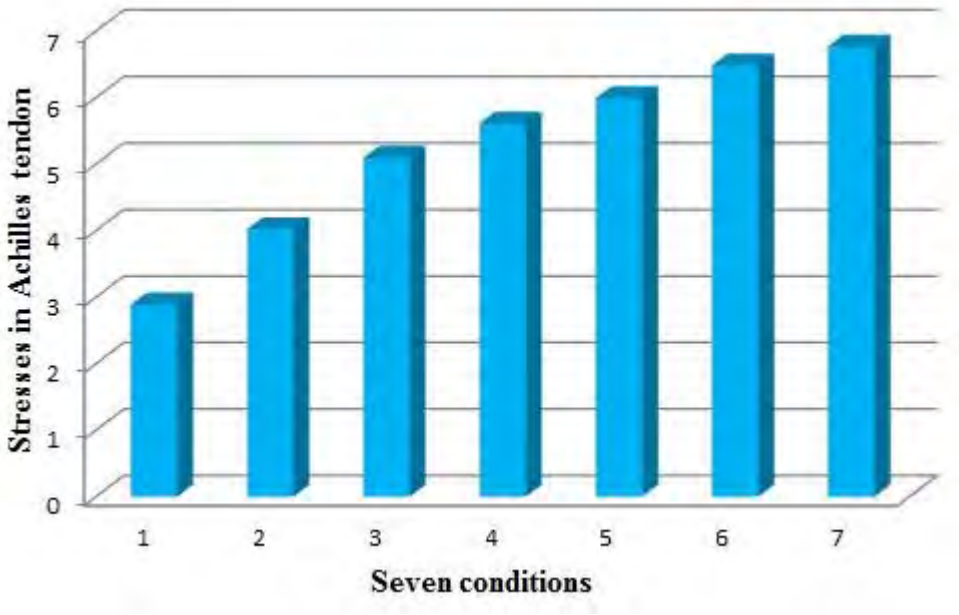
[1]Nanyang Technological University, School of Mechanical and Aerospace Engineering, [2]Nanyang Technological University, Institute for Sports Research, Singapore, Singapore, [3]Ningbo University, Faculty of Sports Science, Ningbo, China

Introduction and Objectives: Barefoot running, also known as minimalism or natural running, is running without shoes or running in thin-soled shoes or 'barefoot running' shoes. Barefoot running has become very popular in last few years amongst more and more recreational as well as competitive athletes. Barefoot running encourages forefoot strike (FFS) pattern whereas majority of runners in shod running tend to use rearfoot strike (RFS) pattern. In fact, different strike patterns during running may have effects on the forces acting on the Achilles tendon, the loading rate, the magnitude of impact peak and so on. These may be the potential factors that can cause injuries in foot and lower extremity. The purpose of this study is to determine the stresses concentration and distributions in the foot and lower extremity of landing during barefoot running using FFS pattern.

Methods: In this study, a detailed three dimensional (3D) finite element (FE) model has been developed based on the manganic resonance images (MRI). 2D images were converted to 3D images in ScanIP to obtain the boundaries of the surfaces of the bones and soft tissue. These 3D images were then smoothed in Geomagics. The smoothed surfaces were then processed in SolidWorks to obtain the solid models of the foot and ankle. Finally, the FE model was developed in Abaqus (Version 6.13). Then the model was validated through comparing the current predicted plantar pressure distributions with the data collected from experiments. The current predictions showed good agreement with the experimental measurement. After validating, the model was then used to investigate the stresses concentration and distributions of landing during barefoot running using FFS pattern.

Results: The simulation results showed that the peak Von Mises stress occurred in the region of Achilles tendon, and the stress values increased with the increasing load applied to the supporting plate. The metatarsals in the forefoot region also sustained higher Von Mises stresses compared with other bone components especially the third and fifth metatarsals. The reason may be the load applied in Achilles tendon increased when landing during barefoot running using FFS pattern compared with RFS pattern.

Figure:



Caption: Figure 1. Peak Von Mises stresses in Achilles tendon during seven conditions

Conclusion: In summary, this study developed a detailed 3D FE model of human foot and ankle to investigate the stresses concentration and distributions of landing during barefoot running using FFS pattern. The predicted results showed good agreement with the experimental measurements. The peak Von Mises stress was found to be in the region of Achilles tendon, and these results are in good agreement with reported scientific literatures. Through the simulation results, the internal stresses and the mechanical responses to facilitate injury prevention during barefoot running can be further investigated.

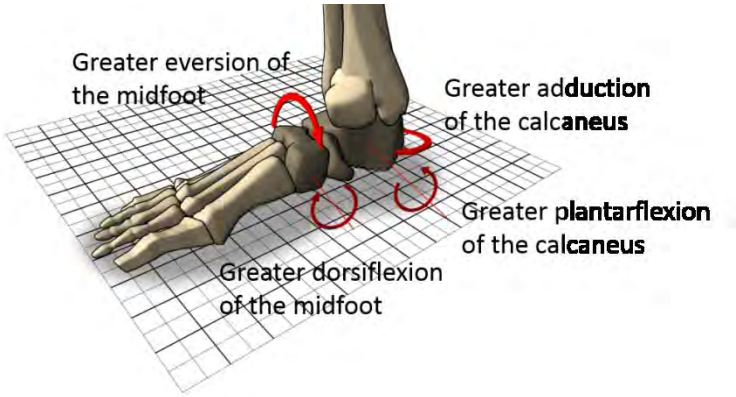
THREE-DIMENSIONAL INTERSEGMENT MOTION OF THE PAEDIATRIC FOOT DURING GAIT: ASSOCIATIONS WITH OBESITY

Ryan Mahaffey [1,*] Stewart Morrison [1] Paul Bassett [2] Wendy Drechsler [1] Mary Cramp [3]

[1]Health, Sport & Bioscience, University of East London, London, [2]Statsconsultancy Ltd, Amersham , [3]Department of Allied Health Professions, University of West England, Bristol, United Kingdom

Introduction and Objectives: Childhood obesity has emerged as a major public health concern with a high level of health burden [1]. Specifically, childhood obesity has been reported to impact on the biomechanical characteristics of the musculoskeletal system [2] and is commonly associated with a pronated foot type and pes planus with implications for long-term dysfunction [3,4]. Previous research to examine relationships between childhood obesity and the foot have focused on static or two-dimensional dynamic analysis [5,6,7]. Limited information has been reported on three-dimensional (3D) dynamic intersegment foot motion in obese children [8,9]. Therefore, the purpose of this study was to explore the relationships between 3D intersegment angular foot motion during gait and obesity in boys age 7 to 11.
Methods: Fat mass (obesity) was measured in fifty-five boys (age 9.55 ± 1.18 years) using air displacement plethysmography. Gait analysis was conducted on the right foot of each participant using the 3DFoot model [10] to capture 3D angular motion of the shank, calcaneus, midfoot and metatarsals. Principal component analysis (PCA) was employed to reduce the multidimensional nature of 3D intersegment foot motion to components from which regression scores were calculated based on variation in the waveform data. Multiple linear regression analysis determined the relationships between obesity and the regression scores from PCA (representing 3D intersegment foot motion) whilst accounting for potential anthropometric and gait related confounding factors. Second order polynomials were fitted to each predictor variable to account for curvilinear relationships. Only those regression scores that were significantly (p<.05) associated with obesity are presented in the results.
Results: PCA determined eight shank-calcaneus, three calcaneus-midfoot, and four midfoot-metatarsal components for multiple linear regression analysis. Table 1 presents the significant regression analaysis findings between components (representing 3D intersegment foot motion during gait) with obesity and confounding variables. Higher fat mass (and shorter stance phase duration) predicted greater plantarflexion of the calcaneus during the first half and end of stance and the end of swing. Greater abduction of the calcaneus throughout stance and swing was also predicted by greater fat mass. Finally, at the midfoot, higher fat mass predicted greater dorsiflexion and eversion (confounded with greater body mass index, height and step length) throughout the gait cycle.

Figure:



Caption: Figure 1. Representation of foot segment angular motion during gait associated with greater obesity.

Conclusion: The results demonstrated significant relationships between obesity and shank-calcaneus and calcaneus-midfoot motion during walking, summarised in Figure 1. The finding of greater calcaneus abduction concurs with previous video-based reports of externally rotated feet in obese children which may be a strategy employed to aid stability [7]. Calcaneal plantarflexion and midfoot dorsiflexion in boys with higher fat mass mirror bone alignment found in pes planus from static radiographic research [5]. Midfoot eversion in boys with higher fat mass is consistent with greater plantar pressures under the medial longitudinal arch in obese children [11]. Altered rearfoot and midfoot motion in children with greater body fat are consistent with the view that obesity affects the structural integrity and function of the foot during walking. Further research is required to understand the implications for structural dysfunction of the foot in obese children.

SS-0021

THE INFLUENCE OF MINIMALIST FOOTWEAR ON METATARSAL BONE STRAINS DURING RUNNING

Colin Firminger [1,*] Matthieu B Trudeau [2] Benno M Nigg [2] W Brent Edwards [2]

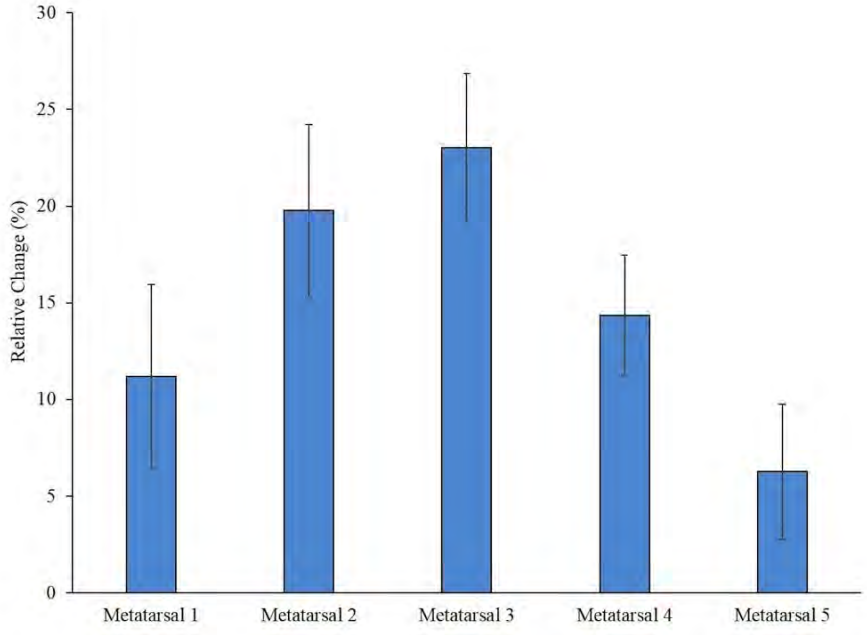
[1]Biomedical Engineering, [2]Kinesiology, University of Calgary, Calgary, Canada

Introduction and Objectives: Strain magnitude plays a fundamental role in the development of metatarsal stress fracture [1] and footwear type has been identified as a potential factor affecting metatarsal strain during running [2]. Minimalist footwear, characterized by a less cushioned and more flexible midsole, is becoming increasingly popular among runners. Our purpose was to quantify the effects of a traditional running shoe and a minimalist running shoe on peak metatarsal bone strain.

Methods: Forty-three participants (20 females: age 28.0 ± 9.5 yrs; height 165.5 ± 5.1 cm; mass 59.7 ± 7.3 kg; 23 males: age 31.0 ± 8.7 yrs; height 177.3 ± 6.3 cm; mass 76.7 ± 8.3 kg) ran 10 trials overground at 3.3 ± 0.5 m/s wearing either a traditional running shoe (i.e., control shoe) or a minimalist running shoe; both shoes are commercially available. Foot kinematics were collected on the left leg and insole plantar pressure data were collected on the right leg concurrently at 240 Hz and 200 Hz, respectively; symmetric gait was assumed. Kinematic data were used to determine metatarsal segment angles throughout stance. Insole pressure data were separated into specific regions of the forefoot in order to capture the forces acting underneath the five metatarsal and five toe regions. Metatarsal angles and forces served as inputs to a musculoskeletal model [3] of the metatarsophalangeal joints to quantify axial forces and bending moments at the mid-diaphysis of each metatarsal. The model assumed that: **1)** each metatarsal was rigidly attached at its base; **2)** axial forces acted through the neutral axis of the metatarsal shaft; **3)** no moment transfer occurred through the metatarsophalangeal joint; **4)** each toe was a single phalange; **5)** plantar muscles inserted inferiorly at the midpoint of the phalanges. Normal stress produced by the sum of axial force and bending moment at the mid-diaphysis was found using standard beam theory. Idealized cross-sectional bone geometry were allometrically scaled to each participant's height and weight. Metatarsal strains were calculated from stresses using Hooke's law, assuming an elastic modulus of 17.0 GPa for cortical bone. Differences in peak strains between shoe conditions were compared using Student's paired t-tests ($\alpha = 0.05$).

Results: Peak strains were significantly greater for all metatarsal bones in the minimalist shoe compared to the control shoe ($p<0.001$); percent changes from control ranged from 6.3-23.0%, depending on bone (Figure 1). Mean absolute magnitudes in peak strain ranged from 1511-5793 με for the control shoe and from 1647-6895 με for the minimalist shoe (Table 1). For both shoe conditions, peak strains were consistently highest at the second metatarsal and lowest at the first metatarsal.

Figure:



Caption: Figure 1: Percent change in subject-average peak metatarsal strains from control to minimalist shoe (± 95% confidence interval). All changes were significant at $p \leq 0.001$.

Conclusion: Our findings suggest that metatarsal bone strains may be higher when running in minimalist shoes compared to traditional shoes, but whether these increased strains are associated with an increased risk of stress fracture remains unknown. Apart from the relatively high second metatarsal strains (≈6000-7000 με), the strain magnitudes calculated herein agree well with experimental strain gauge data [4]; our future work will attempt to determine the source of this discrepancy. Ultimately, this study provides valuable information beyond traditional biomechanical measures that may help to decrease metatarsal bone strain and stress fracture risk through the modification of footwear properties.

Table:

Shoe	Metatarsal 1 Strain (με)	Metatarsal 2 Strain (με)	Metatarsal 3 Strain (με)	Metatarsal 4 Strain (με)	Metatarsal 5 Strain (με)
Control	1511 (157)	5793 (501)	3431 (257)	3169 (271)	2117 (217)
Minimalist	1646 (154)	6895 (599)	4224 (356)	3622 (329)	2255 (245)

BODY MASS INDEX, HBA1C, AGE AND DURATION OF DIABETES AS RISK FACTORS FOR DIABETIC FOOT ULCER

Taeyong Lee [1,*] Jee Chin Teoh [2]

[1]Department of Medical Biotechnology, Dongguk University, Seoul, Korea, Republic Of, [2]Department of Biomedical Engineering, National University of Singapore, Singapore, Singapore

Introduction and Objectives: The lifetime risk to develop foot ulcers in the diabetes population is approximately 25%. 20% of them require major lower limb amputation. The mortal rate is reported to be 10% at time of amputation and 70% within 5 years. The statistics clearly explain the high fatality of diabetic foot ulcer but the early diagnosis of diabetic foot is not yet properly attended.

Diabetic foot risk is usually graded based on neurological assessment such as mono-filaments and vibration perception which are predictive methods of peripheral neuropathy. However, loss of sensation is not the direct reason. In fact, abnormally stiffened tissue that fails to withstand the impact force is a more straightforward explanation of foot ulceration. Therefore it is of utmost importance to quantify the plantar tissue stiffness which can provide the useful information to prevent foot ulcer. The objective of this study is to evaluate the relationship between plantar tissue stiffness and several parameters like age, diabetes duration (years of DM), body mass index (BMI) and HbA1c level. Understanding of these associations is certainly helpful in assigning levels of risk and in customizing foot care plan.

Methods: One hundred diabetes patients were recruited with approval from the NUS Institutional Review Board (IRB). The localized response of plantar soft tissue at hallux, 2nd sub metatarsal head (MTH) pad and heel pad were measured using the indentation system which consisted of a stylus driven by a stepper motor. One end of the stylus indented the tissue and the tissue response was quantified by the force sensor located at the other end.

Results: Two out of the four factors (BMI, HbA1c, Age and years of DM) were plotted against the plantar soft tissue stiffness. As the plantar tissue stiffness increases, the colour scale will move closer to the red spectrum. Selected factors were plotted to evaluate the contribution of each factor combination to describe the plantar soft tissue response. As shown in Fig.1A to 1F, it can be deduced that HbA1c level have a more influential role in altering the tissue stiffness in 2nd sub-MTH. The higher stiffness values, which are represented by the red spectrums, are usually observed in high BMI and high HbA1c score. Meanwhile, lower stiffness values denoted by blue spectrums are found in low BMI and low HbA1c level. Similar results are also found in hallux and heel pad. HbA1c level measures the average level of blood sugar over a period of weeks or month. Prolonged exposure to high blood glucose brings about pathological changes by enhancing reactions between reducing glucose and cellular protein that increases the formation of advanced glycation end products (AGEs) [1]. Accumulation of these compounds decreases the elasticity of tissue by the increased intermolecular cross linking and adversely modified side-chains [2]. Clinical studies have shown the stiffer plantar tissue in diabetic patients as compared to their age-matched control [6, 12]. There has been a large cohort of data showing glycated collagen to be consistent with the HbA1c level [11].

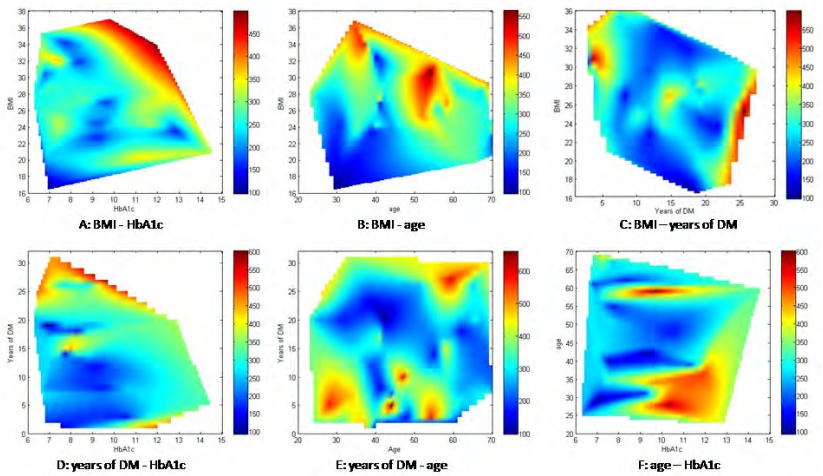
BMI also plays a key role in increasing the plantar soft tissue stiffness as shown in Fig. 1A to 1C whereby red spectrums (high tissue stiffness) are concentrated at high BMI regions. This may be explained by the strong relationship between

high BMI and DM [9, 4, 3, 7,5, 10]. It is also postulated that the loss in weight and BMI effectively improve glycemic control [8]. In other words, high BMI may cause the increase in HbA1c which may undesirably stiffen the tissue.

The results suggested that patients with BMI higher than 25kgm^{-2} or HbA1c >9%, as observed from Fig. 1A to 1F, are likely to have stiffened plantar tissue that required special attention prevent the occurrence of foot ulcer.

On the other hand, age and years of DM did not affect the tissue response much as the color spectrum obtained is not consistent and hence not conclusive. Even in young patients with short duration of diabetes, the tissue stiffness may still be adversely increased as long as the HbA1c level is high (Fig 1F).

Figure:



Caption: Figure 1: Triadic relationship of selected factor combination of 2ndsub-MTH pad. The color scale denotes the tissue stiffness in terms of stiffness variable, K (N/mm).

Conclusion: The results recommended that in the effort to design the foot care plan, patient's HbA1c score and BMI should be paid more attention. Special consideration should be given to the high risk diabetic foot group in high HbA1c score above 9% or BMI >25 kgm^{-2}.

REQUIRED FIDELITY OF FOREFOOT GEOMETRY REPRESENTATION FOR PRACTICAL AND ACCURATE PREDICTION OF PLANTAR PRESSURES USING FINITE ELEMENT ANALYSIS

Scott Telfer [1] [2,*]Ahmet Erdemir [3]James Woodburn [2]Peter Cavanagh [1]

[1]Department of Orthopaedics and Sports Medicine, University of Washington, Seattle, United States, [2]Institute for Applied Health Research, Glasgow Caledonian University, Glasgow, United Kingdom, [3]Department of Biomedical Engineering, Cleveland Clinic, Cleveland, United States

Introduction and Objectives: Integration of patient-specific biomechanical measurements into the design of therapeutic footwear has been shown to improve clinical outcomes in patients with diabetic foot disease. The added use of computational modelling intended to optimise intervention design may help to build on these advances. However, at present, the time and labour required to generate personalised models of foot anatomy and conduct simulations restrict their routine clinical utility. We previously presented a simplified finite element (FE) model of the forefoot that was based on basic geometric shapes to represent both the metatarsals and bulk soft tissues [1]. This approach demonstrated the feasibility of a rapid model development and simulation workflow that can inform clinical decision making with regards to the prescription of footwear design. The aim of the present study is to investigate the level of geometric fidelity required to adequately predict plantar pressures under the metatarsal heads (MTHs). In addition, model development times were investigated to evaluate the feasibility of the proposed models for routine clinical use.

Methods: Dynamic plantar pressure measurements, computed tomography (CT) scans, and 3D surface scans of the right foot were obtained from 8 volunteers.

In total, four FE model designs (one authentically representing detailed anatomy (GEOM) and three simplified) representing the forefoot with varying levels of fidelity were tested for all participants (Figure 1). The GEOM model was used as the reference that the simplified models were compared against, and consisted of geometrically accurate metatarsal and bulk soft tissue components segmented from the CT data. In simplified model 1 (SM1), the metatarsals were represented as spheres scaled to the measured MTH diameters and cylinders scaled to the measured lengths of the bone [1]. The bulk soft tissue was represented as a modified rectangular block. SM2 used the same soft tissue representation, however the MTHs of the lesser metatarsals were modelled as a cylinders standing on their curved surface with width and diameter defined by the width of the MTH geometry and a circle fitted to the sagittal plane view of the MTH respectively. The sesamoids were also represented in this model. SM3 used the same metatarsal design as SM2 but the soft tissue surface geometry was taken from 3D surface scans of the foot.

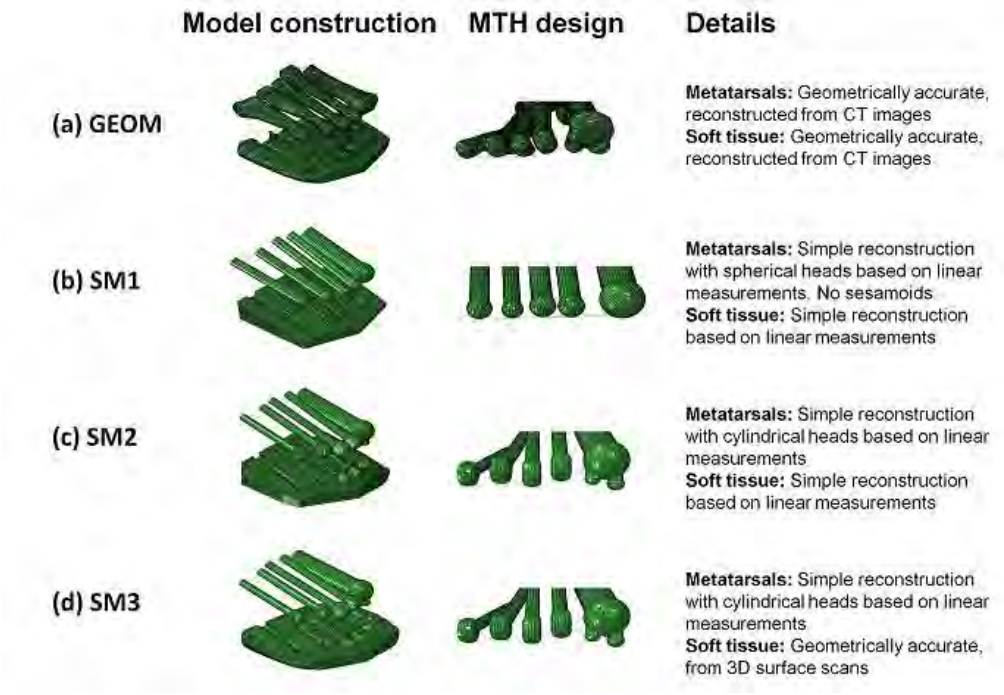
All models were assembled and run in the finite element analysis package Abaqus/Standard (V6.10; Simulia, Providence, RI) using the implicit static solver. Simulations were performed for the instance of peak forefoot loading [1], and the same loading was applied for each participant for barefoot, shod and shod with insole conditions.

The predicted peak pressure across a mask on the plantar surface of the soft tissue component below each MTH was used as the primary basis for comparisons between models. Absolute differences between the anatomical and simplified

models were compared using a repeated measures analysis of variance (α=0.05) followed by post-hoc pairwise t-tests (adjusted for multiple comparisons).

Results: The best performing simplified model design was found to be the SM3 design, which gave mean differences of 13.3kPa (SD 13.4), 12.52kPa (SD 11.9) and 9.6kPa (SD 9.3) for barefoot, shod and insole conditions respectively when compared to the GEOM model. These results were significantly better than the SM2 design in the shod (p=0.017, 95% CI [1.12, 10.32]) and insole (p=0.009 95% CI [1.33, 8.42]) conditions, although there were no statistically significant differences for the barefoot conditions (F(2,8)=3.144, p=0.098). Mean build times for the GEOM and SM3 models were 194 minutes (range 161-228) and 54 minutes (range 48-58) respectively.

Figure:



Caption: Figure 1 - FE model designs

Conclusion: A key factor in producing simplified models with direct patient utility is identifying the minimum dataset required to produce a clinically useful model of the forefoot. The best performing model here (SM3 design) required estimates of plantar tissue thickness, MTH morphology, and full soft tissue surface geometry. All measurements required to produce the simplified models presented in this paper can be obtained using easily accessible clinic-based technologies including ultrasound and 3D surface scanning.

This work has extended the concept of simplified personalised finite element model of the forefoot that can be generated through accessible clinic-based measurement techniques. These models perform adequately in comparison to more detailed FE models. The advantages of this approach, particularly in terms of build time, may improve the broad utility of the technique and bring it closer to clinical feasibility in terms of integration into the process of footwear and insole design.

SS-0024

ON THE INTERACTION OF THE ACHILLES TENDON, PLANTAR HEEL PAD AND PLANTAR FASCIA

Freddy Sichting [1,*] Niels Hammer [2] Thomas Milani [1]

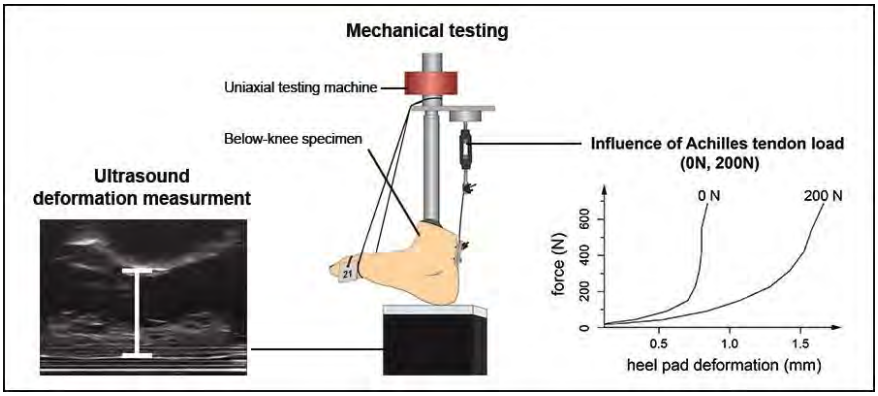
[1]Department of Human Locomotion, Technische Universität Chemnitz, Chemnitz, [2]Institute of Anatomy, University of Leipzig, Leipzig, Germany

Introduction and Objectives: While literature provides consistent evidence that force is transmitted from the Achilles tendon to the plantar fascia through the calcaneus, the plantar heel pad has hardly been considered in this context. However, the fibrous tethering mechanism of the heel pad gives sound evidence to hypothesize that tension of the Achilles tendon or plantar fascia influences heel pad deformation. Proving this hypothesis could shed new light on the damping mechanism of the hindfoot, but remains challenging as will be shown in this study.

Methods: Heel pad deformation of ten below-knee cadaver specimens was recorded using two simultaneous measurement methods. A uniaxial testing machine provided information of force-displacement of the foot while an ultrasound imaging system was used to measure alterations in heel pad thickness (Fig. 1). The setup allowed heel pad deformation to be differentiated from foot displacement in a range from 10 to 680 N at 134 N/s. First, heel pad deformation was measured under different Achilles tendon tensile loads, increasing stepwise from 0 to 200 N with increments of 50 N, with an intact plantar fascia. Then, this procedure was repeated with a transected plantar fascia, resulting in a total of ten different loading scenarios. Maximum heel pad deformation and load-deformation data were analyzed for all scenarios and compared statistically.

Results: Maximum heel pad deformation increased significantly ($p < 0.05$) with increasing Achilles tendon loads (at 0 N: d = 1.59 ± 0.71 mm; at 200 N: 2.41 ± 0.79 mm). Transecting the plantar fascia revealed no further change in maximum heel pad deformation in this particular experimental setup. The load-deformation curves revealed that the heel pad becomes softer with increasing Achilles tendon loads (Fig. 1). Transecting the plantar fascia had no significant effect. Besides the vertical displacement, we were able to detect corresponding horizontal displacement of the calcaneus using the ultrasound records. The horizontal displacement decreased with increasing Achilles tendon load.

Figure:



Caption: Fig. 1: Study protocol to investigate the influence of Achilles tendon and plantar fascia tension on the deformation of the plantar fat pad

Conclusion: First evidence is provided that heel pad deformation might be influenced by the adjacent connective tissues, mainly through tensile load on the Achilles tendon. The explanations for this phenomenon might be manifold and remain unclear. The Achilles tendon may interact directly with the heel pad via collagenous septa of the heel pad. Thereby, the macro chambers of the heel pad might be realigned to a more vertical position, changing its mechanical properties. Another explanation could be the change of calcaneus mobility that depends on Achilles tendon load. This explanation can be confirmed by our observations from the ultrasound measurements, showing an additional horizontal displacement of the calcaneus under load. Both approaches have barely been considered in previous studies on changes in the mechanical properties of the heel pad. The presented findings can contribute to raising awareness of the possible contributions that this functional interdependence between Achilles tendon and heel pad may have in hindfoot biomechanics.

THE RELATIVE IMPORTANCE OF INCLUDING PERSONALIZED HIP JOINT CENTER LOCATION AND MUSCLE LINE-OF-ACTION DEFINITION IN MUSCULOSKELETAL MODELS TO ASSESS HIP JOINT LOADING IN CP-PATIENTS WITH PROXIMAL FEMORAL DEFORMITY.

Lode Bosmans [1]christophe Van Dijck [2]Mariska Wesseling [1]Lennart Scheys [3]Ilse Jonkers [1,*]

[1]Kinesiology department, KU Leuven, [2]Materialise, [3]Department of development and regeneration, KU Leuven, Leuven, Belgium

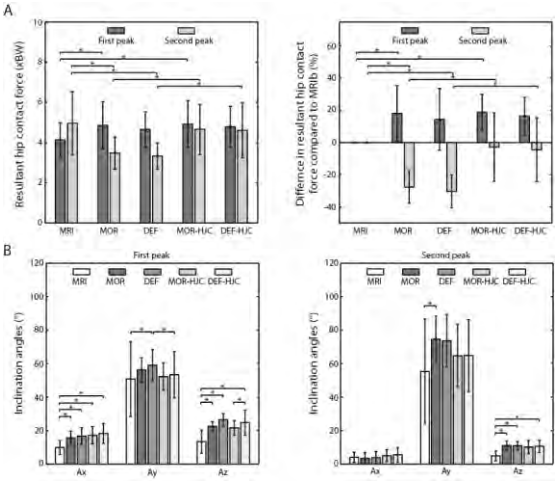
Introduction and Objectives: Children with cerebral palsy (CP) often present proximal femoral bone deformities, such as increased femoral anteversion (FA) and neck-shaft angle (NSA). As generic musculoskeletal models (MSM) do not account for bone deformities, they are not suitable to represent the described population [1]. Personalized MSMs created based on magnetic resonance images (MRI) include the highest level of detail, such as bone geometry, muscle paths, joint center locations and joint kinematics. Different semi-automatic methods have been developed. One of the earliest methods consisted of partially deforming a generic MSM by adapting the bone and muscle geometry of a specific region of interest [2]. Recently, morphing methods have been proposed that morph bone geometry or imaging data onto personalized bone geometry and subsequently transform the muscle points [3]. These methods are more automated and less time demanding. However, the level of subject-specific geometric detail clearly differs from the image-based methods. This study investigates to what extent the approximation of subject-specific detail in these models affects the calculated hip contact forces in patients with proximal femoral deformities. If estimated hip loading only minimally differs between the different model types, this would suggest that deformed and morphed generic MSMs could serve as less time demanding alternatives for image-based MSMs to estimate hip joint loading in this patient group.

Methods: Eight subjects with diplegic CP (8-12 yrs) were included in this study. For each subject, a clinical gait analysis was performed and MRI of the lower extremities were captured. For each subject, six musculoskeletal models were created: (1) a personalized MRI-based model (MRI, [2]); (2) a morphed generic model (MOR) where the generic femur bone geometry was transformed onto the image-based femur geometry using an iterative morphing procedure [3]; (3) a deformed model (DEF) with regional deformation of the generic proximal femur to account for the subject-specific FA, NSA and neck length [4]; (4&5) for the latter two model types, a subject-specific hip joint center (HJC) definition was additionally included (MOR-HJC and DEF-HJC). For each subject, dynamic simulations of gait were generated in Opensim [1] for all models using the subject-specific kinematics. Following static optimization, first and second peak hip contact forces were calculated [5]. The contact forces of the MRI model are used as reference to compare the results between the model types. Results were compared using a Friedman test ($p < 0.05$), with posthoc Bonferroni correction.

Results: For MOR and DEF, the resultant hip contact force is overestimated at the first peak but underestimated at the second peak (Fig. 1a). For MOR, Ax and Az are overestimated at the first peak, indicating a less vertically orientated vector (Fig. 1b). For DEF, an overestimation of all three inclination angles is noticed, indicating a less vertical and posterior orientated vector. At the second peak, Ay is overestimated for MOR whereas Az is underestimated for MOR and DEF. When including the subject-specific HJC in MOR-HJC and DEF-HJC, the estimation of the magnitude of the second

peak of the resultant hip contact force improves for both models (Fig 1a). At the first peak, Ay decreased for DEF-HJC, indicating a less anterior orientation (Fig. 1b).

Figure:



Caption: : Magnitude of (A) the two resultant peaks and (B) the inclination angles of the resultant hip contact force. Significant results ($p < 0.05$) are indicated with an asterix (*).

Conclusion: This study reconfirms the need to include subject-specific detail in MSMs used to estimate hip joint loading in CP-subjects with proximal femoral deformity. Inclusion of subject-specific HJC is key to introduce a relevant description of hip geometry. Nevertheless, as inclusion of subject-specific muscle lines-of-action paths still accounts for 17% and 7% of the difference in hip joint loading (for the first and second peak of the resultant loading respectively), MRI-based musculoskeletal models should remain the standard to evaluate hip joint loading in this population.

Therefore, the deformed and morphed generic MSMs in their present form cannot serve as less time demanding alternatives for image-based MSMs to estimate hip joint loading in this patient group. In future research, the use of bone-geometry based methods in combination with statistical shape modeling techniques that do account for variability in muscle line of action, should therefore be considered in this population.

SS-0026

DEVELOPMENT OF A MUSCLE MODEL PARAMETER CALIBRATION METHOD VIA PASSIVE MUSCLE FORCE MINIMIZATION

Allison L. Kinney* [1], Benjamin Fregly[2]

[1]Department of Mechanical and Aerospace Engineering, University of Dayton, Dayton, OH, [2]Department of Mechanical and Aerospace Engineering, University of Florida, Gainesville, FL, United States

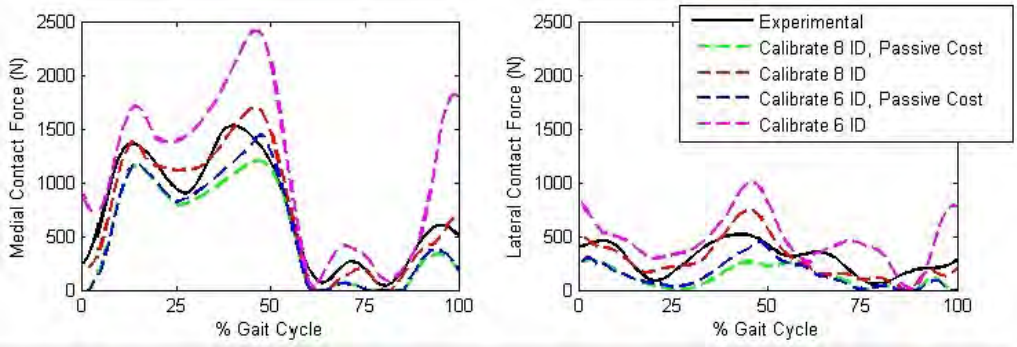
Introduction and Objectives: Computational predictions of subject-specific muscle and knee joint contact forces during walking may improve individual rehabilitation treatment design. Such predictions depend directly on specified model parameter values. However, model parameters are difficult to measure non-invasively. Methods for muscle model parameter calibration have been developed previously [1]. However, it is currently unknown how the musculoskeletal system chooses muscle model parameter values. Previous studies have hypothesized that muscles avoid injury during walking by generating little passive force and operating in the ascending region of the force-length curve [2]. This hypothesis suggests that muscle model parameter values may be selected by the body to minimize passive force. The purpose of this study was to develop a method for calibrating muscle model parameter values and muscle moment arms during walking via minimization of passive force.

Methods: Experimental data were collected from a subject with a force-measuring knee implant [3-4]. A subject-specific model was created in OpenSim [5]. Muscle geometry and muscle model parameter values were transferred from a generic OpenSim model [6]. Inverse kinematics and inverse dynamics analyses were performed for one gait cycle of walking. All muscles were modeled with a rigid tendon muscle model. A reserve actuator was included at each joint. A two-level optimization-based calibration method was developed. The outer level optimization calibrated muscle model parameter values and muscle moment arms with the goal of obtaining a solution with all muscle activations between 0 and 1. Muscle model parameter values were calibrated by optimizing scale factors for tendon slack length and optimal fiber length relative to the generic OpenSim model. Muscle moment arms were calibrated by optimizing offsets that allowed deviations in the moment arms. The inner level optimization optimized the muscle and reserve actuator activations while minimizing the activation and matching the experimental inverse dynamics loads. Four calibrations were performed with the two-level optimization-based approach. During two optimizations, calibration was performed by tracking 8 inverse dynamics loads (3 hip, 3 knee, and 2 ankle) using the in vivo knee contact force data. During the remaining optimizations, calibration was performed by tracking 6 inverse dynamics loads (3 hip, 1 knee, 2 ankle). Two optimizations were performed where passive muscle force was minimized by the outer level optimization. Medial and lateral contact forces were predicted for each optimization and compared with the experimental knee contact forces.

Results: Optimizations that minimized passive muscle force increased all tendon slack length and optimal fiber length values (average: 1.2, range: 1.0 – 1.4) and predicted smaller medial and lateral contact forces relative to the experimental measurements (Figure 1). Optimizations that did not minimize passive muscle force changed tendon slack length and optimal fiber length values minimally (average: 1.0, range: 0.8 – 1.2) and predicted medial and lateral contact forces larger than the experimental knee contact forces (Figure 1). Muscle moment arm offsets for all optimizations were generally

small (average: 0.2 cm) but varied across muscles (range: 0 – 2.6 cm). Calibration with 6 inverse dynamics loads and no passive force minimization predicted the least accurate medial and lateral forces (Table 1).

Figure:



Caption: Medial and lateral contact force predictions

Conclusion: Calibration of muscle model parameter values and muscle moment arms was influenced by passive muscle force minimization. Minimization of passive muscle force caused muscles to operate only in the ascending region of the force-length curve and eliminated passive force in all muscles. Optimizations that did not minimize passive force allowed large passive force generation in some muscles. Calibration without in vivo knee contact force data and passive force minimization represents the common approach used by researchers when contact force data are not available. The high contact force predictions from this approach suggest that excessive passive muscle force may contribute to the general tendency to overpredict knee contact forces.

Table:

	Medial Contact Force		Lateral Contact Force	
	RMSE	R^2	RMSE	R^2
Calibrate 8 ID, Passive Cost	242	0.76	191	-0.84

A NOVEL COMPARISON OF ARTIFICIAL INTELLIGENCE METHODS FOR DIAGNOSING KNEE OSTEOARTHRITIS

Luca Parisi [1,*] Paul Robert Biggs [2] Gemma Marie Whatling [2] Catherine Avril Holt [2]

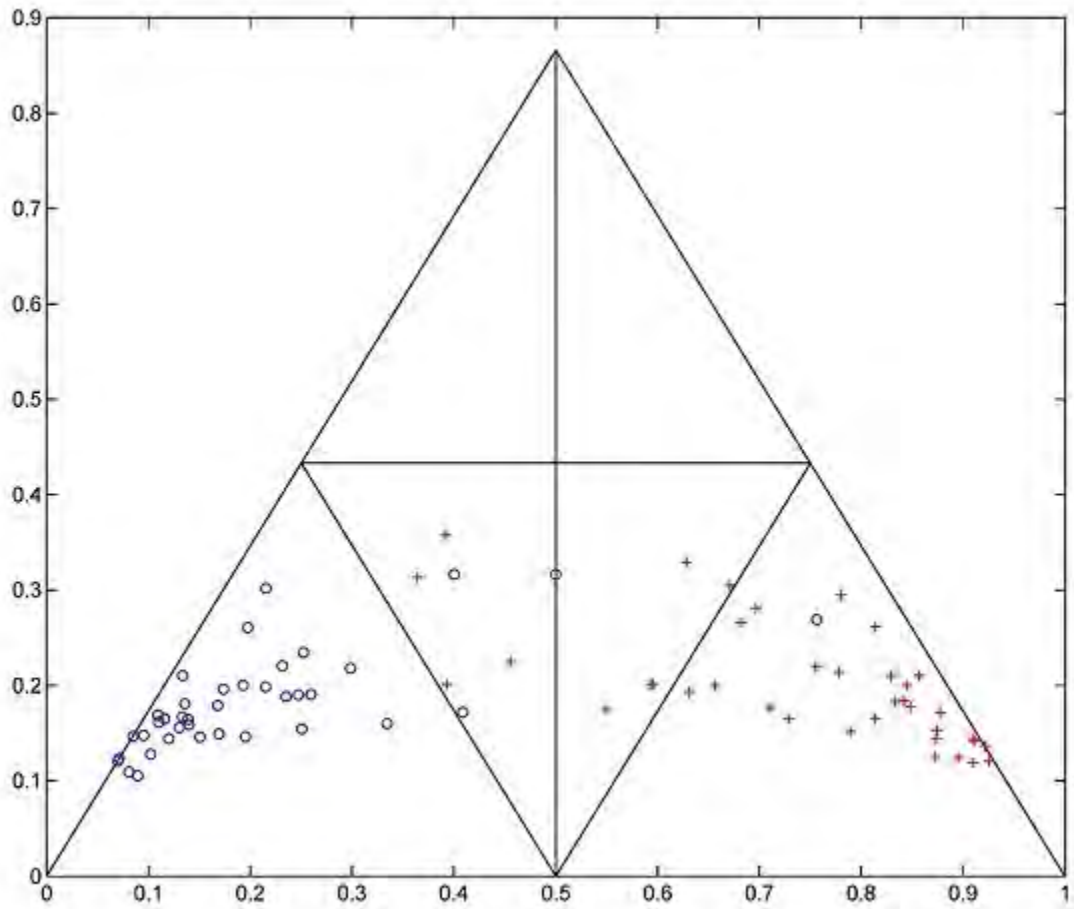
[1]School of Engineering, Medical Engineering, [2]Arthritis Research UK Biomechanics and Bioengineering Centre, Cardiff University, Cardiff, United Kingdom

Introduction and Objectives: Three dimensional motion analysis generates a great wealth of information, which has resulted in a range of mathematical techniques aimed at assisting both clinicians and researchers interpret biomechanical data [1]. Jones [2] successfully developed a technique at Cardiff University that facilitates the classification between pathological and non pathological knee function using Dempster-Shafter theory (DST), demonstrating its effectiveness in comparison to Artificial Neural Networks (ANN) and Linear Discriminate Analysis (LDA) in the classification of osteoarthritic gait. Classication techniques have advanced over the last decade with recent studies reporting high accuracies using ANN [3] and Support Vector Machines (SVM) [4]. To the best of our knowledge, this study proposes, for the first time, to compare the performance and suitability of the (i) Cardiff Classifier, (ii) ANN and (iii) SVM in discriminating between healthy and osteoarthitic knee function.

Methods: As this study involves dealing with long range data sets, a four-dimensional unsupervised Self-Organising Map (SOM) [5] and a supervised Multi-layer Perceptron (MLP) neural networks with one hidden layer having 20 hidden neurons [6], were built through the MatLab neural network toolboxes respectively named as ‘nctool’ and ‘nprtool’ (Mathworks inc., USA). The Lagrangian Support Vector Machines (LSVMs) [7] Machine Learning (ML)-based classification method and the Dempster-Shafter theory (DST)-based classifier (‘Cardiff classifier’) [2] were selected for pattern recognition tasks and classification purposes. Thirty-eight patients with late stage knee osteoarthritis (OA) and thirty-eight healthy volunteers were instructed to complete walking trials at speeds they deemed to be normal. Spatio-temporal gait data (stride length, cadence, body mass index) and principal components of knee kinematic and ground reaction force waveforms were averaged for five gait cycles. Eighteen selected biomechanical and clinical variables formed the input matrix for the three classifiers. After randomising the data, the physiological knee function of healthy volunteers and pathological function due to knee OA were used as desired outputs for the classifiers. In all neural network models tested for classification accuracy in this study, 70% of the data was used for training, 15% for a ten k-fold cross-validation to prevent over-fitting/overtraining [8], whilst the last 15% of the data was deployed for testing in order to assess the out-of-sample classification accuracy of the neural networks. Instead, in both LSVMs and DST-based classifier the leave-one-out cross (LOO) validation algorithm was adopted, introduced in order to maximise the utilisation of the training cohort.

Results: Table 1 below shows the out-of sample classification accuracies associated to each of the four types of classifiers being tested. In Fig. 1 a three-coordinate simplex plot referred to the patient data categorised by the Cardiff classifier is displayed.

Figure:



Caption: Fig. 1 Simplex plot showing how the subjects on the left (blue circles) were correctly classified as healthy subjects, whilst those on the right (red crosses) as patients with knee OA.

Conclusion: Findings indicate that, for the classified patient dataset, the DST-based classifier proved to be the most suitable method for classifying patients with knee OA (Table 1). This is due to its highest out-of-sample classification accuracy amongst the classifiers tested. This clinically relevant result partially validates the Cardiff classifier as a reliable diagnostic tool to assess the knee joint function of patients affected by knee OA. The DST-based classifier's user-friendly interface (Fig. 1) lends itself to further development into a valuable clinical tool, enabling a clinician to objectively characterise knee function without requiring any assistance from biomechanists. There is also future potential to assist with patient assessment and surgical decision making, aimed at optimising patient outcome. Future work is underway to ascertain whether the Cardiff classifier is a clinically suitable technique for improving the accuracy of the diagnosis and monitoring the effectiveness of the prognosis related to other lower limb pathologies.

Table:

Classifier	Out-of-sample classification accuracy
Multi-layer perceptron (MLP) neural network with one hidden layer	81.8%
Four-dimensional self-organising map (SOM)	71.05%
Lagrangian support vector machine (LSVM)	91%
Dempster-Shafer theory-based classifier	93.42%

EFFECTS OF HIGH TIBIAL OSTEOTOMY ON TRUNK, HIP, KNEE AND ANKLE BIOMECHANICS DURING GAIT

Gemma M. Whatling [1 2,*] Sarah Forrest [1 2] Chris Wilson [2 3] Andrew Metcalfe [1 2 3] Salam Ismael [2 3] Cathy Holt [1 2]

[1]School of Engineering, [2]Arthritis Research UK Biomechanics and Bioengineering Centre, Cardiff University, [3]Cardiff and Vale Orthopaedics Centre, University Hospital of Wales, Cardiff, United Kingdom

Introduction and Objectives: Osteoarthritis (OA) affects 8 million people in the UK causing painful, limited movement and altered quality of life. In the case of medial compartment OA a varus deformity develops and one treatment option is a High Tibial Osteotomy (HTO). This surgery corrects varus alignment, relieves pain and shifts the location of force transmission from the diseased medial to the healthy lateral compartment. Studies have shown that this treatment modifies medial knee joint loading, evidenced through reduced external knee adduction moment (EKAM). Less however, is known about changes to overall patient biomechanics and compensatory mechanisms, or the effect of a HTO on other joints and the contralateral limb. We hypothesise that HTO affects biomechanics in other lower limb joints and this abstract reports interim findings from a large, longitudinal HTO study.

Methods: Lower limb and trunk biomechanics were evaluated during gait (n=10, BMI: 29.4 ± 3.7 kg/m^2, age: 51 ± 7 years) using 3D motion analysis. Subjects were analysed pre and post opening wedge, unilateral HTO (12 ± 1 months). The mean mechanical tibio-femoral angle was 5.8(± 3.7)^o. OA severity Kellgren-Lawrence scores were 3(moderate) n=8 and 4 (severe) n=2. 9 subjects received a TomoFix plate and 1 received a Puddu plate. 49 light retro-reflective markers were positioned in a modified Cleveland clinic marker set and 3D motion capture (Qualisys, Sweden and Bertec Corporation) used to record 6 trials of level gait at self-selected speeds. Biomechanical models of each subject were created in Visual3D (C-motion, Inc) to compute temporal, kinematic and kinetic data. Knee Outcome Survey (KOS) and Oxford Knee Score (OKS) were collected. Paired t-tests identified statistical differences ($p<0.05$) in biomechanics and patient reported scores pre and post-HTO.

Results: Biomechanical changes were evident in both lower limbs following HTO. HTO significantly reduced frontal plane knee joint loading (41% and 39% reduction in EKAM peaks 1 and 2 respectively, and 46% reduction in knee adduction angular impulse), associated with significant changes in ankle inversion moment. Both ankles had reduced inversion and dorsiflexion moments. At EKAM peak1 there was a 5% increase in medial GRF, an eversion (0.26±0.2%BW.h) instead of inversion (0.01±0.6%BW.h) moment and dorsiflexion moment reduced by 39%. The inversion moment at EKAM peak 2 reduced by 25%. Hip, knee and ankle rotations were affected in the operative limb. Trunk sway ROM reduced and both hips had increased ROM. Frontal plane trunk ROM decreased by 36% whilst frontal plane hip ROM and sagittal plane knee ROM increased significantly by 19 % and 5% respectively.

Conclusion: HTO reduces medial knee loading and patients report improved function with reduced pain, fulfilling the aims of the surgery. HTO has an effect on knee, ankle and hip biomechanics in the operative and non-operative limbs. OKS and KOS scores increased by 43% and 23% respectively indicating reduced pain, improved function and quality of life. Patients walk differently after surgery and it is important to understand the influence of HTO on other joints.

OSTEOARTHRITIS KNEE BRACE ABDUCTION MOMENT DOMINATES INVERSE DYNAMICS AND MUSCLE FORCE CHANGES IN REDUCING MEDIAL KNEE LOADS

Scott Brandon [1 2,*] Marcus Brown [1 2] Adam Clansey [1 2] Jim Richards [3] Aaron Campbell [2 4] Kevin Deluzio [1 2]

[1]Mechanical and Materials Engineering, Queen's University, [2]Human Mobility Research Centre, Kingston General Hospital, Kingston, Canada, [3]Allied Health Research Unit, University of Central Lancashire, Preston, United Kingdom, [4]Department of Surgery, Kingston General Hospital, Kingston, Canada

Introduction and Objectives: Braces for medial knee osteoarthritis are designed to reduce painful, and potentially injurious [1], compressive loading on the damaged medial side of the joint through application of a frontal-plane abduction moment. However, *in vivo* knee load measurements have revealed that the magnitude of load reduction varies greatly between subjects and brace designs [2]. Previous studies which investigated the mechanical effectiveness of bracing have been limited either in their musculoskeletal detail [3] or incorporation of altered external joint moments and forces [4]. Therefore, the objective of this study was to model the relative contributions of gait dynamics, muscle forces, and the external brace abduction moment to reducing medial compartment knee loads.

Methods: Nine subjects with medial knee osteoarthritis and ten healthy control subjects were recruited for this study (Table 1). Participants completed a WOMAC questionnaire and provided written, informed consent. The study was approved by the institutional ethics review board.

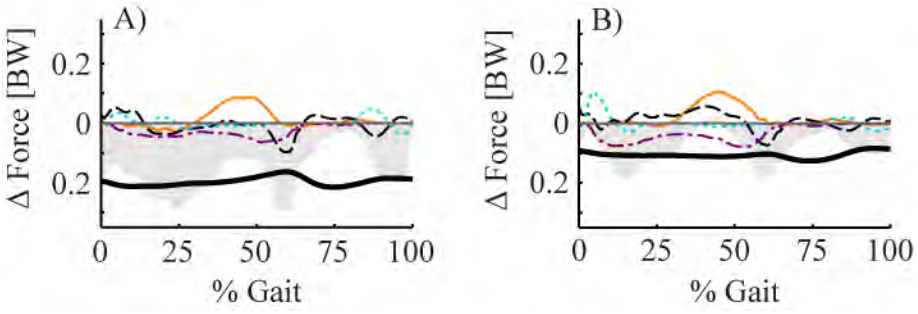
Subjects walked across 6 tandem force platforms, which were embedded in a 20m walkway. Synchronized motion capture (200Hz, Oqus 4, Qualisys, Gothenburg, Sweden), lower-limb electromyogram (EMG, 1000Hz, Trigno Wireless, Delsys Inc., Boston, USA), and ground reaction force data (1000Hz, Custom BP Model, AMTI, Watertown, USA) were recorded using Qualisys Track Manager. Eight gait trials were recorded in each of three brace conditions in the following order: unbraced, OA Adjuster 3 brace (DJO Global), and OA Assist brace (DJO Global). Braces were fitted according to manufacturer guidelines, and adjusted to a maximum level that would be comfortable for four hours. The abduction moment applied by the brace was computed by dynamically measuring brace deflection using motion capture, and multiplying by pre-determined brace stiffness.

For each subject, a representative stride was selected for each brace condition. A generic musculoskeletal model with two legs, a torso, and 96 muscles [5] was modified to include subject-specific frontal plane alignment and medial and lateral contact locations [6]. Inverse kinematics, inverse dynamics, residual reduction, and muscle analysis were performed using OpenSim 3.2 [7]. Muscle forces were estimated using static optimization, and tibiofemoral contact loads were estimated in Matlab [6,8]. Subject characteristics were compared using unpaired t-tests, while joint kinematics, joint moments, joint contact loads, predicted muscle activation (Act) and EMG were compared using a two-factor ANOVA and planned Sidak post-hoc contrasts between brace conditions. Significance (α) was set at 0.05.

Results: OA Assist and OA Adjuster 3 braces reduced medial joint loading by approximately 0.1 to 0.2 BW, or roughly 10%, during stance ($P < 0.01$, Figure 1). This decrease was primarily due to the external brace abduction moment (Figure 1). Joint kinematics and moments were significantly altered in the braced condition ($P < 0.01$); however, the medial knee

load reduction was independent of changes in inverse dynamic joint loads (Figure 1). Decreased quadriceps activation enhanced medial and lateral unloading, while increased gastrocnemii activation inhibited medial unloading (Figure 1).

Figure:



Caption: Figure 1: Contributions of quadriceps (dot-dashed, purple), hamstrings (dotted, cyan), gastrocnemii (solid, orange), inverse dynamics forces (dashed, black), and the brace abduction moment (thick solid, black) to the net change in medial knee contact load (shaded, grey) when osteoarthritis subjects were fitted with OA Assist (A) and OA Adjuster 3 (B) braces as compared with the unbraced condition.

Conclusion: In a sample of ten healthy control and nine osteoarthritis subjects, bracing reduced medial compartment knee loading by approximately 10%, as estimated using a musculoskeletal model. Gait kinematics and joint moments were relatively unaffected by bracing, while gastrocnemii activation increased; therefore, the model revealed that current unloader brace designs must apply a large knee abduction moment in order to reduce medial loading. Future braces should consider innovative designs which could enhance the unloading effect through gait modification.

THE INFLUENCE OF DRILL-GUIDE ANGLE ON STRESS REDISTRIBUTION AFTER ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION

Jie Yao [1,*] Lizhen Wang [1] Yubo Fan** [1 2]

[1]Department of biomedical engineering, School of Biological Science and Medical Engineering, Beihang University,

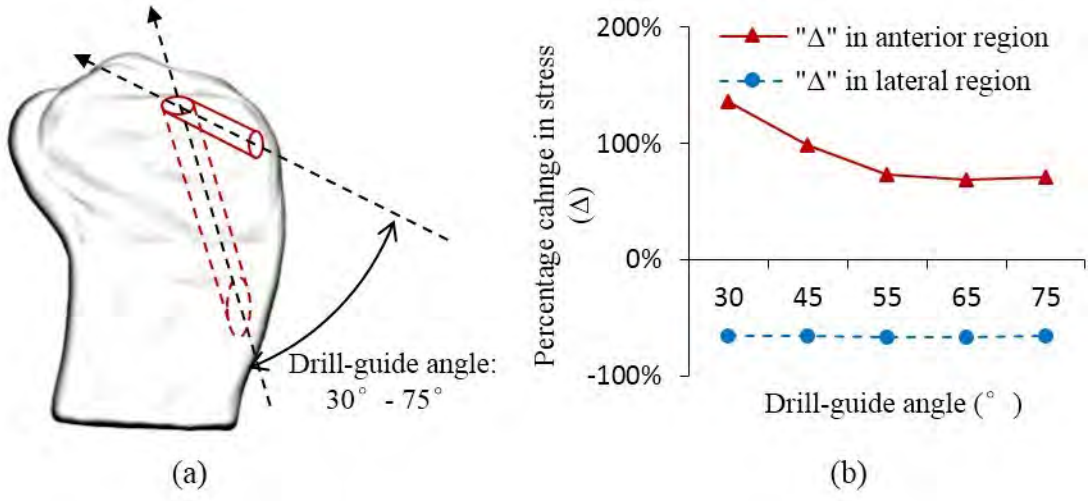
[2]National Research Center for Rehabilitation Technical Aids, Beijing 100176, Beijing, China

Introduction and Objectives: The anterior cruciate ligament (ACL) reconstruction is the predominating treatment for ACL injury [1]. However, the tunnel enlargement and osteoarthritis are frequently reported after the surgery [2, 3]. A possible predisposing factor could be the undesirable bone remodeling due to the post-operative stress redistribution [4]. In this light, this study aims to quantify the stress redistribution in tibia after the ACL reconstruction, and to minimize the stress redistribution by adjusting tibial drill-guide angle.

Methods: The finite element model of the human knee joint was developed from the magnetic resonance images. The model was validated with the experiments and was used to simulate the anatomic single-bundle ACL reconstruction according to the routine surgical procedure. The tibial tunnel was created with the drill-guide angles ranging from 30 to 75 degrees. The stress redistributions in tibia were calculated under the compressive, valgus, rotation loadings.

Results: Among the loadings applied, the compressive loading played a leading role on the stress distribution on the tibial plateau. After the surgery, the stress was increased in the anterior region of the tunnel aperture under the compressive loading, while it was decreased in the lateral region. The severity of the stress redistribution was decreased with increasing the drill-guide angle from 30 to 55 degrees, and it slightly changed when the drill-guide angle was greater than 55 degrees.

Figure:



Caption: The influence of the drill-guide angle on the percentage change in stress (Δ) under the complex loadings including compression, valgus, and rotation. (a) The diagram of tibial tunnel; (b) Δs in the anterior and lateral regions of the tunnel aperture.

Conclusion: ACL reconstruction can cause the stress redistribution in the knee near the bone tunnel wall. The stress redistribution may lead to undesirable bone remodeling and contribute to tunnel enlargement and osteoarthritis. Nonetheless, the severity of the post-operative stress redistribution could be manipulated by adjusting the tibial drill-guide angle. Considering the clinical and mechanical factors together, using the drill-guide angle ranging from 55 to 65 degree could provide a beneficial mechanical environment for the rehabilitation after the ACL reconstruction.

CARDIOVASCULAR SYSTEM RESPONSES TO ACCELERATIONS: A MODEL AND ITS VALIDATION

Yawei Wang [1,*] Jian Ma [1] Lizhen Wang [1] Yubo Fan [1 2]

[1]Key Laboratory for Biomechanics and Mechanobiology of Ministry of Education, International Research Center for Implantable and Interventional Medical Devices, School of Biological Science and Medical Engineering, Beihang University, [2]National Research Center for Rehabilitation Technical Aids, Beijing, China

Introduction and Objectives: Accelerations generated by the high performance aircraft, spacecraft and centrifuge have complicated influences on human cardiovascular system. Such accelerations include positive acceleration (head to foot inertial loading, +Gz), negative acceleration (-Gz), positive or negative lateral acceleration (±Gy), forward acceleration (+Gx) and backward acceleration (-Gx). Influences of postive acceleration on human cardiovascular system have been research hotspots for many decades, because human performance during exposure to positive acceleration stress is limited by two primary factors: loss of vision and loss of consciousness (LOC). It is generally believed that these symptoms are caused by decreased retinal and cerebral blood flow, respectively. Many physiological parameters, such as circulating blood volume, cardiac output, cerebral and spinal cord blood flow of dogs, miniaturized pigs, baboons and human were measured at different +Gz values in several physiological experimental researches. However, insightes on global, dynamic and quantitative response of human cardiovascular system have not been gained, and the detailed mechanism of Gz induced LOC was not very clear now. Moreover, influences of multi-axial accelerations generated by new generation aircrafts when they implemented post-stall maneuvers are not been understood. In this paper, a mathematical model of human closed-loop circulatory system was established for investigating influences of the these accelerations. This mathematical model was built using a fluid-mechanical circuit representation of human closed-loop circulatory system, and was validated using physiological parameters measured in human experiments on the centrifuges from literatures.

Methods: Three basic fluid-mechanical portions of the cardiovascular system were modeled, including the heart and pulmonary system, the systemic venous system and the systemic arterial system. Left and right arms and legs were modeled respectively for including influences of Gy accelerations. Reflex regulation and effects of anti-G suit were also included in this model, as shown in Figure 1.

The heart and pulmonary system: the model of heart and pulmonary system was rather simply represented by a resistance-compliance section, a varying compliance and two valves, based on simplificaiton of a more detailed model. Right atrium, right ventricle, the pulmonary system and the left atrium were simply represented by the resistance-compliance setcion together with a valve. Left ventricle was represented by the varying compliance and another valve.

The systemic venous system: the systemic venous system was comprised of eight segments with three segments for veins in head and neck, one segment for veins in the abdominal cavity, and four segments for veins in the legs. Each segment included a variable resistance and a variable compliance. Varying values of the resistance and compliance represented the effects of venous collapse, which were calculated from nonlinear functions of transmural pressures.

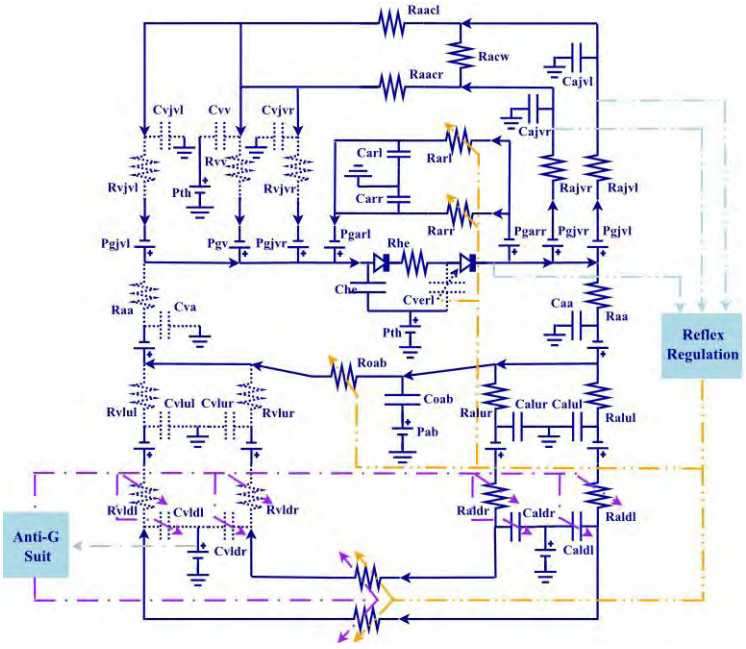
The systemic arterial system: the systemic arterial system was also comprised of eight segments. Each segment included a constant resistance and a constant compliance.

Pressure differences induced by accelerations: Pressures differences induced by accelerations were modeled as electrical sources. In order to produce a net pressure around the circulatory loop, these sources were included in the arteries as well as in the veins.

Reflex regulation and effects of anti-G suit: Reflex regulation was included through using functions from literautes to control heart rate, flow resistances in the arms, legs, and organs in the abdominal cavity. Effects of anti-G suit were added by using functions to control flow resistances and compliances in the legs.

Results: Response of the model to a simulated tilt-up from 0° to a 90° head-up position was in good agreement with test data from literature. However, the recovery time after tilting back to a horizontal position was a little longer than the test data. Simulation results with and without anti-G suit were reasonable compared with physiological parameters measured in experiments of human at 3 g and 5 g +Gz conditions. Model response to a 3 g lateral acceleration showed an obvious change of heart rate but inapparent varying of blood perfusion into organs.

Figure:



Caption: Figure 1 mathematical model of cardiovascular system

Conclusion: This model could be used to investigate influences of different accelerations on responses of human cardiovascular system.

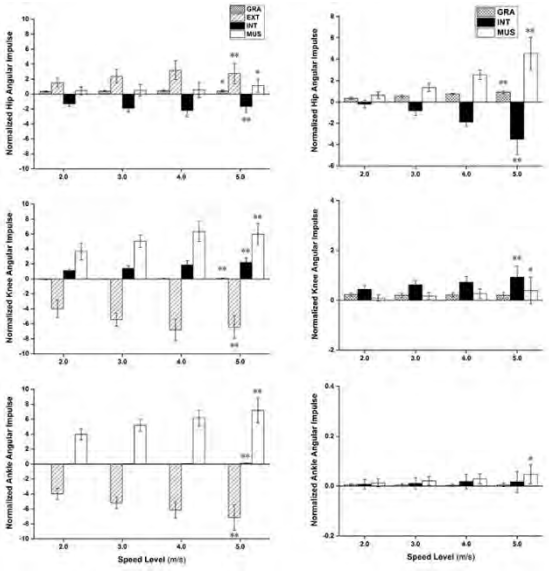
Introduction and Objectives: To fully understand the control and regulation of multi-joint movements, the biomechanical properties of the moving subject, specifically intersegment dynamics, must be considered in the motor control research. A series of research results of upper-limb movement using intersegment dynamic approach have shown that the joints of a multi-articular limb play different roles in movement production according to their mechanical subordination in the joint linkage. A Leading Joint Hypothesis (LJH) has been proposed as an alternative interpretation of control of human movements[1]. However, limited attempts have been made to reveal the underlying mechanism of multi-joint control of lower limbs. This study was to understand the multi-joint control strategy of the lower limbs during running, by studying the intersegment dynamics of the hip, knee and ankle. On the basis of the current literature, we hypothesized that the control strategies were different at these three joints, and the three joints play different roles in lower-limb control during running according to LJH.

Methods: Subjects (n=16, male students) were asked to performed running at 4 different speed (2m/s, 3m/s, 4m/s, 5m/s). Three-dimensional kinematic data were collected via 16 high resolution cameras (200 Hz). The Ground reaction forces were collected by 2 recessed forceplates (1000 Hz). From the collected three-dimensional data, two-dimensional sagittal plane coordinates were extracted. Data from the right lower extremity were used for the following analyses. The lower limb was modeled as a linked-segment system (thigh, shank, foot) with frictionless joints at the hip, knee, and ankle. One of the trails containing valid force plate contacts was analyzed for each movement of the subjects. The intersegmental dynamics analysis was conducted with a customized program. Torques at each joint were separated into five categories: net torque (NET), gravitational torque (GRA), interactive torque (INT), external contact torque (EXT), and muscle torque (MUS). NET is the sum of the other four components[2]. All the torques were normalized by the product of body weight (N) and height (m). An impulse analysis was used to evaluate the contribution of each component to the NET. The positive impulse of the torque component (MUS, EXT, INT or GRA) was computed as the torque integral during intervals where the torque component acted in the same direction as the NET. Accordingly, a negative impulse of the torque component was computed during the intervals where the torque component acted in the opposite direction to the NET. All positive and negative impulses were summed for each torque component within each cycle to yield a total impulse for the entire phase. A one-way ANOVA with repeated measures was used to test the effect of speed on the kinetic data. A conservative level of significance was set at $\alpha = .05$.

Results: During the stance phase at all running speed (Figure 1a), the dominant joint torques which provided the positive contribution to the hip movement were EXT (e.g. speed level 5m/s, 2.8±1.4). EXT counterbalanced the negative effect generated by INT. But MUS at the knee (e.g. speed level 5m/s, 6.0±1.5) and the ankle (e.g. speed level 5m/s, 7.2±1.7) play the dominant role at these two joints, and provided the main positive contribution to counter the negative effect from EXT. During the swing phase (Figure 1b), the dominant joint torques which provided the positive contribution to the joint

movement were MUS (e.g. speed level 5m/s, 4.5±1.5) at the hip, but INT at the knee (e.g. speed level 5m/s, 0.9±0.4) and the ankle (e.g. speed level 5m/s, 0.1±0.01). Significant differences were found in each kind of impulses among different speed levels, especially INT (e.g. INT at knee in swing phase from speed level 2 to 5m/s: 0.4±0.1 vs 0.6±0.2 vs 0.7±0.2 vs 0.9±0.4, p<.01).

Figure:



Caption: Fig.1 Impulses at hip, knee & ankle during stance (a) & swing phase (b) in 4 different speed running. Positive values indicate that the torque component had the same sign as NET and contributed to the NET impulse. The impulse was negative when the component was opposite in sign to the NET.

Conclusion: During the stance phase, the knee & ankle were the leading joints according to the Leading Joint Hypothesis (the active muscle torques were dominant for the joint movement), while the hip was the subordinate joint (passive torque was dominant for the joint movement). During the swing phase, the hip became the leading joint which accelerate or decelerate the whole limb (MUS became the dominant), while the knee and ankle were the subordinate joints, the movement of which were conducted by the INT. Therefore, the central nervous system not only exploits the muscle strength, but also the gravity of the limbs, the external contact force and the inertia force for movement organization, to perform effective and “economical” limb movement.

ROBOTIC-ASSISTED PROSTATE TUMOR LOCALIZATION USING NEEDLE ROTATION FORCE

Xiaoyu Liu [1,*] Lizhen Wang [1] Wei Yao [2] Yubo Fan** [1]

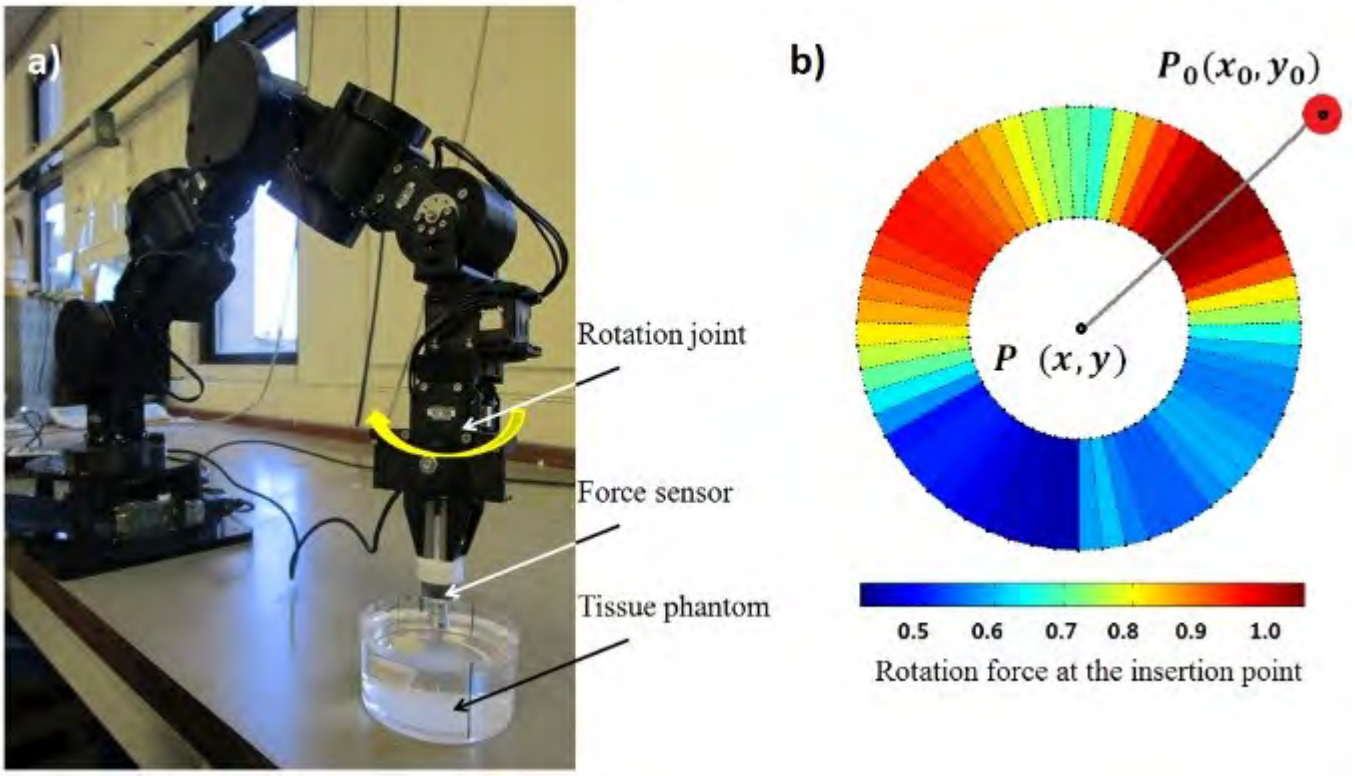
[1]School of Biological Science and Medical Engineering; Yifu Building,Beihang University, Beijing, PR China., Key Laboratory for Biomechanics and Mechanobiology of Ministry of Education, Beihang University, Beijing, PR China., Beijing, China, [2] Department of Biomedical Engineering, University of Strathclyde, Department of Biomedical Engineering, University of Strathclyde, 106 Rottenrow, Glasgow, Glasgow, United Kingdom

Introduction and Objectives: Prostate cancer (PCa) is the first leading cause of male cancer dearth in the UK and many developed countries [1]. Although PCa is not so commonly found in Chinese and other Asian men, there has been a significant increase in the incidence of this cancer in these countries over recent decades [2]. Accurate localization of the prostate tumor is critical to effective early-stage PCa diagnosis and treatment. Robot-assisted technologies have been developed to guide tumor localization using TRUS and MRI imaging. Recently, force-guided technology has been introduced to localize tumors in robotic system. PCa can be identified by analyzing insertion forces on the needle. However, this technology only allow for determining the depth of a tumor on the path of needle insertion. Spatial localization of the tumor by needle forces is a significant challenge in prostate biopsy and brachytherapy. Currently, we have proposed a novel robot-assisted procedure for tumor localization by means of needle rotation forces. This procedure enables to determine the planar location of a prostate tumor, which is expected to be used in robot-assisted minimally invasive systems for prostate biopsy and brachytherapy.

Methods: We validated the robot-assisted procedure by experiment on tissue phantoms that offer simple and controllable environments for repeatable tests. A silicon material (Young's modulus 15 kPa) and a rubber button (Young's modulus 75 kPa) were used to simulate normal and harder tumor tissues respectively. A 7-DOF robotic manipulator (Cyton Gamma 1500, Robai Corporation, MA) was used to perform needle motion including vertical insertion, deviation and 360-degree rotation (Figure 1a). Firstly, a needle was driven into a prostate phantom vertically at a velocity of 1 mm/s. When an abnormality of the force data (F_z) was found during insertion, a refined analysis was conducted to determine whether the tumor is on the path of the needle insertion. If there is no indication that the tumor is inserted, the needle is then driven to perform a 2.5-mm planar deviation and a 360-degree rotation at a velocity of 1 mm/s. A 6-axis force/torque sensor (Nano17, ATI Industrial Automation, US) was used to measure the rotation needle forces.

Results: When an abnormality was found in the force data (F_x, F_y), the direction of the tumor's location can be identified since the harder tumor made a difference in the force during needle rotation. The mapping of tumor localization using needle forces by performing two needle rotations is shown in Figure 1b. It can be seen that the rotation force reached the maximum value when the needle just rotated toward the position of the tumor. The degree (θ) corresponding to the maximum needle force is the direction of the tumor location.

Figure:



Caption: Figure 1 Robotic-assisted Prostate Tumor Localization Using Needle Rotation Force: a) Experimental setup; b) The mapping of tumor localization using needle forces.

Conclusion: The novel robot-assisted procedure, needle rotation, was validated to achieve tumor localization in the prostate phantom test. The proposed procedure is promising for further research by means of *ex vivo and in vivo* animal and human experiments. This procedure is expected to be used in robot-assisted systems for prostate biopsy and brachytherapy.

LOCOMOTION DYNAMICS OF GECKO: PATTERNS OF REACTION FORCES ON INCLINES?

Zhendong Dai [1,*] Zhouyi Wang [1] Aihong Ji [1]

[1]Nanjing University of Aeronautics and Astronautics, Nanjing, China

Introduction and Objectives: Locomotion is essential character of animals, and excellent moving ability results from the delicate sensing the reaction forces acting on body and modulating the behavior to adapt the motion requirement. In natural circumstance, animals have to move on various inclined surface, how animals adapt their behavior on the inclines is an interesting topic which attracted a lot of researches. In fact, there were a lot of studies were carried out when human or other mammals walk or run on shallow inclines (slope angle less than 60 degree), there were some studies when animals, such as geckos, cockroachs. Only our group measured the reaction forces of gecko moving on overall inclines, namely, floor, wall and ceiling. We found that the patter of reaction forces of gecko on the three different substrates are absolutely different, the questions we are going to ask here 1) How do the patterns of reaction forces change with slope angles and what slope angle is the critical angle at which the pattern of reaction forces change? 2) What factor induces the gecko to change the patter of reaction forces? Here we try to answer first question by measuring the reaction forces of gecko moving on various inclines and set up mechanical models to explain why the pattern change on the specific slope angle.

Methods: *Tokay geckos*, from Guangxi, China, were used in experiment (63.4±2.6g mass, snout-vent length: 138.4±6.3mm, mean ± s.d., N=8). The geckos were housed in two cages connected by an aisle to train them to move through the aisle of the force measuring array (FMA). The FMA was rotated step by step (30° per step) to imitate different incline surfaces. Synchronously to the force measurement (500Hz), a high speed camera (iSpeed-3, Olympus, 1280×1024 pixels) recorded each trial at 500 Hz. Moving behavior results from the continuous force action, so impulse of the forces were introduced to present the force effects. The orientation of foot in the stance phase was reflected by the orientation angle of foot between the fore-aft direction and the vertical line which is perpendicular to a line connecting the tips of the first and fifth toes.

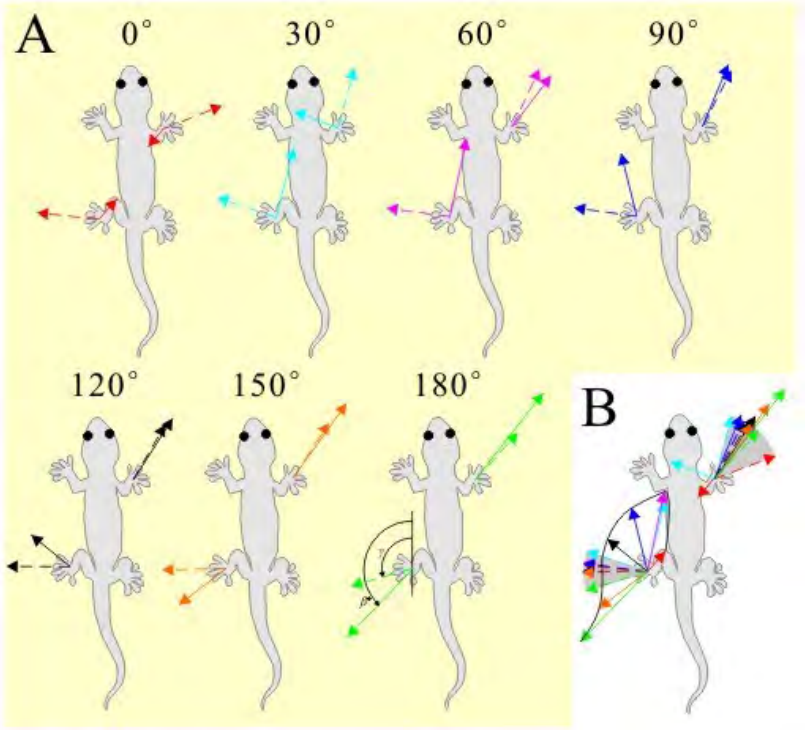
Results: The moving speed of geckos decreased with incline angle. The duty factor of locomotion is heavily affected by the incline slope when the angle is larger than 90°, it is 0.54 when climbing on the wall (90° incline) and 0.84 when crawling on the ceiling (180° incline).

The lateral force impulses I_L acting on the front and hind limbs increased with respect to inclines, and the I_L acting on front limb increased faster than that acting on hind limb. The results suggest that lateral force become more important on larger slope inclines. The fore-aft impulse I_F acting on front limb increases with increase of incline. The front limb generated negative I_F when gecko move on non-horizontal surface, which suggests that the front limb plays an important role as a brake on horizontal surface while playing a role of propulsion on non-horizontal surface. The hind limb generated positive I_F that appeared to act as a source of propulsion over the range of the incline angle from 0° to 120°, but changed to act in the role of braking from 150° to 180°. The front limb provided negative normal impulses I_N to pull the center of mass

toward incline when inclines were larger than 90°. Alternatively, the hind limb began to provide negative I_N when the incline became greater than 120°.

The shear force impulse I_S acting on the hind limbs undergone obvious turning backwards as indicated by the solid lines in Figure 1. The change in the hind foot's orientation angle is not obvious, yet, indicated by the dotted line in Figure 1. These results may be explained by the fact that the angles between each adjacent flexible toe are noticeably different from one another.

Figure:



Caption: Figure 1 The relationships among the shear force impulse, orientation angle of the feet, and the incline angle. (A) Change in the shear force impulses and the orientation angle of gecko on different inclines. (B) Overprinting the shear force impulses and the orientation angle of gecko on different inclines.

Conclusion: The detailed three-dimensional reaction forces acting on an individual limb demonstrate that accurate force control is a benefit necessary to secure highly reliable attachment on inverted inclines and to enhance locomotion abilities. The pattern of reaction forces in response to inclines is directly linked to the favorable trade-off between locomotor maneuverability and stability. The geckos respond to increased inclines with a sort of threshold effect. The mechanisms revealed by above study help us to improve the performance of robots and expand its scope of application.

AGE-RELATED CHANGES IN CENTER OF MASS TRAJECTORIES AND ACCELERATION DURING OBSTACLE CROSSING

Le Li [1,*] Na Chen [1] Yurong Mao [1] Chenming Ma [2] Lifang Li [1] Dongfeng Huang [1]

[1]Rehabilitation Medicine, First Affiliated Hospital, Sun Yat-sen University, [2]School of Engineering, Sun Yat-sen University, Guangzhou, China

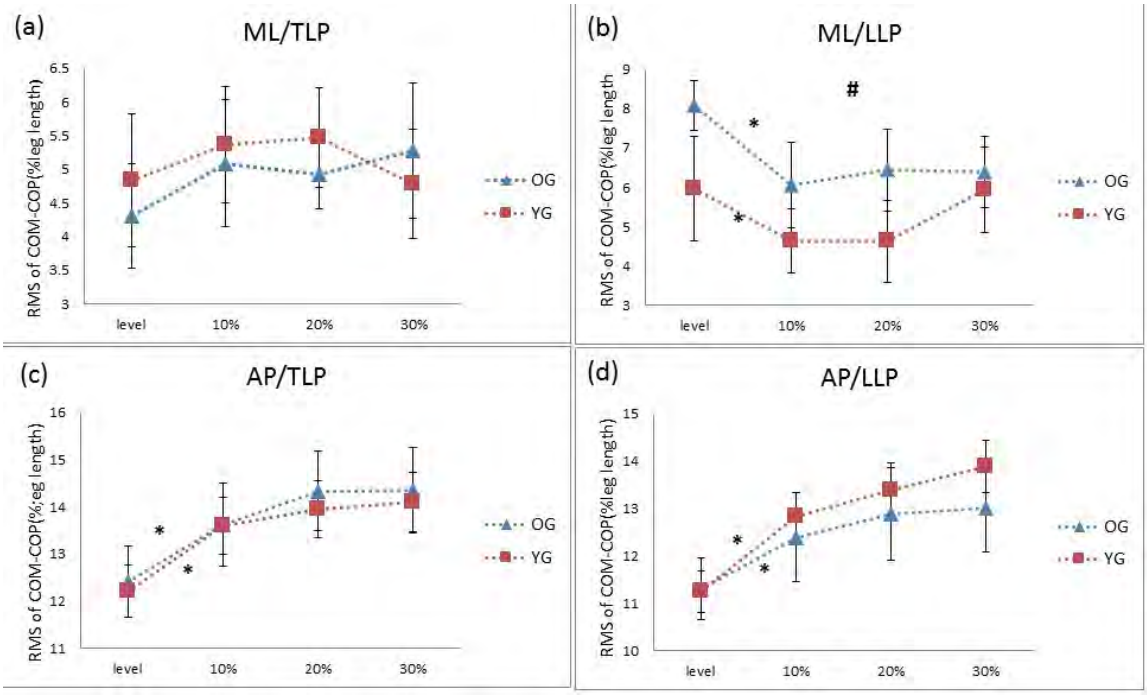
Introduction and Objectives: Background: Tripping over obstacles may cause falls in the elderly while falls to the side is one of the determinant risk factors for traumatic hip fracture.

Objective: To analyzed and compared the spatial relationship of different trajectories when cross over obstacles by elder people and young group and to find the balance control mechanism.

Methods: 12 healthy elder adults and 12 healthy adults were divided to elder group and young group. Full-body three-dimension motion analysis system and force plates were used to capture and explore the characteristics of dynamic balance when crossing 10%, 20%, and 30% height of leg length of obstacles. The RMS (root mean square) value of the COM-COP distance as well as the peak COM acceleration in horizontal direction was calculated.

Results: The older adults exhibited greater average medio-lateral (ML) COM-COP distances during the leading limb stance phase after crossing the obstacle and lower anterio-posterior (AP) peak COM acceleration during the double support phase as they just about to crossing the obstacle. A moderate negative linear relationship was also found between peak AP COM acceleration and the crossing time which increased as the obstacle height increased.

Figure:



Caption: Fig. 1. Mean COM acceleration patterns in a crossing stride of 4 trials of level walking or 4 trials each of 3 heights obstacle crossing of a male young subject. ML: medio-lateral direction, AP: anterio-posterior direction.

Conclusion: Root mean square (RMS) of COM–COP divergence and peak acceleration of COM has been suggested to be a useful measurement to provide valuable insight into balance and postural control in human body. The larger average ML COM-COP distances indicate high-risk of falling sideways in elderly.

Table: Table1 The spatiotemporal parameters of the unobstructed trial of the old and young group.

	Cadence (steps/min)	step time (s)	step length	walking speed (/s)
old	100.15±9.66	0.60±0.07*	0.66±0.06	1.11±0.19
young	108.05±8.35	0.56±0.05*	0.71±0.04	1.30±0.15

THE EFFECT OF CERVICAL FLEXION AND EXTENSION ON THE C5-6 AND C6-7 DISC AS MEASURED ON MAGNETIC RESONANCE IMAGING

Areej Elmaazi [1,*] Chris Morse [1] Sandra Lewis [1] Islay McEwan [1]

[1] Exercise and Sports Science, Manchester Metropolitan University, Manchester, United Kingdom

Introduction and Objectives: Cervical pain and its associated dysfunction is one of the most common musculoskeletal complaints in adults in Western society. Research suggests that one of the causes of neck pain is a sustained forward head posture [1]. This head posture is commonly adopted by people for prolonged periods while using modern technological devices such as laptops, tablets and mobile phones. The posture of the spine while in this position involves flexion of upper and lower cervical segments. One of the potential causes of pain while sustaining this posture may be the pressure this induces on the lower cervical discs which have been shown to be pain sensitive structures [2]. Research in the lumbar spine has shown that in healthy discs, there is migration of disc material away from the area of compressive force such that flexed postures (e.g. slouched sitting) causes posterior migration of disc material [3, 4]. No in vivo studies have been completed to confirm whether cervical discs also conform in a similar manner to the biomechanical pressures caused by various spinal postures. The purpose of this study was to assess, with the use of magnetic resonance imaging (MRI), whether flexion and extension of the cervical spine cause immediate, predictable changes in position of the posterior nucleus pulposus of the C5-6 and C6-7 discs.

Methods: Nineteen asymptomatic volunteers (nine males and ten females) between the ages of 21 and 49 years (mean = 33.7, SD = 9.1) were used to assess the effects of three different cervical spine postures on position of the nucleus pulposus. They were placed supine in a 0.2 T MRI scanner with sagittal images captured of the cervical spine in a neutral, followed by a flexed and finally an extended position. Position of the mid-posterior section of the disc nucleus was measured, in centimetres, relative to a line connecting the mid-section of posterior end of the vertebral bodies superior and inferior to the disc. If the mid-posterior section of the nucleus fell posterior to this line the measurement was recorded as a positive number. If it fell anterior to this line the measurement was recorded as a negative. If the posterior nucleus fell exactly on the line the measurement was recorded as zero. Measurements taken in all three cervical positions were compared at the C5-6 and C6-7 disc levels. The OsiriX Imaging Software program for Apple Macs was used for all disc measurements. A one-way repeated measures ANOVA was conducted to determine whether there were significant differences in posterior nucleus pulposus position with the cervical spine placed in neutral, flexion and extension in supine lying. Level of significance was set to 0.05.

Results: The change in cervical position elicited significant changes in position of the posterior nucleus pulposus for both the C5-6 ($p = .003$) and the C6-7 disc ($p = .000$). There were significant differences in disc position between neutral and flexion and between flexion and extension at the C5-6 disc level. There were statistically significant differences between all cervical positions at the C6-7 level (please see table 1).

Conclusion: This study examined the effects of three cervical spine postures on position of the nucleus pulposus at the C5-6 and C6-7 disc level in asymptomatic volunteers. Studies assessing healthy lumbar discs have shown that the

nucleus pulposus moves in a predictable manner when the lumbar spine is placed in various flexed and extended postures. The findings from this study also show that the cervical disc moves in a predictable manner with the nucleus pulposus in a flexed posture having a greater posterior position than in an extended posture at both the C5-6 and C6-7 disc levels. This may have implications for work and leisure activities involving sustained forward head postures. Although posterior disc prolapse has been poorly correlated with incidence of neck pain, reducing its occurrence with appropriate posture may help prevent the development of more significant disc extrusions which have been linked with pain and paraesthesia [5]. It is also important to note that cervical extension caused a reduction in posterior disc migration which may be useful as evidence to support directional therapeutic rehabilitative techniques.

Table:

Disc level	Comparison	Mean Difference	P value
C5-6	Neutral vs Flexion	.071	.010
	Neutral vs Extension	.032	.249
	Flexion vs Extension	.103	.006
C6-7	Neutral vs Flexion	.104	.000118
	Neutral vs Extension	.046	.045
	Flexion vs Extension	.058	.005

Caption: Table 1. Mean difference (cm) between disc positions and significance values for each comparison.

SS-0039

THE EFFECTS OF EXPERIMENTALLY INDUCED LOW BACK PAIN ON SPINE ROTATIONAL STIFFNESS AND LOCAL DYNAMIC STABILITY.

Gwyneth Ross [1,*] Matthew Mavor [2] Stephen Brown [3] Ryan Graham [1 2]

[1]School of Kinesiology and Health Studies, Queen's University, Kingston, [2]School of Physical and Health Education, Nipissing University, North Bay, [3]Department of Human Health and Nutritional Sciences, University of Guelph, Guelph, Canada

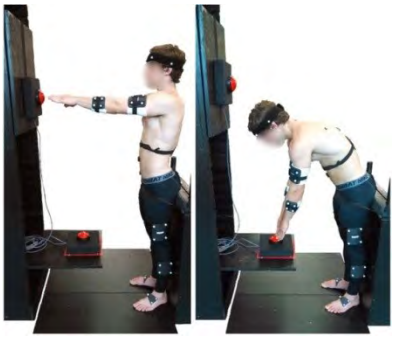
Introduction and Objectives: Local dynamic stability, quantified using the maximum finite-time Lyapunov exponent (λ_{max}), and the muscular contributions to spine rotational stiffness can provide pertinent information regarding the neuromuscular control of the spine during movement tasks [1]. Studying patients with low back pain (LBP) is traditionally difficult due to: large variation in subjective pain ratings across individuals; high numbers (80-90%) of non-specific diagnoses (i.e. there is no accurate or precise diagnosis and no valid and objective diagnostic tool); no pain-free data exist to compare results to; and accurate maximum voluntary contractions are nearly impossible to obtain [2,3]. The primary goal of the present study was to assess if experimental capsaicin-induced LBP affects spine stability and the neuromuscular control of repetitive trunk movements in a group of healthy participants with no history of LBP.

Methods: Fourteen healthy males were recruited for this investigation. Participant mean age, height, and mass were 21.79 years (SD = 2.8), 180.51 cm (SD = 7.0), and 77.83 kg (SD = 9.1), respectively. Upon arrival, participants filled out two questionnaires related to kinesiophobia: 1) Tampa Scale for Kinesiophobia (TSK), and 2) The Pain Catastrophizing Scale (PCS) [4]. Each participant was then asked to complete three trials of a repetitive trunk flexion/extension task (Figure 1), at a rate of 0.25Hz for 35 cycles: 1) baseline, 2) in pain, and 3) recovery (1 hour later). Pain was induced using a heat-capsaicin model using over-the-counter topical 0.075% capsaicin cream. Throughout these trials, trunk kinematics and electromyography were monitored as per [1], and directly before and after each trial participants rated their pain on a 100mm visual analogue scale (VAS). The local dynamic stability of spine kinematics and the muscular contributions to spine rotational stiffness were extracted using published methods [1]. Local dynamic spine stability was assessed using the maximum finite-time Lyapunov exponent (local divergence exponent), λ_{max} [1]. Conversely, rotational stiffness was calculated about all three primary axes of movement by entering data into an anatomically-detailed EMG-driven biomechanical model consisting of 58 muscle lines of action representing seven bilateral muscle groups crossing the L_4/L_5 spinal joint [1]. Then, to get an estimate of total stiffness the three axes were summed, and the mean, maximum, and minimum stiffness were extracted across all cycles and averaged [1].

Results: The capsaicin cream was successful in inducing significantly higher levels of pain than those observed at either baseline or recovery ($p<0.001$). Local dynamic stability and the minimum muscular contributions to lumbar spine rotational stiffness were significantly impaired during the low back pain trial compared to the baseline trial ($p<0.05$); additionally, there was a trend for these measures to recover after one hour rest (Table 1). Strong correlations were found between increased perceived levels of pain and decreased spine stability and rotational stiffness. There were also strong

correlations between increased kinesiophobia and perceived pain levels, and decreased spine rotational stiffness and stability.

Figure:



Caption: Figure 1. Experimental protocol. Participants were required to repetitively touch the instrumented targets with their hands held together to the beat of a metronome at a rate of 0.25Hz.

Conclusion: This study provides evidence that low back pain induced by capsaicin can effectively impair/inhibit spine rotational stiffness and local dynamic stability. Our current research is assessing changes to these same variables during pain induced via interspinous ligament injections, as well as further studying the relationship between kinesiophobia and LBP. An overarching goal of this research is to develop an objective diagnostic tool for assessing spine impairment and treatment effectiveness in chronic LBP patients.

Table:

Mean (SD) Results				Repeated-Measures ANOVA P-Value Results			
	Baseline	Capsaicin	Recovery	Main Effect	Baseline vs. Capsaicin	Baseline vs. Recovery	Capsaicin vs. Recovery

THE IMPACT OF SIT-STAND WORKSTATIONS ON MUSCLE ACTIVITY AND SPINAL SHRINKAGE IN OFFICE WORKERS

Ying Gao [1,*] Neil Cronin [1] Arto Pesola [1] Taija Finni [1]

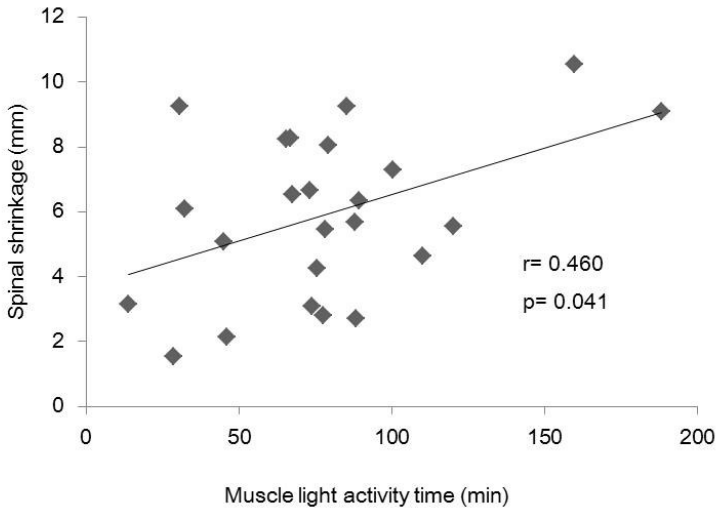
[1]Neuromuscular Research Center, Department of Biology of Physical Activity, University of Jyväskylä, Jyväskylä, Finland

Introduction and Objectives: Prolonged sitting time is adversely associated with cardio-metabolic and musculoskeletal health outcomes [1, 2]. To prevent these risks in a highly prevalent group of office workers, reducing sitting time by means of sit-stand workstations is an emerging trend but further evidence is needed regarding their health benefits. This study compared muscle activity and inactivity time, and spinal shrinkage between office workers who used either a sit-stand workstation or a traditional sitting workstation. We also quantified spinal shrinkage before and after a workday and examined whether there was an association between spinal shrinkage and locomotor muscle activity during work time.

Methods: This cross-sectional study compared work time muscle activity and spinal shrinkage between healthy office workers (aged 24-62, 58.3% female) who used either a sit-stand workstation (Sit-stand group, n=10) or a traditional sitting workstation (Sit group, n=14). During one typical workday, muscle inactivity and activity from quadriceps and hamstrings were monitored by electromyography (EMG) shorts and spinal shrinkage was measured using stadiometry before and after the workday. The differences between groups were tested by independent t-test or Mann-Whitney U and the correlation between the total muscle activity time and spinal shrinkage was studied by a partial correlation.

Results: Compared with the Sit group, the Sit-stand group had less muscle inactivity time (66.2±17.1% vs. 80.9±6.4%, p=0.014) and more muscle light activity time (26.1±12.3% vs. 14.9±6.3%, p=0.019) with no difference in spinal shrinkage (5.62±2.75 mm vs. 6.11±2.44 mm) (Table 1). Spinal shrinkage was positively associated with muscle light activity time (min) (r=0.460, p=0.041, Figure 1).

Figure:



Caption: FIGURE 1. Relationship between locomotor muscle activity and spinal shrinkage during a workday

Conclusion: This study was performed in an ecologically valid setting and provides evidence that sit-stand workstations promote metabolic health by increasing muscle light activity time and reducing inactivity without harmful effects on spinal shrinkage.

Table:

Characteristics	Sit group (n=14)	Sit-Stand group (n=10)	All (n=24)	p for group difference
EMG-derived muscle activity				
Recording time (min)	392.3±23.5	420.1±65.9	403.9±47.0	0.770
Inactivity time (%)	80.9±6.4	66.2±17.1	74.8±13.9	**0.014**
Activity time (%)	19.1±6.4	33.8±17.1	25.2±13.9	**0.014**
Light activity time (%)	14.9±6.3	26.1±12.3	19.6±10.6	**0.019**

THE KINEMATIC ENVELOPE OF THE THUMB CARPOMETACARPAL (CMC) JOINT

J.J. Trey Crisco [1,*] Tarpit Patel [1] Eni Halilaj [1] Douglas Moore [1]

[1]Orthopaedics, Brown University, Providence, United States

Introduction and Objectives: The unique and important positioning of the thumb with respect to the hand is achieved through the unconstrained articulations at the thumb carpometacarpal joint (CMC). The articular surfaces of the CMC joint are considered saddle–shaped, and motion of the metacarpal is often idealized as rotation about two orthogonal axes. These primary kinematics of the CMC joint were skillfully described in a cadaver study by Hollister et al. [1], who demonstrated that the extension-flexion (FE) and abduction-adduction (AA) axes are non-orthogonal and non-intersecting. Additionally, Edmunds (2011) proposed that the soft tissues surrounding the CMC joint generate a stabilizing screw-home motion at the end of thumb flexion. A screw home mechanism requires a coupled rotation and/or translation; however, previous experimental studies have not described translation or rotational coupling of the thumb CMC joint. The purpose of this study was determine the in vivo kinematics of the thumb CMC joint during normal physiology motions and then to develop a mathematical description of the envelope of screw axes that completely defines these kinematics.

Methods: After IRB approval, CT volume images were acquired of one hand from 44 healthy subjects (20 M, age 47.9±14.2; 24 F, age 45.4±11.8) with the thumb in five positions: neutral, extension, flexion, abduction and adduction. Kinematics among all possible combinations of positions were computed and described using helical axis of motion parameters and reported with respect to a coordinate system aligned with the directions of principal curvature on the trapezium. A two-way ANOVA (sex x age) was used to evaluate differences in the mean screw axis location and position as a function of sex and age. Root mean square error (RMSE) was used to assess the validity of the mathematical model that was developed to describe the envelope of CMC kinematics.

Results: Differences in the mean kinematic variables with sex and age were small and not statistically significant. Across all subjects the FE rotation axis was offset 26.7° (1 SD = 13.1°) from the ulnar-radial coordinate axis (azimuth) and elevated 21.1° (13.1°). The AA axis was oriented 4.4° (11.2°) from the dorsal-volar coordinate axis (azimuth), and elevated 25.3° (13.5°). The minimum distance between the FE and AA axes was 9.2 mm (2.5 mm) and angle between the axes was 124.1° (18.7°). Interestingly, substantial translation was coupled with the FE and AA rotation: For every ~10° of flexion, the MC1 translated 1 mm ($p < 0.0001$, $R^2 = 0.617$) in a volar-radial direction and for every ~6° of abduction the MC1 translated 1 mm in a dorsal-radial direction ($p = 0.026$, $R^2 = 0.1132$).

Defining the azimuth angle (azi) of the HAM axis as the independent variable, each HAM variable in the set {t,ele,Qx,Qy,Qz} was a cyclic function of azi and a discrete Fourier analysis was successfully fit to each variable with RMSEs of 0.64 mm, 14.5°, 1.5 mm, 1.3 mm. and 1.3 mm, respectively.

Conclusion: This study reports the in vivo kinematics of the thumb CMC joint and demonstrates that a complete envelope of motion exists and it includes the previously reported non-orthogonal and non-interesting axes of extension-flexion and abduction-adduction. In the healthy cohort studied, sex and age were not notable factors in the kinematics. We found substantial translation coupled to the rotational DOF which has not been widely reported. Our approach to the

mathematical description was founded on the observation that the CMC joint has two primary directions of motion: extension-flexion and abduction-adduction, and all the other primary motions are components of these two motions. This observation enabled us to define the azimuth (azi) orientation of the screw axis in the articular plane as an independent variable with a cyclic domain. A harmonic function could then be fit to the elevation and position of the screw axis, as well as the screw translation as a function of the magnitude of rotation (θ). As such, once the magnitude of the thumb rotation and its direction were specified, the locations of the screw axis and the associated translations were completely defined by the reported harmonic functions.

PHYSIOLOGICAL AND PROSTHETIC ANKLE BEHAVIOUR ON CROSS-SLOPES

Coralie Villa [1 2,*] Karine Langlois [2] Xavier Bonnet [3] Pascale Fode [1] Christophe Sauret [2] Francois Lavaste [1 2] Helene Pillet [2]

[1]CERAH, INI, Créteil, [2]Institut de Biomécanique Humaine Georges Charpak, Arts et Métiers ParisTech, Paris, [3]R&D, Proteor, Seurre, France

Introduction and Objectives: Cross-slopes walking is a common situation of daily living in which one has to adapt to the transverse inclination of the ground relative to his progression direction. This situation described as limiting for lower limb amputees has yet barely been studied in the literature [1][2][3]. Dixon et al. [1] highlighted that non amputee subjects gait is mainly adjusted on cross-slopes with changes in ankle behavior in the frontal plane. The aim of the study was to investigate ankle adjustments in the frontal plane during cross-slopes walking compared to level walking in a population of non amputee people and lower limb amputees.

Methods: Seventeen non amputee subjects, thirteen transfemoral amputees and fifteen transitibial amputees wearing their own prosthetic components were asked to walk back and forth at a comfortable speed on a flat pathway and on a cross-slopes device inclined of 6° both instrumented with four force platforms (AMTI, 100Hz) in a motion analysis lab equipped with eight optoelectronic cameras (Vicon V8i, UK) [4]. Anatomical frames, segmental and articular kinematics and kinetics of lower limbs were computed according to Pillet et al. [4].

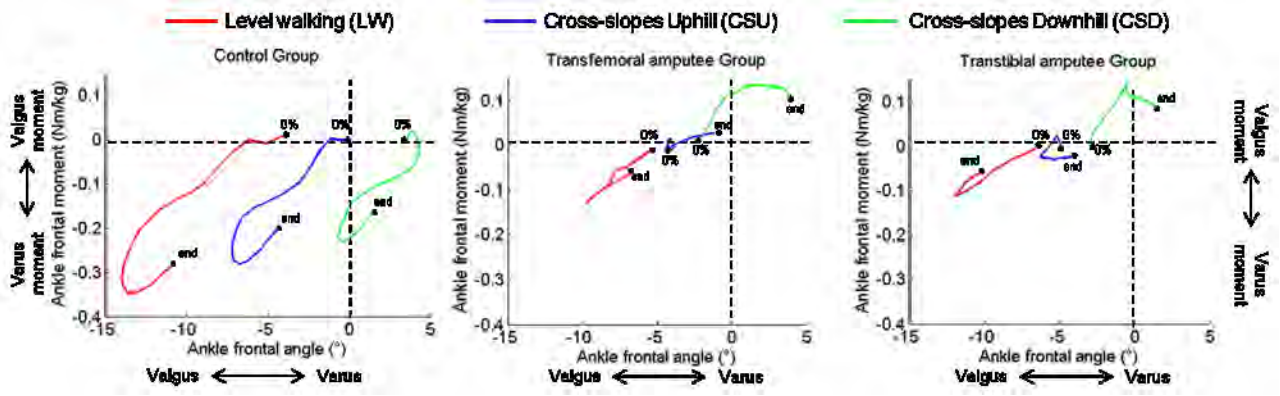
Particularly, ankle angle and moment in the frontal plane were studied during stance phase of gait cycle when the lower limb is loaded: from heel strike to the end of the single limb support. The analyses were conducted for the residual limb (amputee groups) or the left lower limb (control group) during level walking (LW), cross-slopes walking with the limb uphill (CSU) and cross-slopes walking with the limb downhill (CSD).

Results: The figure summarizes the ankle frontal plane behaviour in all situations for all groups.

In the control group, a shift of the ankle angle was observed at heel strike. This ankle angle adjustment was on average of -4.0±1.8° between LW and CSU (towards valgus) and of +3.5±1.0° between LW and CSD (towards varus). In addition, compared to LW, the maximum valgus ankle angle and maximum varus ankle moment during stance significantly increased in CSU (-6.6±1.1° and --0.06±0.08Nm/kg between CSU and LW) and decreased in CSD (6.7±1.1° and 0.03±0.10Nm/kg between CSD and LW). In addition to these adjustments, from heel strike to the end of the single limb support, the ankle internal moment remains a varus moment in all situations and the ankle showed a similar pattern of behaviour among situations.

In the transfemoral (TF) and transtibial (TT) groups, prosthetic ankles behaved in a different way. During LW prosthetic ankles reached on average very low values of ankle angle amplitude and maximum varus moment (angle amplitude TF: 1.8±1.8°, TT: 2.3±1.7°, Controls : 10.9±4.4° / max moment TF: 0.04±0.09Nm/kg, TT: -0.01±0.17Nm/kg, Controls : -0.30±0.17Nm/kg). On cross-slopes, unlike controls, prosthetic ankles were adjusted according to the slope inclination. Indeed, the ankle internal moment and angle changed sign in both groups : were observed a valgus angle and varus moment in CSU and a varus angle and valgus moment in CSD. Prosthetic ankles were passively adjusted to cross-slopes according to the changes in mediolateral direction of the ground reaction force among conditions.

Figure:



Caption: Ankle moment vs ankle angle in the frontal plane between heel strike (0%) and the end of single limb support during stance phase (end) for LW (blue), CSU (red) and CSD (green) in the two amputee patients groups (residual limb) and the control group (left lower limb)

Conclusion: Physiological ankles were in a pre-adapted position at heel strike resulting in a similar evolution of the moment during cross-slopes walking uphill or downhill and level walking. Prosthetic ankles only provided passive adjustments on cross-slopes. To facilitate amputee people locomotion on cross-slopes, prosthetic design should better reproduce physiological ankle behaviour on cross-slopes including the shift of the initial valgus angle position at heel strike according to the slope inclination.

SS-0044

LOWER-LIMB KINEMATICS AND KINETICS DURING AMPUTEE RUNNING: A NEW APPROACH

Stacey M. Rigney [1,*] Anne Simmons [2] Lauren Kark [1]

[1]Graduate School of Biomedical Engineering, [2]School of Mechanical and Manufacturing Engineering, University of New South Wales, Sydney, Australia

Introduction and Objectives: Recent athletics and sprinting competitions have seen lower-limb amputee athletes use carbon-fiber running specific prostheses (RSPs), which behave as leaf springs by storing and returning energy during the stance phase of running. The geometry and inherent behavior of such prostheses violate a number of assumptions utilized in inverse dynamics calculations [1]. Nevertheless, gait analysis of amputee running frequently utilizes these assumptions erroneously for a number of reasons, primarily efficiency and convenience [2]. As an alternative to the conventional two-link segment model of the shank and foot, a multiple-link segment (MLS) model consists of a number of rigid segments connected by torsional springs and dampers to represent the behavior of the prosthesis during loading. This type of model has been previously utilized in forward simulations of amputee walking gait [3], but its value in high-energy activities, such as sprinting, is yet to be determined. Therefore, the aim of this study is to assess the value of MLS models in amputee sprinting, and to optimize prosthesis modeling by determining the minimum number of segments required to best represent prosthesis behavior.

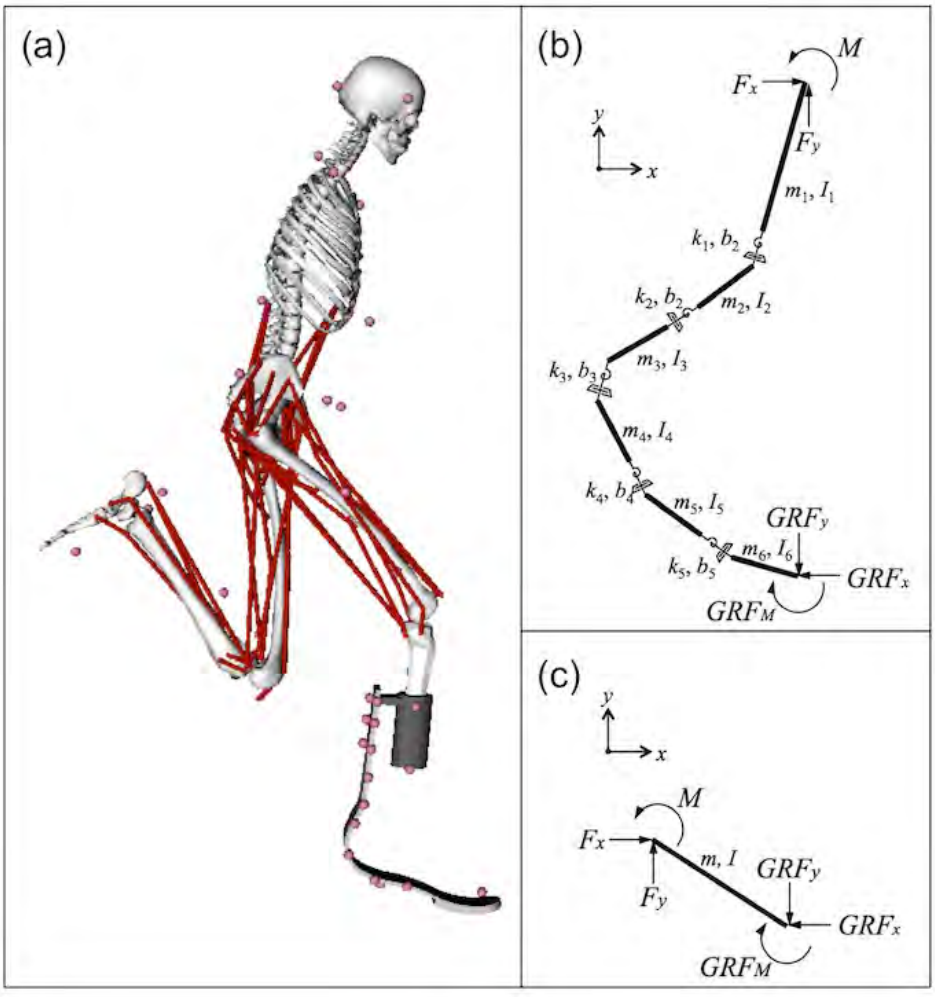
Methods: Experimental gait analysis was performed at the Australian Institute of Sport in accordance with UNSW Australia Human Research Ethics Committee approval HC13054. A 16-year-old female right-sided transtibial amputee of mass 58kg and height 163cm sprinted at maximum speed along an indoor 100m straight running track instrumented with eight Kistler 9287B 1000Hz force plates and 20 VICON MX T40-S 250Hz motion capture cameras. Both a Full Body Plug-in-Gait (PiG) and custom set of passive-reflective markers were placed on the subject, where the custom set included seven additional markers placed along the lateral side of the prosthesis, three on the posterior side and two on the lateral side of the socket.

Post-processing of the experimental data was conducted in the open-source musculoskeletal modeling software OpenSim. A generic full-body, no arms musculoskeletal model [4] was scaled according to the experimental trajectories of both the PiG and custom marker sets (Figure 1a). The MLS mathematical model of the prosthesis consisted of six rigid bodies defined by at least two markers each, connected in series via single degree-of-freedom torsional springs and dampers (Figure 1b). The PiG marker set defined the virtual foot (Figure 1c) and shank segments connected via a pin joint. A half factorial Design of Experiments analysis was used to investigate the significance of each of the five joints at a 95% confidence level, resulting in 16 configurations of the MLS model. The comparison criteria consisted of peak hip flexion during swing phase, peak hip extensor moment, minimum knee flexion during stance phase and peak knee extensor moment for both the right and left legs using each of the MLS models and the PiG model.

Results: For the hips and knees of both legs, the peak flexion angles and moments calculated using the MLS models, averaged across all configurations, were significantly different ($p<0.001$) in comparison to the PiG model results (Table 1, columns 3-5). When considering individual MLS configurations, every joint was found to significantly affect at least one

variable of interest (Table 1). For example, joint 1 alone did not affect right hip flexion, however when combined with joint 4 the results were significant. Overall, the calculated lower-limb kinematics and kinetics were highly sensitive to model selection.

Figure:



Caption: Figure 1 – Models used during gait analysis: (a) full-body musculoskeletal, (b) multiple-link segment and (c) conventional virtual foot segment.

Conclusion: During this study, the calculation of hip and knee angles and moments during amputee running has been shown to be highly sensitive to the selection of link segment model ($p<0.001$). Instead of using a traditional PiG model for gait analysis of amputee running, we recommend a MLS model consisting of at least six segments. Future work in the area should include incorporation of this MLS custom marker set directly into motion capture software for all clinical applications involving RSPs.

Table:

Limb	Variable	PiG	16 x MLS		Significant MLS joints and/or combinations of joints
			Mean	Std Dev.	
Right	Hip Flexion	56.8	66.3	0.26	1+4
	Hip Moment	-750.2	-656.2	20.3	2, 3+5, 4, 2+3, 5
	Knee Flexion	11.4	21.1	0.275	1+3, 4
	Knee Moment	-436.5	-469.5	12.7	Nil
Left	Hip Flexion	61.5	73.3	0.989	1+3, 3
	Hip Moment	-751.6	-728.0	12.4	Nil

SS-0045

INVESTIGATION INTO RAMP DESCENT AMBULATION FOR TRANSFEMORAL AMPUTEES WHEN USING AN INTEGRATED PROSTHESIS

Nadine Stech [1,*] Aliah F Shaheen [1] David Ewins [1]

[1]Centre for Biomedical Engineering, Department of Mechanical Engineering Sciences, University of Surrey, Guildford, United Kingdom

Introduction and Objectives: Much research has been undertaken on level ground ambulation to gain a fundamental understanding of transfemoral amputee gait. Ramp ambulation has not been considered to such an extent even though gait is highly influenced by the surface inclination, as can be seen in non-amputee gait studies [1].

This study has investigated the influence of braking actions of an integrated knee and ankle prosthesis for transfemoral amputees. The integrated prosthesis working through a single controller allows the implementation of different braking strategies at both joints. Non-amputee studies have shown a negative net energy for ramp descent where the ankle and knee joint absorb much of the energy [2]. Therefore, it was expected that incorporating a braking action into an integrated prosthesis would be beneficial.

Methods: Four established transfemoral amputees of K3 level participated in the gait study and signed consent was given. Each amputee used the integrated prosthesis, which consists of a microprocessor controlled hydraulic ankle and a microprocessor controlled hybrid knee joint working through a single controller. This controller enabled adjustment of (braking) resistance levels wirelessly. The prosthesis was aligned by an experienced prosthetist and the alignment was not changed throughout the data collection.

Kinematic and kinetic data were collected using a Codamotion Gait Analysis system and a Kistler force plate. The force plate was integrated in a 5° degree ramp. The level of declination was chosen as it falls within the guidelines of UK building regulations [3]. Data from the 4 sensors in the knee and ankle units were also collected.

The internal resistances of the knee and ankle joints were adjusted and their influence on the gait of the volunteers was investigated. Four scenarios were considered:

a) No braking action of the limb
b) Braking action of the ankle
c) Braking action of the knee
d) Braking action of the knee and ankle as an integrated limb

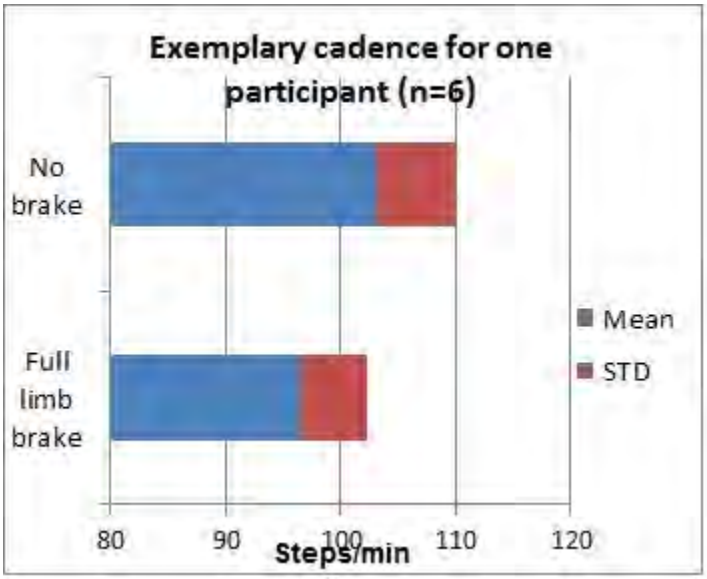
For each of those scenarios the optimal resistance levels at a normal self-selected speed were established before the formal data collection took place. In each case, the resistance was adjusted until the participant and the prosthetist were satisfied that it was providing sufficient but not too much support.

Additionally, subjective feedback was also collected. Each participant and the prosthetist rated the gait performance with regard to perceived safety and smoothness of each scenario independently.

Results: The ground reaction forces show clearly the influence of braking in the ankle, as the peak value and the timing of the braking impulse (posterior forces) is more pronounced.

The ankle had an impact on gait from early to mid-stance particular on the anterior-posterior ground reaction force and the sagittal plane ankle bending moment, whereas the knee showed its damping influence in mid to late stance. Most participants described the ramp ambulation using the integrated limb brake as giving more control over the prosthesis. In most cases self-selected speed as well as cadence was lower using the integrated limb brake, as illustrated in the figure below. Transfemoral amputees have the tendency to accelerate during ramp descent with increasing momentum; a lower self-selected speed therefore indicates that they have more control over their gait.

Figure:



Caption: Exemplary Cadence for Ramp Descent Ambulation

Conclusion: The gait study showed that the amputees perceived a braking action in the whole limb during ramp descent as beneficial. They felt safer and that they had greater control of the prosthetic limb. The braking resistance level of the knee was found to be a very sensitive parameter.

A larger follow-up study is required to investigate in more detail the effects of the integrated limb brake and the impact of the setting of the knee and ankle braking resistance levels, e.g. on different gradients or with different self-selected speeds.

SS-0046

DIFFERENCES IN PELVIS AND THORAX KINEMATICS DURING THE STANDING TURN FOR PEOPLE WITH A UNILATERAL TRANS-TIBIAL AMPUTATION.

Tina Smith [1,*] Matthew Taylor [2] Siobhan Strike [3]

[1]Institute of Sport, University of Wolverhampton, Walsall, [2]University of Essex, Essex, [3]University of Roehampton, London, United Kingdom

Introduction and Objectives: The standing 180° turn is a common activity of daily living, however there is little biomechanical research on how this movement may be achieved, especially in people with a trans-tibial amputation. Previous research on turning while walking has indicated a reorientation of the trunk and pelvis [1] and that changing the direction of motion requires 3D motion at the ankle [2]. The simplest standing turn is made up of three turning steps. The address position prior to initiation of the turn is followed by a preparatory, turn and a depart step. It is possible that in order to execute these steps effectively a turn from standing will require even more ankle joint motion due to the increased demand to rotate about the longitudinal axis. As mobility at the ankle is compromised for amputees increased pelvic and thoracic contribution to the movement may be a compensatory mechanism adopted.

The aim of this research was to determine the contribution of the pelvis and thorax to movement about the longitudinal axis for each step of the turn when turning to either side from the intact or prosthetic limb.

Methods: Seven participants (height 1.76±0.06m; mass 85.2±9.6kg; time since amputation 16±10y) took part in the study. Participants were instructed to complete a standardised task which involved walking to a counter 3m away, picking up a slide rule and moving it 30cm, replacing it on the counter, turning through 180° and returning to the start point. This mimicked a task in which turning is embedded.

Data were collected with a 9-camera infrared system, sampling at 120Hz, recording 34 reflective markers attached to the participants according to the Vicon Plug-in-Gait model. Data was filtered using a low-pass Butterworth filter (cut-off frequency 6Hz). Pelvis and thorax transverse angular displacement for the double and single stance phase of each step of the turn, and the full turn were determined for turns from the intact and prosthetic limb. The turn direction (from intact v prosthetic limb) was determined by the stance limb during the turn step.

Results: All participants completed a turn using a prep, turn and depart step for both turn directions. Significantly greater pelvis and thorax angular displacement were exhibited in the single stance (SS) phase of the turn step (pelvis $p = .025$; thorax $p = .035$) when turning from the intact limb. When turning from the prosthetic limb significantly greater pelvis and thorax angular displacement (pelvis $p = .013$; thorax $p = .009$) occurred during the depart step when the intact limb was in SS (Table 1). No further differences were observed.

Conclusion: For turns in both directions, much of the directional change occurred when the intact limb was in stance. This meant that when the intact limb was in stance for the turn step, the reorientation was achieved mainly in that step (~74° of pelvic and thorax rotation in SS) and when the turn was completed from the prosthetic side (prosthetic limb in stance during the turn step), the reorientation mainly occurred in the depart step (~61° of pelvic and ~54° of thorax rotation in SS), when the intact limb was in stance (Table 1). Previous research on turning bias in trans-tibial amputees has

suggested no bias from the intact or prosthetic limb when repeatedly performing standing 180° turns [3]. The difference in the protocol, which adopted a shorter approach and completion of a turn embedded within a set task, may explain the turning bias evidenced here.

The adoption of the prep step and the observed strategy to favour the intact limb in order to perform much of the turn is suggestive of the amputees adopting a precautionary approach when completing a standing turn. This may have rehabilitation implications where amputees should be made aware of the restrictions when turning from the prosthetic limb and be taught how to turn effectively.

Table:

	From Prosthesis	From Intact
Preparatory Step	(SS on intact limb)	(SS on prosthetic limb)

PRELIMINARY EVALUATION OF A MICROPROCESSOR-CONTROLLED KNEE ANKLE PROSTHESIS (MAKP) FOR ABOVE KNEE AMPUTEES.

Bonnet Xavier [1,*] Francis Djian [1] Boris Dauriac [2] Coralie Villa [3] Isabelle Loiret [4] Noel Martinet [4] Helene Pillet [2]

[1]R&D, PROTEOR, Seurre, [2]Institut de Biomécanique Humaine Georges Charpak, Arts et Métiers ParisTech, Paris, [3]CERAH, INI, Creteil, [4]IRR, Nancy, France

Introduction and Objectives: Prosthetic knees and feet design have benefited from important technical improvements over the last few decades. Microprocessor-Controlled Prosthetic knees have improved the safety and the functional outcomes of above knee amputee and became the gold standard of care in above knee prosthetics [1]. The control of the knee flexion during stance improved the walking ability both during stair [2] and slope descent [3]. In spite of these active engineering developments, patients continue to report some difficulties for ambulation, emphasized during outdoor activities [4].

Some of these difficulties could be attributed to the lack of ankle adaptations to different terrain. In literature, some authors highlighted this lack of adaptation to stairs [2] and slopes [5]. Thus, with stairs, step-by –step descent is made possible by placing the prosthetic foot on the edge of the step allowing the progression of the tibia during stance [6]. This strategy would be a consequence of the lack of mobility of the ankle resulting from the fixed stiffness of conventional prosthetic feet.

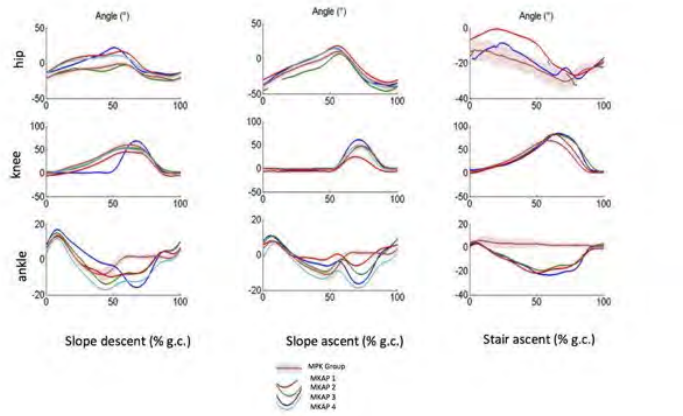
Some microprocessor-controlled prosthetic ankles are now available for both below knee and above knee amputees. In particular, some designs allow ankle movement during the swing phase. By increasing toe clearance, they reduce the risk of falling and allow adjustment of ankle position according depending on the slope [7]. Other designs including hydraulic devices were developed to adapt the ankle resistance during stance depending on the terrain [8]. Motorized design were recently presented [9-10]. Design of above knee amputee prosthesis must fit the following criteria: limited weight, reduced adaptation time and robustness.

The objective of the study was to evaluate a passive Microprocessor-controlled Knee Ankle Prosthesis (MKAP) able to mimic various adaptations quantified for asymptomatic people in slopes and stairs.

Methods: Four above-knee amputees were fitted with the prototype of MKAP. Motion capture of 54 markers placed on the patient according to the protocol described by Pillet [11]. Acquisitions were made in 3 situations of daily living simulated using instrumented devices: level ground, a ramp inclined at 12% (7°) and a 4-step staircase. From the marker set, kinetic and kinematic of 18 body segments were computed. A control group was formed with ten above-knee amputees fitted with a conventional Microprocessor-controlled Prosthetic Knee (MPK) and an Energy Storing and Return Foot (ESARF).

Results: Fig. presents the sagittal kinematic of the hip, knee and ankle of the prosthetic limb during slope ascent and descent and stair descent for the ten MPK users (shaded area) and for the four MKAP users (solid lines). Compared to MPK, MKAP allows a wider range of motion of both the prosthetic knee (especially during stair descent) and prosthetic ankle both during stance and during swing.

Figure:



Caption: Prosthetic limb kinematics in the sagital plane

Conclusion: The limited range of ankle motion in conventional prosthetic feet does not allow amputees to keep the foot flat on the floor during ramp descent. The prototype, by allowing a reduction of the “equivalent” stiffness succeeds in restoring a large foot flat period during the single limb support phase on the prosthesis, securing this critical phase of gait. During slope ascent, the ankle dorsiflexion during swing helps the user to increase toe clearance reducing the risk of falling. During stair descent, the ankle motion range during stance avoids risky positioning of the prosthetic foot on the edge of the step. Very recent work done by Vanderbilt Unniversity have detailed the functioning of a motorized ankle/knee prosthetic system designed for above knee amputees [10]. This prototype is able to provide power to assist prosthetic movements. This power can be useful when ascending stairs but current prototypes have to be made more reliable, quieter and lighter to benefit amputees in real life [12]. Some functions (adaptation of the ankle in stance, swing dorsiflexion, knee control) can be passively achieved with a hydraulic microprocessor controlled ankle/knee system increasing the ability to walk on various terrains.

A LOWER-LIMB AMPUTEE MUSCULOSKELETAL MODEL FOR QUANTIFYING STUMP-SOCKET KINEMATICS AND KINETICS

Ryan Wedge [1,*] Andrew LaPre [2] Frank Sup [2] Brian Umberger [1]

[1]Department of Kinesiology, [2]Department of Mechanical and Industrial Engineering, University of Massachusetts Amherst, Amherst, United States

Introduction and Objectives: There are an increasing number of people with lower limb amputations resulting from both traumatic and vascular causes. Skin breakdown is a common problem experienced by amputees due to the motion and forces between the stump and socket. The stump soft tissues were not designed to withstand the forces they attenuate inside of the socket, which can lead to pressure ulcers[1]. The motion and forces of greatest concern are socket pistoning and flexion-extension. Pistoning refers to translational motion in the axial direction, while socket flexion-extension is the rotation that occurs in the sagittal plane, due to a bending moment created by the ground reaction force. While these loading mechanisms are known to exist[2], the actual magnitudes and patterns of loading at the stump-socket interface (SSI) over a continuous gait cycle have not been fully characterized. In previous musculoskeletal modeling studies, the SSI has usually been assumed to be rigid[3], which may be a limitation when musculoskeletal models are used to understand amputee locomotion. Explicitly modeling the SSI will provide insights as to the motion and loading at the SSI. Our long-term goal is to use this approach to aid in the development of new prostheses that can reduce these loads and decrease the incidence of soft tissue injury. The specific purpose of this study was to examine the stump-socket kinematics and kinetics during walking in transtibial (TT) amputees using a musculoskeletal model with a compliant SSI.

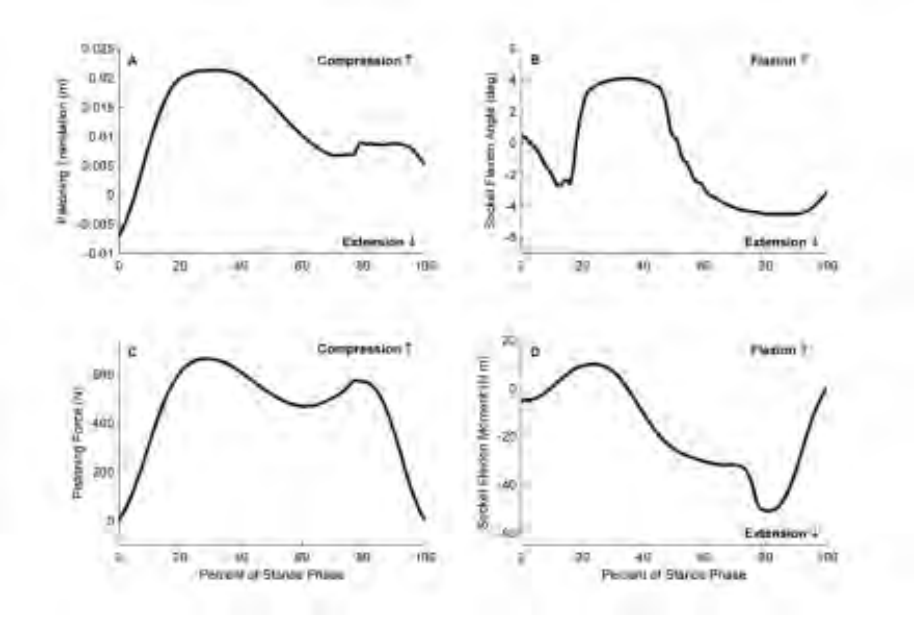
Methods: We created a three-dimensional unilateral TT amputee model by modifying one of the standard gait models provided with OpenSim (gait2354). We created a residual tibia/fibula (stump segment) that is connected to the socket via a joint at the most distal aspect of the stump, representing the SSI. The socket and pylon were connected to a split-toe flex foot via a pin joint. The entire model has 25 degrees of freedom, including pistoning and flexion-extension at the stump-socket joint. To demonstrate the utility of the model, results are presented for a female subject with a left-side TT amputation (height: 1.80 m; mass: 68.04 kg) who performed three overground walking trials at her preferred speed (1.31 m/s). Kinematic data were captured using a full-body marker set and were synchronized with ground reaction forces measured using three force platforms. Inverse kinematics and inverse dynamics analyses were performed in OpenSim and results were averaged over the three trials.

Results: Joint Kinematics and Kinetics: The hip, knee and ankle joint angles and moments for the prosthetic and intact limbs were in general agreement with corresponding data in the literature. For example, the magnitude of the knee extension moment in the first half of the stance phase was greatly reduced on the prosthetic side compared with the intact limb. Data collected for a second subject show similar results.

Stump-Socket Kinematics and Kinetics: There was 3.4 cm of pistoning translation and 8° of socket flexion-extension at the SSI (Fig 1). The 3.4 cm of pistoning agrees with previous studies using radiographic techniques[2]. The peak pistoning force occurred in the first half of stance and was 663 N, which is near one bodyweight (667 N). The peak extensor

moment at the SSI was 51 N m (Fig 1), which was of similar magnitude to the intact-side peak knee extensor moment. Unlike typical joint kinetics, the relatively large pistoning force and bending moment is borne by a small area of soft tissue that is not meant to withstand such loading, and may contribute to tissue damage. By directly modeling the SSI in TT amputees during locomotion, we can gain greater insights as to the motion and forces that play a role in skin breakdown. In future work, the model will be used to predict individual muscle forces, which will help reveal the accommodations made by amputees to walk. This will also provide a basis for predicting novel prosthesis designs that can reduce stump-socket loading without disrupting the way amputees naturally walk.

Figure:



Caption: Stance Phase Socket Kinematics and Kinetics Figure 1: Pistoning motion (A), Flexion and extension motion (B), Pistoning force (C), Flexion and extension moment (D)

Conclusion: Including degrees of freedom at the SSI in a TT amputee musculoskeletal model provided potentially useful information about stump-socket mechanics, while yielding similar joint mechanics as have been previously reported in the literature.

MULTI-PARAMETRIC EVALUATION OF MOBILITY USING SINGLE-LOCATION WEARABLE SENSOR: APPLICATION TO STROKE PATIENTS

Kamiar Aminian [1,*] Fabien Massé [1] Roman Gozenbach [2] Anisoara Paraschiv-Ionescu [1] Andreas Luft [2]

[1]Laboratory of Movement Analyisis and Measurement, EPFL, Lausanne, [2]University of Zurich, Zurich, Switzerland

Introduction and Objectives: To restore their mobility stroke survivors undergo an intensive rehabilitation program, throughout which, the patient's *capacity* is tested using clinical scores. However, these tests are not necessarily reflect the actual patients *performance* in daily life [1] and there is need for an objective evaluation of patient's performance in daily conditions. In despite of advances in wearable technologies for monitoring patients' physical activity in daily-life, for the stroke population, existing systems are limited in the number of parameters [2, 4-7] and use multiple sensor locations, which could hinder the subject. The objective of this study is to provide a system with single sensor located on the trunk and multiple parametric assessment [2, 3] of mobility in daily-life addressing 1) the characterization of (sit-to-stand and stand-to-sit) postural transitions (PT); 2) the classification/quantification of the activities and 3) a meta-analysis of these activities and PT through their temporal pattern and distribution.

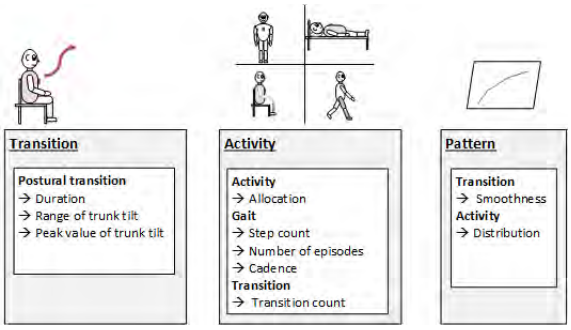
Methods: The measurement system consisted of a small sensor device (Physilog®, GaitUP, CH) attached on the trunk including an inertial and a barometric pressure sensor. The data collection was carried out on 7 stroke patients (age: 52.1±11.4 y.o) in their home environment and last for minimum 3 days (8 hours/day). The balance impairments and the capacity of daily-living activity were evaluated by the Berg Balance Scale (BBS) and the Barthel Index (BI). A control population of 10 elderly subjects (age: 70.8±2.8 y.o) was recruited to highlight the discriminative parameters using Wilcoxon's ranksum test ($p<0.05$). Mobility metrics were extracted in daily-life related to three categories (Figure):

- Transition (PT duration, range and peak value) [5];
- Activity (walking/posture allocation, step count, cadence [2] and number of PT [5]);
- Pattern (power-law scaling coefficient of the distribution of the number of steps per walking episodes and their duration [11] and smoothness of PT [8]).

Metrics were extracted from a PT recognition [9] and an event-based activity classification algorithm (accuracy of 90.5%)[10]. The degree of association between capacity (clinical score) and performance (mobility metrics) was computed using the Spearman's correlation coefficient (ρ).

Results: Table indicates that most of the mobility metrics are discriminative. The balance capacity (BBS) was significantly correlated with faster PT ($\rho=0.82$, $p=0.03$) and higher rate of PT ($\rho=0.79$, $p=0.04$) which are consistent with the literature [12, 13]. The percentage of time spent standing was significantly correlated with the BI ($\rho=0.80$, $p=0.04$) suggesting the overall functional capacity is associated with the ability of the patients to remain in an upright posture. The smoothness metric was significantly correlated ($\rho=0.80$, $p=0.04$) with the BI. Results are consistent with literature [2,14]. At least one metric within each category (transition, activity, pattern) was associated with clinical score showing the relevance of each category.

Figure:



Caption: Mobility metrics extracted in daily-life related to Transition, Activity and Pattern

Conclusion: Providing the small sample size, results with stroke patients should be interpreted with care. Nevertheless, the results obtained so far, confirmed that the proposed system is convenient for long-term monitoring and the multi parametric approach provides a good picture of the performance of the patients during real world condition. The association of the proposed metrics with clinical score is a powerful tool for a personalized rehabilitation program.

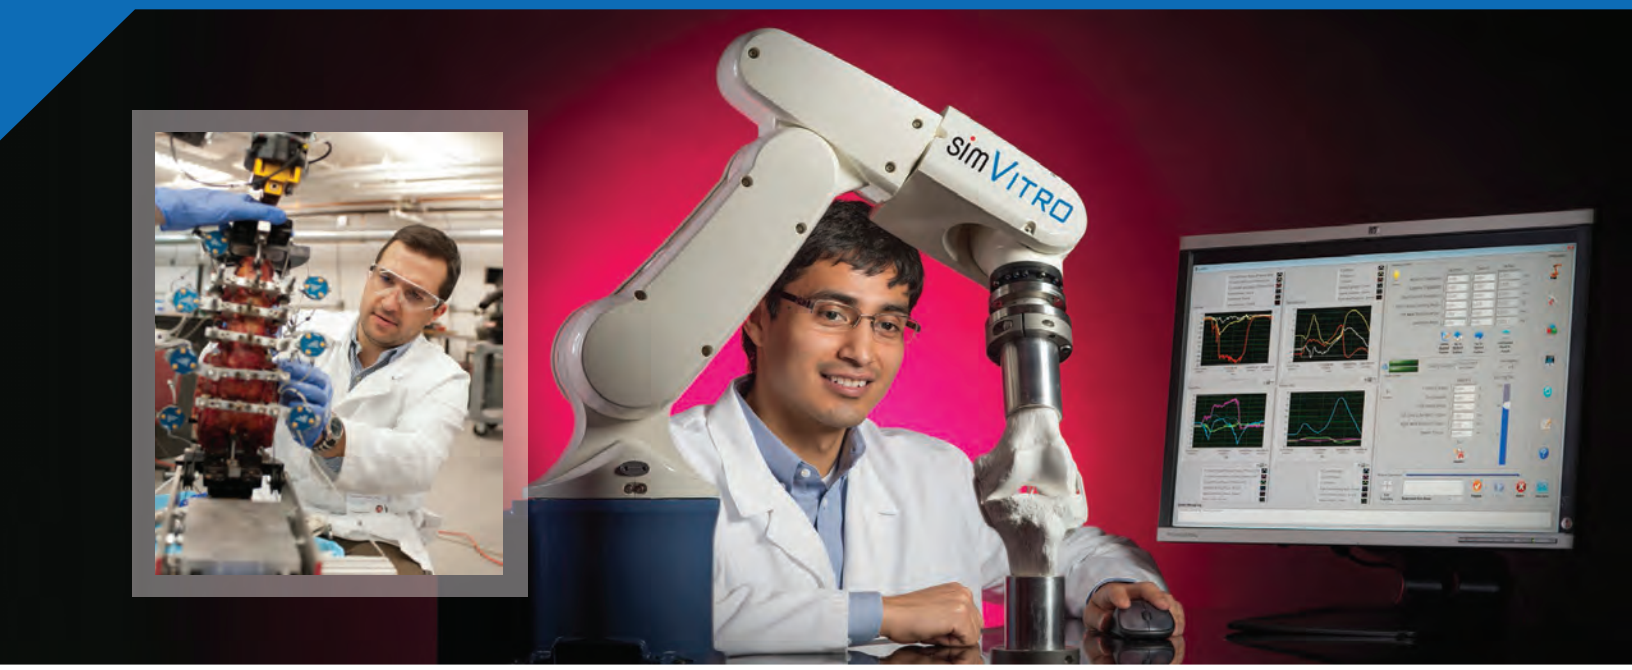
BIOROBOTICS DEMONSTRATION



Simulation Solutions are pleased to be demonstrating the Siemens PLM range of robotic simulation software and its application to simulating human joint motion. The simulation software can be used in conjunction with a KUKA robot to facilitate physical testing.

Simulation Solutions are also excited to be launching the simVITRO range of products from The Cleveland Clinic Foundation. Designed as a universal musculoskeletal simulator it has the following benefits:

- Reduce cost and time to publishing your scientific discoveries
- Select the specimen module(s) that match your research program
- Utilise International Society of Biomechanics standards for joint coordinate systems
- Customise sensors and measurements unique to your particular application via the plug-in style architecture
- Build around new or existing robotic or sensor infrastructure in your laboratory or testing facility. Get the power of simVITRO while leveraging your current capital equipment.

Simulation Solutions is delighted to announce its partnership with Motion Analysis Corporation.

Motion Analysis Corporation is the world's largest manufacturer of high performance optical instrumentation systems that test and measure movement. Their systems combine hardware, software and electro-optical techniques with standard computer and camera hardware. These systems evaluate motion in a wide variety of applications, including patient positioning, evaluation of surgical procedures, and measurement of positions and forces during cadaveric testing.

SS-0050

KNEE AND BODY ALIGNMENT IN THE FRONTAL PLANE DURING FIVE FUNCTIONAL EXERCISES USED IN REHABILITATION

Kate Button [1 2,*] Paulien Roos [1] Paul Rimmer [1] Robert van Deursen [1]

[1]Healthcare Science, Cardiff University, [2]Physiotherapy Department, Cardiff & Vale University Health Board, Cardiff, United Kingdom

Introduction and Objectives: Frontal plane biomechanics during functional exercises are of interest in rehabilitation to evaluate recovery of neuromuscular control and re-injury prevention. Dynamic valgus is used in rehabilitation to describe knee alignment during functional exercises. External knee adductor moment (EKAM) reflects joint loading and is influenced by a number of factors including frontal plane knee and trunk alignment [1,2]. Alterations in sagittal plane knee kinematics and kinetics have been observed in individuals with anterior cruciate ligament (ACL) deficiency (ACLD) and reconstruction (ACLR) compared to controls [3, 4]. However, it is not clear whether dynamic valgus and changes in trunk alignment commonly occur and what the implications are for joint loading and knee stability. Therefore, five functional movements were compared to determine the role of frontal plane knee and trunk alignment.

Methods: ACLD, ACLR, and healthy participants performed four repetitions: walking (WLK), jogging (JOG), double and single-leg squatting (DLS & SLS), and single-leg hopping (HOP). Each task was executed at preferred speed/distance. Motion data were collected using the VICON full body marker set. Parameters calculated were: peak knee external flexor moment (PkKnFlM) and knee flexion angle at this peak (KnAngatPkM), peak EKAM (PkEKAM), dynamic valgus (DynValgus), and trunk lean. A repeated measure ANOVA and Bonferroni adjustment for comparisons were used to investigate differences between WLK and the other tasks for the three groups.

Results: Results are reported for 29 ACLR (height: 1.74±0.07 m, mass: 80.0±10.1 kg, age: 30.1±9.6 years, gender: 8 female, 21 male), 28 ACLD (height: 1.78±0.09 m, mass: 81.9±14.8 kg, age: 31.0±7.8 years, gender: 5 female, 23 male) and 29 control subjects (height: 1.73±0.11 m, mass: 73.5±16.4 kg, age: 28.0±6.9 years, gender: 10 female, 19 male). All parameters were significantly different between the five tasks ($p<0.05$), but the Group by Task interaction was only significant for PkKnFlM ($p<0.01$). Except for WLK, the ACL groups carried out the tasks with smaller moments compared to the controls. KnAngatPkM was different between groups ($p<0.05$). The ACLD group consistently used less flexion for all activities and did not depend on task requirements. The results for all the variables are summarised in Table 1. In the frontal plane, no significant differences occurred for Group*Task interactions or between groups for PkEKAM, DynValgus, and TrunkLean. Therefore, all groups seemed to use similar frontal plane movement strategies for all activities.

Conclusion: Movement adaptations in ACLD and ACLR seem to occur most obviously in the sagittal plane, i.e., a reduced peak external knee flexor moment and for ACLD a reduced knee flexion angle at this time point. No differences were found in frontal plane kinematics or kinetics between ACL groups and controls. Except for walking, it seems that regardless of task difficulty the response in ACL groups was a reduction in overall knee loading which could be considered a protective mechanism. It is not entirely clear why movement adaptations were not observed in the frontal

plane, but it may be that other aspects of frontal plane behaviour such as motor control and stability likely need to be considered.

DOES LONG-TERM PASSIVE STRETCHING ALTER MUSCLE-TENDON UNIT MECHANICS IN CHILDREN WITH SPASTIC CEREBRAL PALSY?

Nicola Theis [1,*] Thomas Korff [2] Amir Mohagheghi [2]

[1]St Mary's University, [2]Brunel University, Middlesex, United Kingdom

Introduction and Objectives: The aim of the present work was to investigate the effects of 6-weeks passive stretching on *triceps surae* muscle and Achilles tendon stiffness in children with spastic cerebral palsy (CP). Following the intervention, muscle stiffness decreased with no alteration to the tendon. This reduction was accompanied by an increase in muscle fascicle strain but not in resting fascicle length. Further studies should investigate the functional implications of these results.

Cerebral Palsy causes motor impairments during development. Children with CP may experience excessive neural and mechanical muscle stiffness [1]. The clinical assumption is that excessive stiffness is the main reason for reduced range of motion and functional impairments in CP [2]. As such, passive stretching is widely used to reduce stiffness, with a view to improving function for children with CP. However, current research evidence on passive stretching in CP is not adequate to support or refute the effectiveness of stretching as a management strategy to alter muscle and tendon mechanics [3]. Thus, the purpose was to identify the effect of 6-weeks passive ankle stretching on *triceps surae* and Achilles tendon mechanical properties in children with spastic CP.

Methods:

Thirteen ambulant children with spastic diplegic or quadriplegic CP (age 10.3 ± 3.0 y; GMFCS III-IV) participated in this study. Children were randomly assigned to an experimental or control group. None had received any form of lower limb surgery 24 months prior to participation in the study, and none had received Botulinum toxin injections to the legs 4 months prior to participation.

The experimental group underwent 6-weeks of passive ankle dorsiflexion stretching applied by a physiotherapist, for 15 minutes (per leg), 4 days per week, whilst the control group continued with their normal routine. Before, after and 3-weeks post intervention, the mechanical properties of the medial gastrocnemius muscle and fascicles, and the Achilles tendon were measured using a combination of motion analysis, ultrasonography and dynamometry. Briefly, a passive rotation of the right ankle joint was applied at 10 deg·s^{-1} through the available ROM. Simultaneously, medial gastrocnemius muscle belly, fascicles and Achilles tendon lengths were measured using B-mode ultrasonography (Megas GPX, Esaote, Italy; 45 mm Linear array probe, 10 MHz transducer scanning) and motion analysis (Motion Analysis, Santa Rosa, USA).

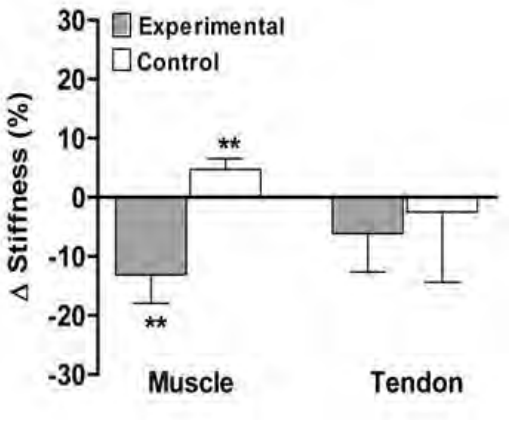
Achilles tendon stiffness was calculated as the change in passive ankle torque divided by the corresponding change in Achilles tendon length. A surrogate measure of “total *triceps surae* muscle stiffness” was also derived from the data by dividing passive ankle torque and elongation of the medial gastrocnemius muscle. Muscle and tendon stiffness were calculated from the slope of the torque-elongation curves corresponding to 20-80% of each participants peak torque. Muscle, tendon and fascicle lengths at maximum dorsiflexion were divided by their resting lengths to give strain values.

Mixed design ANOVAs with repeated measures on each dependent variable were used to assess the effects of stretching.

Results:

Following the intervention, the experimental group demonstrated a 3° increase in maximum ankle dorsiflexion. This was accompanied by a 13% reduction in *triceps surae* muscle stiffness, with no change in tendon stiffness (Figure 1). Additionally, there was an increase in fascicle strain following the intervention but with no changes in resting length. This suggests muscle stiffness reductions were a result of alterations in intra-/extra-muscular connective tissue and not due to an increase in sarcomere number. These results remained 3-weeks post-intervention but had begun to return towards baseline. Our results demonstrate that 6-weeks of passive stretching caused lasting increases in maximum dorsiflexion and reductions in muscle stiffness.

Figure:



Caption: Figure 1. Change (Δ) in muscle and tendon stiffness pre- to post-intervention in the experimental and control groups (values are mean ± SD, **p < 0.01).

Conclusion:

Collectively, the results of this study confirm the clinical assumption that passive stretching can reduce muscle stiffness for children with CP. Moreover, the present study shows for the first time that such reductions were associated with changes in the mechanical properties of muscle but not the tendon. Future studies should investigate this from a clinically-relevant perspective as to whether this reduction in stiffness leads to improvements in gait parameters and gait efficiency in children with CP.

TRAINING WITH OFF-LOADED BODY WEIGHT IN A LOWER-BODY POSITIVE PRESSURE CHAMBER IMPROVES PHYSICAL FUNCTION IN PATIENTS WITH MUSCULAR DYSTROPHY

Bente R R. Jensen [1,*] Martin P Berthelsen [1] Edith Husu [2] Sofie B Christensen [1] Kira P Prahm [2] John Vissing [2]

[1]Biomechanics and Motor Control Lab., Integrated Physiology, Nutrition, Exercise and Sport, [2]Neuromuscular Research Unit, Department of Neurology, Rigshospitalet, University of Copenhagen, Copenhagen, Denmark

Introduction and Objectives: Recent studies suggest positive effects of physical training in patients with muscular dystrophy [1]. However, patients with severe muscular dystrophies have limited possibilities to perform normal exercise protocols due to their weakness. The aim was to study functional effects of combined strength and aerobic anti-gravity training in severely affected patients with Becker and Limb-Girdle muscular dystrophies.

Methods: Eight patients (age: 36 ± 4 years, weight: 73 ± 5 kg, height: 176 ± 3 cm, gender: 6 males and 2 females) participated in a 10-week control period followed by 10-week of progressive strength and aerobic training (3 times/week, 40 min sessions) in a lower-body positive pressure (LBPP) environment, which offered weight support of up to 80% of their body weight (BW). The LBPP system consisted of a treadmill surrounded by a pressure chamber (G-trainer P200, Alter-G, USA). Strength training (treadmill at standstill), included squats, calf raises and lunges with three series of each exercise. When the patient could perform more than 12 repeats (squats and lunges) or 15-20 repeats (calf raises) at a specific %BW, then the load was increased by 5%BW to ensure training progression. Aerobic training consisted of walk/run, jogging on the spot or high knee-lift, initially at 50%BW support. Isometric knee extension and flexion strength as well as isometric rate of force development (RFD) (extension) were measured before and after the training period.

Results: Isometric knee extension and flexion torque were 0.50 Nm/kg (15% of expected value) and 0.48 Nm/kg (37% of expected value), respectively [2]. Thus, H/Q ratio was 0.96, which is more than twice of the expected value, indicating that knee extensor muscles are among the most affected muscles. Absolute knee extension RFD was 229±75 Nm/s and relative RFD was 540±49 %MVC/s. Relative RFD corresponded to values from an age and sex matched group whereas absolute RFD values corresponded to approx. 20% of expected values. These data confirm that the patients suffer from a muscle disease whereas the nervous system functions adequately. It is therefore possible that optimization through motor learning is feasible in this patient group.

Training (compliance 91%) improved functional leg muscle strength. Thus, squat series performance increased from 30%BW/leg to 38 %BW/leg, calf raises increased from 56%BW/leg to 75%BW/leg and lunges increased from 55%BW to 67%BW from week two to week 10. The first week was considered as familiarization. In contrast, neither isometric knee extension strength nor RFD increased in response to training.

Conclusion: Anti-gravity training improved functional leg muscle strength despite no change in isometric knee extension strength and absolute RFD were found. There are two possible explanations for these findings. One is that anti-gravity training, performed in LBPP, improves muscle strength of other muscles than the weak knee extensors, which we assessed. Alternatively, it may relate to a neural adaptation involving motor learning.

COMPENSATION STRATEGIES FOR EXPERIMENTALLY REDUCED MUSCLE FUNCTION DURING SQUATS

Teresa Flaxman [1,*] Tine Alkjaer [2] Erik Simonsen [2] Michael Krogsgaard [2] Daniel Benoit [1]

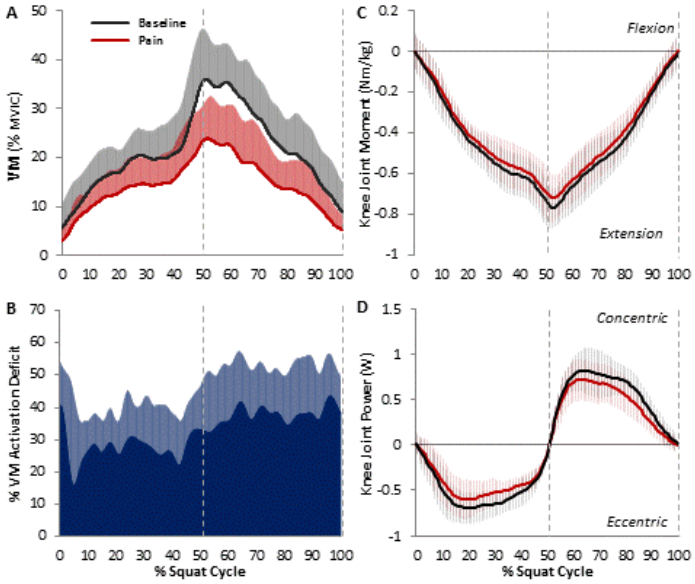
[1]University of Ottawa, Ottawa, Canada, [2]University of Copenhagen, Copenhagen , Denmark

Introduction and Objectives: ACL injured individuals typically experience severe deficits in voluntary knee extensor muscle strength, which is thought to be a main contributor to decreased stability and self-perceived functionality [1,2]. Since the average time injured individuals participate in studies can range from 3 months – many years post-injury [2,3], results may be confounded by compensation strategies; thus, the simulation of injury-like conditions may provide more valuable insight on the effect of muscle weakness to joint stability. The aim of this study was to evaluate changes in muscle activation and joint moments with experimentally reduced quadriceps muscle function during squatting. This is achieved with intra-muscular injections of hypertonic saline, causing a perception of pain and a centrally mediated reduction in muscle activation [4]. Similar to Henriksen et al. [5], we propose that intramuscular hypertonic saline injections into the vastus medialis (VM) will cause a reduction in activation and knee extensor moments. Compensation for this deficit will be observed in the contralateral limb, evidenced by increased knee extensor moment.

Methods: 22 young healthy adults participated in this study. Each subject was tested on 2 days separated by 1 week. During a test day, one type of intra-muscular saline solution (either a hypertonic-pain inducing or isotonic-sham) was injected into VM of the dominant leg. Subjects performed 2 sets of 20 squats during 2 conditions: baseline and during experimental pain. Kinematics, kinetics and surface electromyography of 10 muscles of the dominant leg were recorded. Squats cycles were time normalized to 100% with ascent and descent phases determined by peak knee flexion angles. EMG was processed to a linear envelope and each muscle's activation was integrated for the descent and ascent phases. Between condition differences in muscle activation, peak knee joint angles, moments, and power were tested with Wilcoxon Signed Rank Tests (α=0.05).

Results: Results of 7 subjects (4 males, 3 females) from the hypertonic session are presented. Time to peak knee joint angle and joint flexion and extension velocities did not significantly differ between conditions (T-test $p > 0.05$). There was a significant reduction in knee flexion angles of both legs, and knee extension moment and power of the test leg (Fig C and D). VM had significant reduction in integrated muscle activation during both descent and ascent phases (Fig A). Peak VM activation levels were reduced by an average of 43% (Fig B). During the ascent phase, a significant reduction in integrated vastus lateralis (VL) and biceps femoris (BF) was also observed.

Figure:



Caption: Group mean and standard deviation over entire squat cycle of: A) VM activation normalized to maximum voluntary isometric contraction (%MVIC), B) Percent (%) VM activation deficit (Baseline-Pain/Baseline*100), C) Knee joint flexion-extension moment (Nm/kg), and D) Knee joint extensor power (W).

Conclusion: This study sought to evaluate neuromuscular compensation strategies to experimentally induced muscle pain, resulting in voluntary muscle inhibition, during squatting. The hypertonic saline injections to VM caused a reduction in voluntary muscle activation, thus reducing knee extensor moments and power. Compensation for this deficit was thought to occur in the contralateral limb; however, this was not the case. Further investigation of the hip and ankle joint contributions is required. Participants with ACL deficiency commonly display increased activation of antagonistic hamstrings and gastrocnemius during functional activities[2,3]. Interestingly, no compensation strategies, as evidenced by increased activations of adjacent muscles, were observed. Rather, VL and BF were reduced ascent. Although it is unlikely to return to pre-injury activity levels, ACL deficient subject's functional stability increases over time [6]. Perhaps the lack of an acute response to muscle weakness is a main contributor to the extreme functional instability immediately after injury? Differences observed between ACL deficient and controls may rather be indicative of rehabilitation effects or chronic adaptations. However, further research on muscle weakness and its effect on knee joint stability immediately after injury are warranted.

Rehabilitation

SS-0054

SMART MONITORING OF KNEE RANGE OF MOTION AND ACTIVITY TYPE FOR KNEE REHABILITATION.

Enrica Papi [1,*] Margarita Kotti [1] Irina Spulber [1] Pantelis Georgiou [1] Alison McGregor [1]

[1] Imperial College Lodon, London, United Kingdom

Introduction and Objectives: The goal of rehabilitation in patients suffering from knee osteoarthritis is to improve knee function, minimize pain and mitigate further disease progression. The beneficial effect of rehabilitative interventions, however, is often lost due to poor compliance coupled with low levels of physical activity. The use of wearable technology to deliver rehabilitation could increase the availability and accessibility to treatment for patient populations [1]. Furthermore, the richness of information that can be acquired over an extended period of time could inform treatment for individualised and targeted interventions and, motivate patients using markers of performance. To comply with patients' preferences of unobtrusiveness and discreetness, a flexible conductive sensor unit was developed that can be integrated into clothing to create a wearable system. The aim of this study was to assess the reliability of the wearable system in monitoring the knee range of motion and its ability to classify activities of daily living.

Methods: The sensor unit consists of a conductive flexible polymeric composite material cut into a thin strip (0.02x50x100mm). This was secured to a pair of commercially available leggings to coincide with the anterior aspect of the right knee. A sensing node with embedded analogue interface circuitry for the sensor and hosting a Bluetooth module, was used to wirelessly acquire data. A data set was collected from 12 healthy adults (Age 27±5 years, Height 1.7±0.1 m, Body Mass 66±12 kg), tested twice, while wearing the smart leggings and performing four different activities: walking, running, stair ascent/descent. Data were acquired at 122 Hz and filtered with a 4^{th} order Butterworth filter with 10Hz cut-off frequency. The sensor output range was evaluated as surrogate of knee sagittal range of motion and its test-retest reliability assessed by mean of intra-class correlation coefficient. A decision classification tree algorithm, using a splitting Gini's index, was applied for classification of the activities performed. The features used in the classifier were obtained from a power spectral density analysis of the signal output: median frequency, total power of the spectrum, and peak frequency. The data set was split into training and testing subsets with a ratio of 80:20.

Results: Sensor output time varying waveforms resemble typical knee sagittal kinematics curves. Repetitive patterns were obtained among participants in the sensor output range reflecting the knee sagittal range of motion expected for the activities performed. High reliability (ICC >0.8) was found amongst all participants. The prediction accuracy achieved with the classifier developed was as high as 89.7%.

Conclusion: The results demonstrate the overall system performance in estimating knee range of motion and activity performed. The system consisting of a flexible sensor unit interfaced with a wireless node allowed for continuous and reliable monitoring of the knee movement in unconstrained environments. Good activity discrimination was achieved via a simple classifier employing spectral features of the signal output. The ability of measuring knee range of motion in the context of the activity performed represents an advantage of the system proposed over available technology. Measuring joint function unobtrusively outside a laboratory setting in fact still represents a challenge. Objective data on mobility

function in real life environments could support the management of knee OA enhancing the clinical benefits of rehabilitation.

The reliability of the wearable system has been demonstrated. Further testing will be conducted considering more tasks, involving an osteoarthritis population and to translate sensor output to degrees quantities. The use of other classification approaches will be explored to enhance the activity recognition accuracy. Finally a feedback tool will be developed to report the information to clinicians and patients.

ENDPOINT MOBILITY IN BIMANUAL MANIPULATION: INSIGHTS FROM GOLF BALL STRIKING

Fredrik Tinmark [1 2,*] Anton Arndt [1 2] Maria Ekblom [1 3] John Hellström [4] Kjartan Halvorsen [5]

[1]Biomechanics and Motor Control Laboratory, GIH - The Swedish School of Sport and Health Sciences, [2]Department of CLINTEC, [3]Department of Neuroscience, Karolinska Institutet, Stockholm, [4]The School of Health and Medical Sciences, Örebro University, Örebro, [5]Department of Information Technology, Uppsala University, Uppsala, Sweden

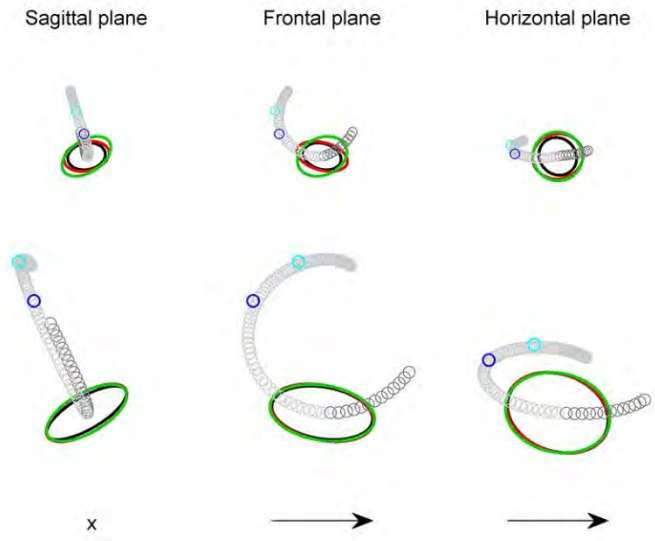
Introduction and Objectives: The possibility of modulating the inertia (and mobility), stiffness and damping of the endpoint/end-link is a feature of redundant manipulators such as the human arm [1]. Modulation of stiffness and damping is made possible by co-activation of antagonists. Endpoint mobility (EP mobility) represents the inertial behaviour of the manipulator, and is the inverse of the inertia tensor for the endpoint [1]. Recent work suggest that human subjects are able to predict EP mobility and use these predictions to influence movement choice [2,3]. Although the concept of mobility may be used to reveal strategies of the motor control system, the experimental condition has thus far involved one upper limb only. In bimanual manipulation tasks, modulation of EP mobility is made possible by changing the configuration of not only one: but two upper limbs. Here, we attempt to gain insight into the modulation of EP mobility in bimanual manipulation using golf as model. We hypothesized that the upper limbs in golf ball striking collaborate to promote movement parallel to endpoint path and resist (unwanted) movement in other directions. In addition to test this: we determine how each arm separately and both arms together influence EP mobility; and whether endpoint mobility are dependent upon path length or skill level.

Methods: Ten male professional golf players and 10 amateurs with an intermediate skill level participated. Spatiotemporal data were collected using a Polhemus Liberty electromagnetic tracking system with a sampling frequency of 120 Hz. The experimental task consisted of striking golf balls at slow, medium and fast endpoint speeds to promote the regulation of path length. EP mobility was calculated for 2 endpoints (grip center and clubhead) and for 3 different models corresponding to: left arm + club; right arm + club; and left arm + right arm + club. The model of each arm used 6 DOFs for defining the glenohumeral joint, 2 DOFs for the elbow, and 2 DOFs for the wrist. The connection between hand and club was assumed rigid. For calculating EP mobility, methods presented by Halvorsen et al. [4] were employed. Digitized anatomical landmarks were used to define segment lengths, orientation of local coordinate frames and joint centers. Segment inertia parameters were obtained from de Leva [5]. Statistical analyses were performed using repeated measures ANOVAs and Tukey HSD tests. Significance level was set at $P < 0.05$.

Results: The major axis of the EP mobility ellipsoid (model including both left and right arm) was not aligned with endpoint path for midhands but this was the case for the clubhead. Statistical analysis revealed that 3D angles between the major axis of the EP mobility ellipsoid and movement direction for the clubhead were less than 45° (8-18°) irrespective of group, model and test condition. Projections of EP mobility ellipsoids for both groups combined at the fast test condition are illustrated in Figure 1 and are representative also for the slow and medium test conditions. Note that endpoint path increased from slow (blue circle) to medium (light blue circle) and to fast (grey circles) endpoint speeds.

Moreover, time series data (not shown) revealed that EP mobility varied substantially during movement duration. In line with our hypothesis maximal EP mobility along path and minimal EP mobility normal to path was reached at ball impact, irrespective of group, model and test condition.

Figure:



Caption: Figure 1 - Mean endpoint mobility ellipses and mean endpoint movement paths for the fast test condition. Values for both groups are combined (n = 20). The upper row depicts ellipses and paths for the endpoint – grip center. The middle row depicts the corresponding variables for the endpoint – clubhead. Black ellipses are used for the model including both arms, red ellipses for the left arm model and green ellipses for the right arm model. Endpoint paths are grey before impact and dark grey after impact. Blue and magenta circles refer to start of endpoint paths for slow and medium test conditions, respectively. The bottom row shows target direction.

Conclusion: Redundant mechanisms such as the human arm can be configured in many different ways while performing the same task. The observed alignment of the EP mobility ellipsoid support the notion that intrinsic factors with anisotropy strongly influence configuration choice. The observed alignment and approximately invariant magnitude of EP mobility between test conditions were likely chosen to facilitate endpoint control and to promote endpoint accuracy at ball impact.

IDENTIFYING BODY ROTATION FEATURES DURING THE GOLF SWING USING PRINCIPAL COMPONENT ANALYSIS

Aimee Smith [1 2,*] Jonathan Roberts [1] Steph Forrester [1] Pui Kong [3]

[1]Sports Technology Institute, Loughborough University, Loughborough, [2]Institute of Sport Research, Nanyang Technological University, Singapore, United Kingdom, [3]Physical Education & Sport Science Academic Group, National Institute of Education, Nanyang Technological University, Singapore

Introduction and Objectives: Body rotation has been identified by golf coaches [1] and in the biomechanical literature [2] as a key technical parameter during the golf swing. In particular, X-factor (the difference in axial rotation between upper thorax and pelvis) at top of the backswing and maximum values have been widely linked to measures of performance such as clubhead linear velocity [2]. However, this approach to data analysis results in portions of data being neglected and potentially important information overlooked. Furthermore, previous studies have often analysed differences in body rotation parameters between groups of golfers of different abilities and it is not known the extent to which body rotation varies between golfers of similar abilities. Techniques such as principal component analysis (PCA) can overcome these limitations and has been used to identify unique features in sporting movements [3].

Therefore, the purposes of this study were to use PCA to identify X-factor features throughout a drive in a group of highly skilled golfers and to examine the relationship with clubhead linear velocity.

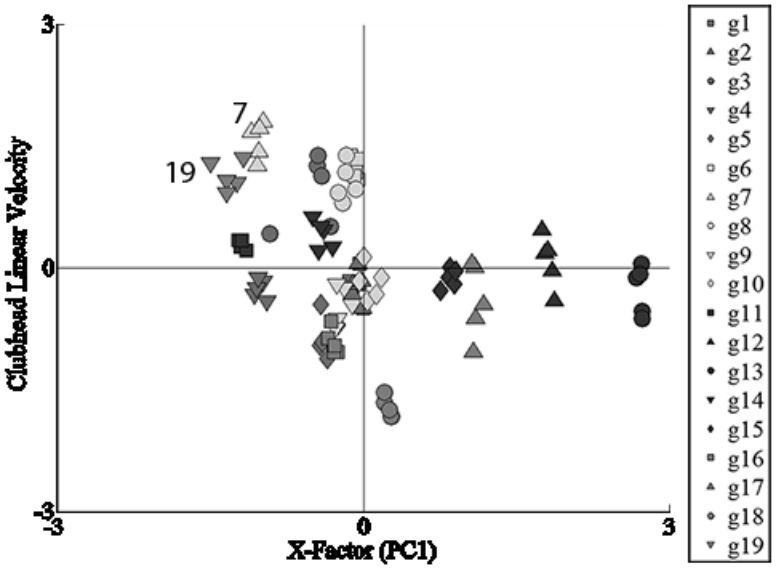
Methods: Whole body kinematics were recorded for 24 low handicap golfers (handicap range +3 to 4; age = 26 ± 7; height 179.5 ± 7.3 cm; weight 79.4 ± 13.1 kg) using a 13 camera Vicon Nexus motion analysis system (250 Hz). The golfers performed ten drives towards a predefined target, from which five trials were analysed. Following data reconstruction and labelling, Visual 3D was used to build the golfer model. Clubhead linear velocity was measured using the TrackMan launch monitor.

X-factor was computed as the axial rotation between the upper thorax and pelvis segments. Each swing was temporally aligned between, takeaway (TA) – top of the backswing (TB), TB – impact (IMP) and IMP – mid-follow through (MidFT). A PCA was performed on X-factor using Matlab. Principal components (PCs) were considered until at least 90% of the variance in the original data was cumulatively explained. Each PC was biomechanically interpreted. The relationship between X-factor PCs and clubhead linear velocity were explored using a two-tailed Spearman's correlation ($p < 0.05$).

Results: The PCA revealed that X-factor required two PCs to explain more than 90% of the variance between golfers. Principal component one (PC1 = 70.5%) explained the difference in X-factor magnitude from mid-backswing to mid-downswing. High negative PC1 scores represented Principal component two (PC2 = 18.9%) largely explained the variance in the rate or range of X-factor from TA to TB and the timing of the change in X-factor near TB. The scatterplot of X-factor PC1 score and clubhead linear velocity displayed a weak trend ($r = -0.33$, $p < 0.05$) (Figure 1). Golfers 7 and 19 recorded the greatest clubhead linear velocities (49.7 $m.s^{-1}$ and 48.6 $m.s^{-1}$ respectively) and had similar X-factor PC1 scores, however they varied greatly in PC2 scores and in X-factor profiles. Hence, this result suggests that the magnitude of X-factor alone cannot fully explain clubhead linear velocity. Brown et al. [4] also suggested that body rotation

parameters alone, in particular, X-factor at key events, could not explain differences in clubhead linear velocity in a group of low handicap female golfers.

Figure:



Caption: Figure 1. Scatterplot of X-factor PC1 scores (i.e. magnitude) against standardised clubhead linear velocity showing weak correlation ($r = -0.33$, $p < 0.05$)

Conclusion: The scatterplot relationship between X-factor PC1 scores and clubhead linear velocity could suggest that a greater magnitude of X-factor, throughout the swing, would lead to increased clubhead linear velocity. However, the weak linear correlation ($r = -0.33$) suggests there could be more explanatory factors than X-factor magnitude which influenced clubhead linear velocity. Future studies should examine the inter-relationship between further biomechanical parameters during the golf swing and examine the relationships to other measures of performance related to accuracy.

SS-0057

THE NEUROMECHANICAL ADAPTATIONS TO ACHILLES TENDINOSIS

Yu-Jen Chang [1,*] Kornelia Kulig [1]

[1]Division of Biokinesiology and Physical Therapy, University of Southern California, Los Angeles, United States

Introduction and Objectives: Human movement is initiated, and executed in hierarchical system. The central nervous system (CNS) plans, initiates, and sends motor command to muscle. The muscle generates force and pulls on the tendon. The tendon modulates muscle force and controls movement of bone. Components lower in the hierarchical system send feedback signals to assist CNS in planning. Therefore, a successful movement relies on the integrity of all components involved in this hierarchical system. If a component lost its integrity, the entire system has to adapt to that deficiency. Degenerated Achilles tendon exhibits lower stiffness and elastic modulus. This is partly due to disorganized collagen bundles manifested on a sonogram as quantifiable changes in the speckle structure. The descending drive from the CNS will be altered to compensate local mechanical deficit. These modulations in CNS motor commands will lead to altered agonist, synergist, and antagonist activation. The purpose of this investigation was to study the effect of tendon degeneration on its mechanical characteristics, neuromechanical behavior of surrounding musculature, and to explore the existence of CNS modulation accompanying tendinosis. We hypothesize that degenerated tendon will lead to diminished tissue mechanical properties, protective muscle activation patterns, and up-regulated descending drive from the CNS (Fig).

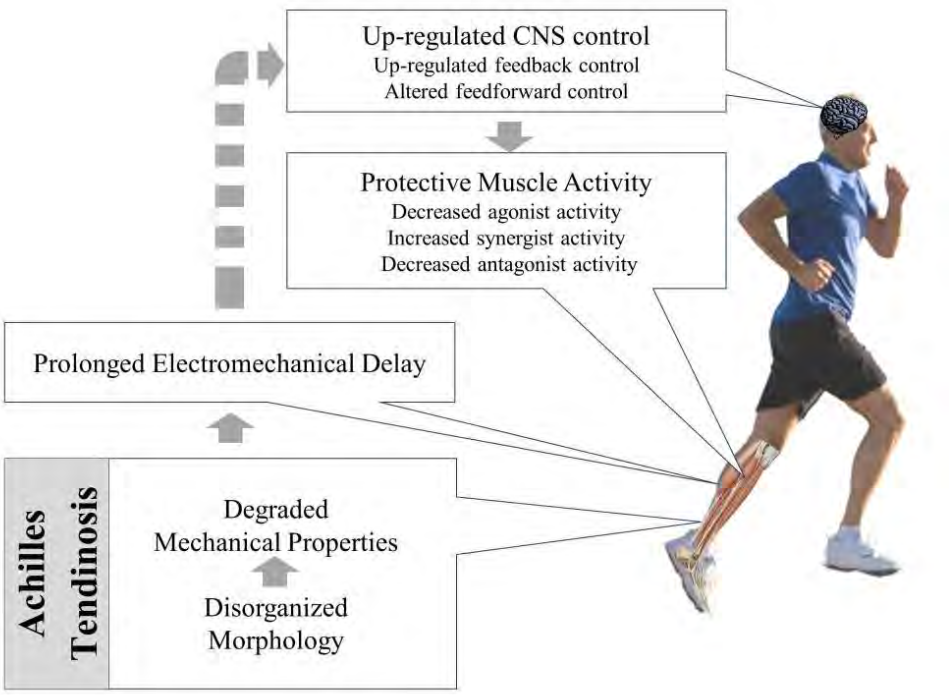
Methods: Nineteen individuals participated (9 with unilateral Achilles tendinosis). Tendinotic subjects were pain free at the time of study. Ultrasound images were acquired on Achilles tendons for morphological analyses. Participants performed ramped maximal voluntary isometric plantarflexion on dynamometer while torque output was recorded. The elongation of tendon was obtained by a combination of ultrasound imaging and motion capture. Evoked H-reflex and V-wave were tested on medial gastrocnemius. Kinetics and EMG data were collected while the subjects performed single-legged hopping. All data were obtained on both limbs of all subjects to allow for side-to-side comparisons.

Eight parameters were derived from the signals collected. 1) Micromorphology: obtained by performing 2D FFT on the sonogram rendering a peak spatial frequency (PSF) variable. 2) Stiffness: determined by the slope on the later 40% of the force-elongation curve obtained from ramped isometric contraction. 3) Electromechanical delay (EMD): time interval between evoked gastrocnemius EMG onset and torque output. 4) Preactivation: time interval between gastrocnemius activation and vertical ground reaction force onset during single legged hopping. 5) Maximal H-reflex: motor neuron excitability at the spinal level. 6) Maximal V-wave: H-reflex under the influence of volitional activation, hence reflects the decending command from higher center. 7) EMG based contribution index (CI). 8) EMG based Co-Contraction Ratio (CCR). Independent sample t-test with Bonferroni correction for multiple comparisons was used to test the impact of Achilles tendinosis on side-to-side discordance of those 8 variables between groups.

Results: Mean side-to-side discordances for control and tendinotic groups are presented in the Table. The independent sample t-test with correction for multiple comparisons showed significantly different side-to-side discordance in all variables. The averaged side-to-side differences in the control group were lower (variable 1, 3, and 6), very similar

(variable 2, 5, 7, and 8), and higher (variable 4) than the Standard Error of Measurement (SEM) (Table). The 2ms difference between legs in Gastrocnemius preactivation was likely due to leg dominance. In contrast, side-to-side differences in the tendinotic subject exceeded the SEM in all variables (Table). This error based analysis further supports the robustness of the findings.

Figure:



Caption: Hypothetical framework of how Achilles tendinosis affects its mechanical properties, muscle-tendon interaction, and CNS modulation.

Conclusion: This study is the first to investigate the impact of a long standing musculoskeletal degenerative disease on multiple levels of neuromuscular system. Strong evidence presented in this study indicates that long standing Achilles tendon degeneration results in a compliant tendon, which affects motor command from CNS, hence imposes changes in the activation and coordination of muscles involved in a locomotive task.

Table:

	Tendinotic (n=9)	Healthy (n=10)	SEM

SS-0058

ON THE USE OF IN VIVO EQUINE DATA TO INFORM A MECHANOSTATISTICAL MODEL OF CORTICAL BONE REMODELLING

Xiaoming Wang [1,*] Helen Davies [2] David Thomas [3] John Clement [3] Raj Das [4] Justin Fernandez [1]

[1]Auckland Bioengineering Institute, University of Auckland, Auckland, New Zealand, [2]Faculty of Veterinary and Agricultural Science, [3]Melbourne Dental School, University of Melbourne, Melbourne, Australia, [4]Dpt. Mechanical Engineering, University of Auckland, Auckland, New Zealand

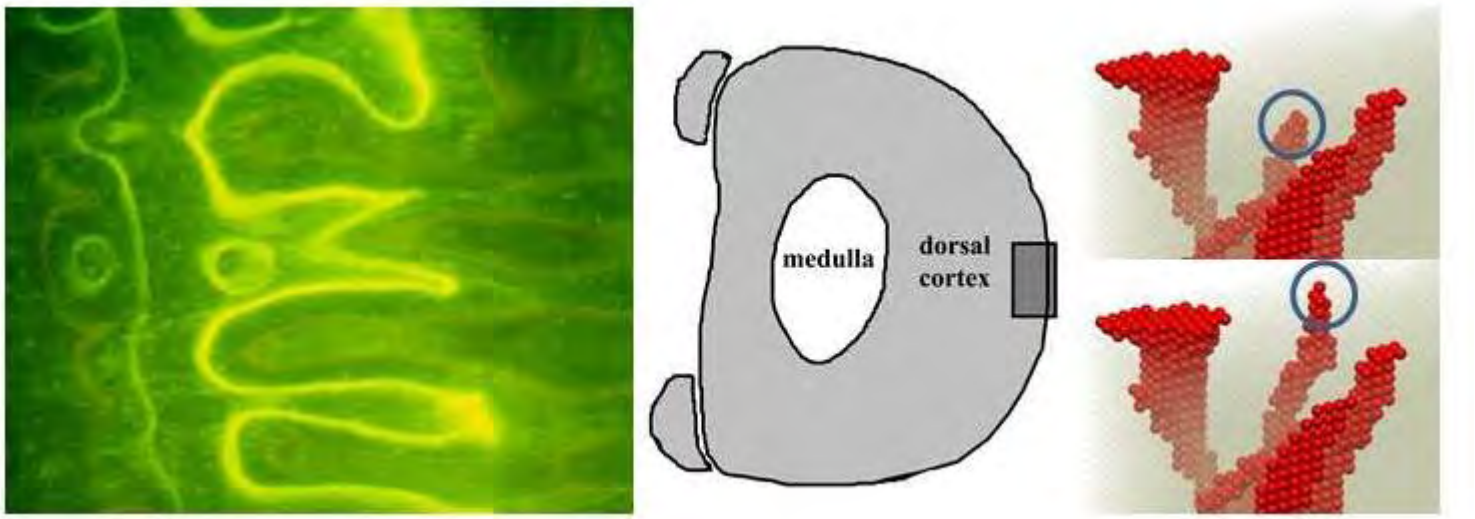
Introduction and Objectives: The equine model is highly suited to investigating human cortical bone behaviour. It has similar haversian structures (unlike murine models); has a fetlock joint (which is similar to the human knee); offers the ability to measure *in vivo* data; and is recommended by the U.S. Federal Drugs Administration (FDA) for comparative joint research, making it a useful animal model for translation of findings to the human. The primary objective of this study was to develop a 3D multiscale equine model of cortical bone behaviour that is informed by measured *in vivo* bone growth rates and bone strain. The secondary objective was to make this model useful in practice by developing a surrogate model to link micro cortical bone behaviour to the whole bone.

Methods: Two bone biopsies taken from the dorsal cortex of the cannon bone of size 4 mm × 3.5 mm × 2 mm were imaged at 5 μm resolution using an Xradia MicroXCT machine. The cortical structures were extracted using a snake algorithm in ITK-SNAP and voxel meshed in Hypermesh for finite element simulation in Abaqus. A cortical bone remodelling algorithm was integrated [1] that used stress stimulus to initiate bone growth and bone density responses according to the well-known 'mechanostat' developed by Frost [2]. Bone remodelling rates were adapted from biostained images taken from the equine cannon bone (Figure 1, left) during controlled periods of exercise (trot, canter, gallop, rest) with known speeds of 4 m s^{-1}, 10 m s^{-1} and 17 m s^{-1} and 0 m s^{-1}, respectively [3]. These were linked to *in vivo* bone strain measured from strain gauges placed on the dorsal cortex (Figure 1, centre) and ranged from 2.6 μm/day (trot) to 12.7 μm/day (gallop). It was observed that horses trained at galloping speeds continued to show significant bone growth during the post-gallop rest period. This motivated the development of a 'fading memory' model, whereby recent loading histories are remembered. A 3D haversian 'cutting-cone' model was included (Figure 1, right) to describe haversian tunnelling and replacement of old and damaged bone. Finally, to make this model useful in practice we trained a surrogate model using partial least squares regression (PLSR) to predict micro-architecture (shape) and homogenised Young's modulus given known whole body loads.

Results: The cortical bone model predicted the fine filamentary tunnelling behaviour that was primarily in the longitudinal direction of bone. Surrounding loads caused the haversian canals to oscillate in shape similar to that observed in synchrotron imaging and micro CT. The haversian canals showed merging behaviour and predicted formation of 'super osteons' [4] and Volkmann canal-like behaviour. This suggests that increase in porosity may be due to merging of haversian canals. The memory effect was shown to generate continued bone growth even after loading stimulus was removed. This was consistent with the data measured from horses that raced at speeds of up to 17 m s^{-1} and continued to show significant *in vivo* bone growth during post-exercise rest. The surrogate model was used to predict bone shape and

Young's modulus for bone not used in the training set. Both shape and homogenised Young's modulus were predicted with average errors of less than 1%.

Figure:



Caption: Figure 1: (Left) biostained image depicting bone growth; (Middle) equine strain gauge data; (Right) micro cortical bone remodelling.

Conclusion: The equine model provided information on *in vivo* bone growth rates and bone strain which was essential for informing computational prediction. The threshold nature that linked remodelling rates to distinct speeds and bone strains supports the use of the classical bone remodelling mechanostat. This is in contrast to other popular models, such as mice models, which do not have haversian canals and present a challenge when controlling their loading environment; and human models, which only presents limited end of life data where the history of loading is unknown.

The prediction ability of the presented surrogate model can inform whole bone strength changes rapidly and accurately without expensive computation. The influence of disease and drug effects at the micro level can also be incorporated and additional synthetic data can be generated for scenarios not experimented on. Translation to the human may be achieved by scaling the equine remodelling rates and strain thresholds, which are generally higher for horses. The results of this study are currently being developed for inclusion in the open-source IUPS Physiome project repository [5] for evaluation and sharing by the scientific community.

PIEZOELECTRICITY MODULATES MECHANICS OF COLLAGEN STRUCTURES

Cameron P. Brown [1,*] Jennifer Boyd [1] Antony Palmer [1] Mick Phillips [2] Charles-Andre Couture [3] Maxime Rivard [3] Philippa Hulley [1] Andrew Price [1] Andreas Ruediger [3] Francois Legare [3] Andrew Carr [1]

[1]NDORMS, [2]Biochemistry, University of Oxford, Oxford, United Kingdom, [3]EMT, INRS, University of Quebec, Varennes, Canada

Introduction and Objectives: Collagen is the most abundant protein in the human body, and plays a dominant role in the functioning of many tissues. The complex hierarchical structure of a collagen fibril provides interesting mechanical, chemical and electrical properties, allowing it to modulate tissue structure and therefore function. Through organisation and interactions on the nanometre to micrometre scales, collagen can work effectively in a wide variety of tissue configurations to provide exceptional mechanical performance, tuned to specialised applications. Here, we examine the role of collagen piezoelectricity in the mechanical function and interactions of collagen structures in soft tissues.

Methods: Human tendon and cartilage samples were snap frozen, cryosectioned and mounted for imaging with scanning probe and interferometric second harmonic generation (ISHG) microscopy. Scanning probe microscopy (Cypher AFM, Asylum Research, High Wycombe) was performed using intermittent-contact mode and lateral piezoresponse force microscopy (PFM). ISHG microscopy was performed as described in Rivard et al. (*1*) This showed the magnitude and sign of the average second order nonlinear optical susceptibility $\chi^{(2)}$ within the focal volume of the laser, which is equivalent to the piezoelectric tensor **d**.

Modelling was undertaken in two stages. First, a model of two interacting fibrils was developed to investigate the effect of the piezoelectric property of collagen. A 2-D implicit model was developed in Abaqus (v 6.11), using piezoelectric elements. Collagen was modelled as linear elastic isotropic (E=200 MPa; (*2*) v=0.35), with the $\mathbf{d}_{15}$ coefficient of the piezoelectric tensor 1 pm/V. The two fibrils of interest were loaded in compression and shear by adjacent external fibrils to simulate a continuous boundary condition. The resulting electrical potential across each fibril was calculated for both similar and opposite polarisations.

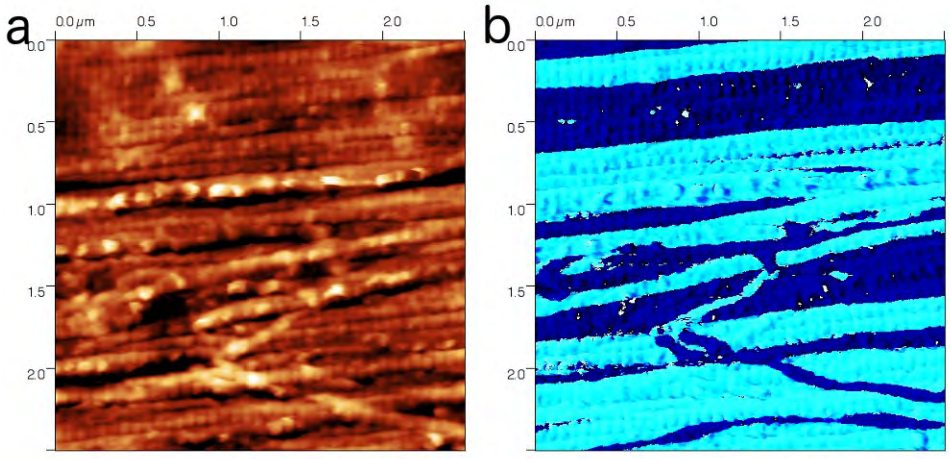
Using the electrostatic attraction or repulsion caused by the piezoelectric response as an input, a second set of models was developed to investigate the effect of piezoelectric domains in the context of multiple fibril interfaces. These used a 2-D explicit solution with 20 fibrils of the same material properties as the two-fibril model.

Results: Using PFM we observed distinct piezoelectric domains on the tens of nanometre to micron scale resulting from the organisation of collagen fibrils (Fig 1). A constant piezoelectric property ($\mathbf{d}_{15}$ coefficient) was measured across each fibril and along its length. The magnitude of the $\mathbf{d}_{15}$ coefficient was approximately 1 pm/V. A dominant polarity was observed in any given region, broken by individual, or small groups of, oppositely polarised fibrils. Similar patterns were observed on a larger scale using ISHG. Domains of positive and negative $\chi^{(2)}$ were maintained over distances of 5 to 50 μm perpendicular to the fibrils, splitting the tissue into domains of predominant collagen fibril polarity.

Increased effective friction at interfaces caused by attractive forces within piezoelectric domains locked the fibrils together, thus increasing storage of elastic energy within each domain prior to the onset of slip. Elastic energy storage was an order of magnitude higher within a domain than at its boundary. When slipping did occur, the high friction within the domains increased the dissipation of energy. The piezoelectric domains in the 20-fibril system increased the frictional dissipation of energy by 30-50%, or 20-25% when normalised against external work. Between the domains, a slip plane with reduced friction was formed due to electrostatic repulsion, providing a mechanism for restructuring under load and relieving local stress.

The increased capacity for energy storage appears to be coupled with fracture resistance. The higher local shear stress environment inside domains will control the location of individual fibril fractures due to the 'sticking' effect. By fracturing within a domain, the attractive forces will more effectively redistribute stress across and along a domain than at an interface, protecting against the formation of a critical fracture cluster. By modulating load sharing, and increasing the effective strength distribution by forming small bundles, catastrophic failure is further suppressed due to blocking effects.

Figure:



Caption: Scanning probe image of tendon showing (a) morphology and (b) piezoelectric phase, indicating piezoelectric domains as light (phase=0) or dark (phase=pi) regions.

Conclusion: Piezoelectric domains formed by collagen organisation have a distinct mechanical role, modulating fibril interactions from the tens of nanometre to the hundreds of micron scales, allowing tissues to tune energy storage, dissipation and damage resistance.

EARLY IN SITU SITE-SPECIFIC CHANGES IN CHONDROCYTE BIOMECHANICAL RESPONSES DUE TO A PARTIAL MENISCECTOMY IN THE LATERAL COMPARTMENT OF THE MATURE RABBIT KNEE JOINT

James Fick [1,*] Ari Ronkainen [1] Andrew Sawatsky [2] Ryan Madden [2] Walter Herzog [2] Rami Korhonen [1]

[1]Department of Applied Physics, University of Eastern Finland, Kuopio, Finland, [2]Facult of Kinesiology, Human Performance Laboratory, University of Calgary, Calgary, Canada

Introduction and Objectives: Although previous research[1,2] was conducted to investigate early changes in rabbit knee joint cartilage at 3 days after a partial meniscectomy (PM)[1,2], there is no study that has focused on early changes associated with *in situ* chondrocyte deformation responses as a result of a PM. Our objective was to determine if early changes in cell biomechanics are present in the superficial layer of knee joint cartilage at 3 days following a PM.

Methods: Ten skeletally mature female New Zealand White rabbits (13 ± 1 month) underwent a PM of the lateral meniscus of a randomly selected knee joint. Each meniscus had ~45% (± 15% standard deviation) of its anterior horn removed and the opposite knee was left intact. Three days after the PM, rabbits were euthanized and the knee joints were harvested. The operated knee joints formed an experimental group (n = 10) and the intact knee joints formed a contralateral (control) group (n = 10). Joint tissues were stained with fluorescein conjugated Dextran at 4°C for 5 hours prior to compression and cell imaging. Samples were mounted with dental cement into a custom built sample holder. The following sites were tested: patella, femoral groove, femoral condyles (medial and lateral) and tibial plateaus (medial and lateral).

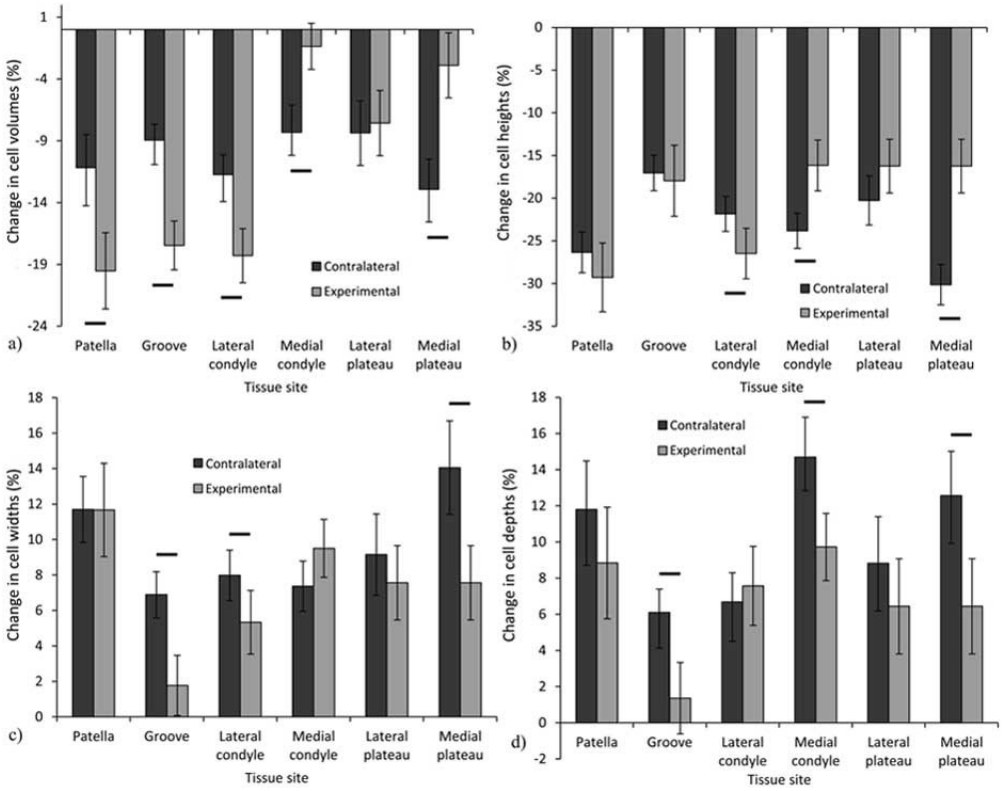
Compression and cell imaging: A custom-designed *in situ* indentation system[3] mounted on to the stage of a confocal laser scanning microscope (Zeiss Inc.) was utilized for testing. A light-transmissible glass indenter (ϕ = 2mm) mounted on the stage with a x40-magnification objective was used to capture optical sections before and after sample compression. Sections were collected at 0.5 μm increments in the optical direction and up to 60 μm depth from the sample surface. A surface pressure (2 MPa) was applied to the samples at an average speed of 10 μm/s [4]. After reaching the desired stress level, the displacement was held constant for 20 minutes to reach an equilibrium state. The samples were then imaged in this compressed state. Cells from each set of optical image sections were identified and had their volumes and dimensions (e.g. cell height, width and depth) determined[4].

Statistics: The percentage change in cell volume, height, width and depth due to cartilage compression was determined at each site and for the experimental and contralateral knees (mean ± 95% confidence interval). Statistical differences between the experimental and contralateral knees were assessed with Student's T-tests ($p < 0.05$).

Results: Cells from both the patellar and femoral groove tissues in the experimental group experienced greater volume decreases ($p < 0.05$) expanding less in their lateral directions relative to cells from the contralateral group ($p < 0.05$ in groove). Cells from the lateral femoral condyle in the experimental group experienced greater volume decreases deforming more in the axial direction (height), expanding less in width relative to cells from the contralateral group ($p < 0.05$). In contrast, cells from the medial femoral condyle and tibial plateau in the experimental group had smaller decreases in volume, deforming less in the axial direction, relative to cells from the contralateral group ($p < 0.05$). This

finding is consistent with earlier experiments conducted on anterior cruciate ligament transected rabbits where patellar chondrocyte volumes decreased less (compared to contralateral patellar cells) and even increased relative to cell volumes before loading[4]. Interestingly, previous work utilizing a PM technique (with sectioning of ligaments) reported proteoglycan loss from knee joint tissues as early as 3 days post-surgery[1,2]. Our preliminary analysis of tissue composition indicates that the greatest proteoglycan loss occurs in medial tibial plateau cartilage (where osteoarthritic-like changes in cell biomechanics were also observed), while no proteoglycan loss occurs in the lateral tibial plateau cartilage (where cell biomechanics remained unaltered). Thus, these biomechanical changes in cell responses between groups from different sites within the knee joint likely reflect localized alterations in tissue composition/structure.

Figure:



Caption: Percentage changes in cell volumes (a), heights (b), widths (c) and depths (d) due to cartilage compression across each site, between groups. Solid black bars denote significant differences ($p < 0.05$); number of cells analyzed from the contralateral group patella and lateral condyle = 90 cells/site, all other remaining sites in each group = 100 cells/site.

Conclusion: Our results demonstrate that biomechanical responses of chondrocytes within the mature rabbit knee joint are altered in a highly site-specific manner at 3 days following a partial meniscectomy of the lateral meniscus.

SS-0061

THE EFFECT OF IMPACT LOAD ON THE MECHANICAL PROPERTIES OF CHONDROCYTES AND ITS ASSOCIATION WITH CYTOSKELETON COMPONENTS

Zhexing Wang [1]Andrea O'Connor [1]Geoff Stevens [1]Peter V.S. Lee [2,*]

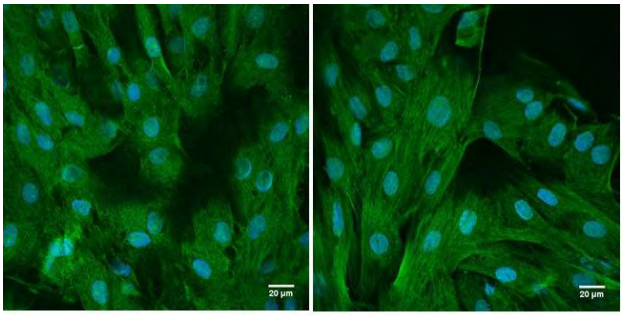
[1]Chemical and Biomolecular Engineering, [2]Mechanical Engineering, University of Melbourne, Melbourne, Australia

Introduction and Objectives: The primary cells within the articular cartilage (AC) are the chondrocytes and these cells are responsible for the maintenance of the extracellular matrix (ECM), which is the weight bearing component in AC. The activities of the AC chondrocytes are closely regulated by the mechanical forces applied to the cells. Therefore any changes to the mechanical properties (e.g. stiffness) of chondrocytes could have a significant effect on how chondrocytes sense physical forces in the AC environment. The objective of this study is to investigate whether the mechanical properties of chondrocytes can be altered by impact damage on articular cartilage, which is a leading cause of post-traumatic osteoarthritis, and its association with the cytoskeleton components within the cells.

Methods: Osteochondral explants of 8mm diameter consisting of cartilage/ subchondral bone from porcine knee joints were subjected with two different impact loads using an instrumented drop tower device. The impact energy density (3.75J/cm^2 and 7.5J/cm^2) was calculated by the potential energy generated by the drop weight and height divided by the explant cross-sectional area. The chondrocytes were then isolated from the explants and the Young's moduli and viscosity of three groups of isolated chondrocytes (non impact, impact at 3.75J/cm^2, impacted at 7.5J/cm^2) were measured using the micropipette aspiration technique[1]. The density of the cytoskeleton in the impacted and non-impacted chondrocytes was analysed by confocal fluorescence microscopy and ImageJ software by staining for F-actin.

Results: Chondrocytes from both 3.75J/cm^2 and 7.5J/cm^2 impacted groups exhibited a significantly higher Young's modulus ($p < 0.05$) and higher apparent viscosity ($p < 0.05$) compared with the control group (Table1). No significant difference was found in these parameters between the specimens impacted at different energies ($p > 0.05$). Moreover, we found the F-actin fluorescence intensity (Fig.1) was significantly different between the impacted and control specimens ($p < 0.05$).

Figure:



Caption: Figure 1. The fluorescence images of chondrocytes from control and impacted specimens

Conclusion: This study investigated how chondrocytes respond to mechanical loadings on a cellular level by utilising the micropipette aspiration technique and F-actin fluorescence intensity analysis. The results showed that the mechanical properties of articular chondrocytes can be altered by impact injury, but an increased impact loading did not have a measurably greater influence. The changes in mechanical properties of post-impact chondrocytes are associated with alterations in their cytoskeleton.

Table:

	Young's modulus (kPa)	Apparent viscosity (Pa· s)	F-actin fluorescence intensity (mean gray value per cell)
Control	0.23±0.022	2.19±1.16	1.24±0.08
3.8 J/cm^2 impacted	0.30 ± 0.045	3.13±1.37	1.7±0.3
7.5 J/cm^2 impacted	0.29 ± 0.032	3.19±1.58

ANISOTROPIC NONLINEAR VISCOELASTIC MODELLING OF TRABECULAR BONE

Krishnagoud Manda [1,*] Robert Wallace [2] Erika Sales [1] Francesc Levrero Florencio [1] Pankaj Pankaj [1]

[1]University of Edinburgh, School of Engineering, Institute of Bioengineering, [2]University of Edinburgh, Department of Orthopaedics , Edinburgh, United Kingdom

Introduction and Objectives: Most musculoskeletal simulations assume that the bone to be linear time-independent elastic material though it has been previously recognized that in reality its mechanical response is time-dependent [1]. It can be hypothesized that the time-dependent behaviour can be related to its micro-architecture, but such relationships are yet to be established. Predicting the time-dependent behaviour of the trabecular bone is a significant step towards better understanding of the mechanical behaviour of the normal and diseased bone including fracture.

In the present work we modelled the trabecular bone with a nonlinear anisotropic viscoelastic material model and developed a numerical recursive iterative algorithm based on implicit stress integration principles and thereby predicted the time-dependent behaviour of the trabecular bone. The model was validated using compressive relaxation experiments on the trabecular bone samples using a loading stage in a micro-CT scanner. The nonlinear constitutive parameters were estimated based on the experimental data.

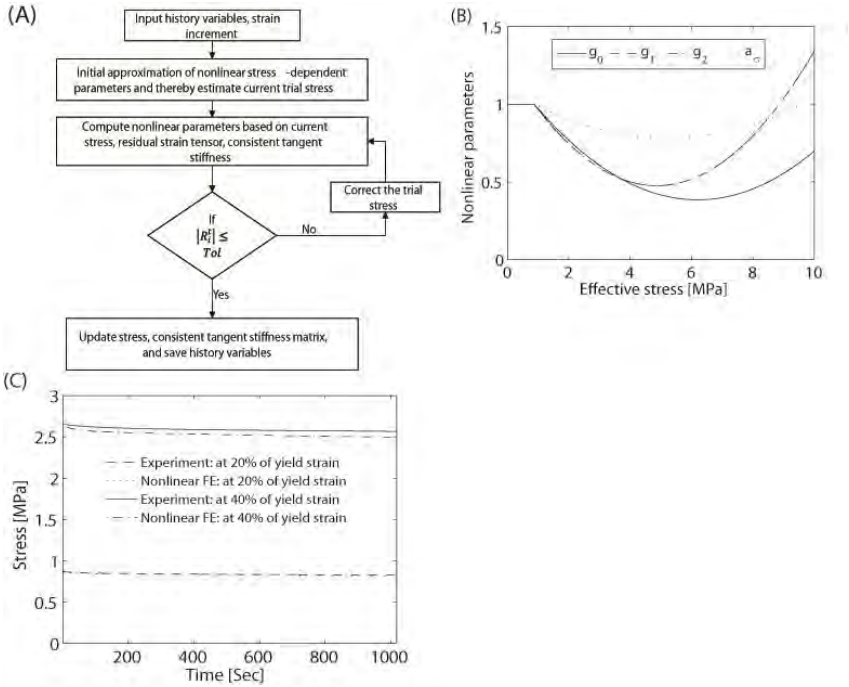
Methods: An implicit recursive iterative numerical algorithm was developed for modelling of the anisotropic time-dependent behaviour of the trabecular bone based on [2,3]. The numerical algorithm was implemented in the context of nonlinear finite element structural analysis as a user defined material subroutine (UMAT) to be used with ABAQUS (Simulia, Dassault Systemes, RI, USA) interface. The subroutine is called at each integration point of FE mesh for each global iteration with the input of state variables and converged values of stress and strain from the previous time step. The strain components are known at the beginning of each time increment and stress and consistent tangent material Jacobian are updated at the end of each time increment. The hereditary integrals are saved as state variables at the end of each increment. The iterative algorithm was presented as a flow chart, Fig. 1(a). The nonlinear stress dependent parameters (g_0,g_1,g_2 and a_σ) were expressed as polynomial function of effective stress based on the experimental data, Fig. 1(b). The transient relaxation and strain compliance functions were represented with Prony series. The anisotropic, nonlinear capabilities of the developed algorithm were verified with analytical examples of triaxial tension/compression and simple shear.

Human femoral heads were harvested and the trabecular bone samples were cored-out to the size of 10.64 mm diameter with constant water irrigation. The ends of the samples were cut parallel using low speed saw to a mean size of 12 (±0.65) mm. The compression tests were performed using a loading stage mounted in a micro-CT Skyscan 1172 (SkyScan, Kontich, Belgium) and simultaneously scanned at intermittent stopping points. The Prony series parameters representing linear viscoelastic model were estimated by nonlinear curve fitting based on the experimental relaxation curves. The observed stress relaxation curves for one of the samples are shown in Fig. 1(c) at two different strain levels equivalent to 20% and 40% of yield strain respectively, ensuring that it remains in the elastic regime. The relaxation behaviour was observed to be linear viscoelastic until strain equivalent to 20% of yield strain, and beyond that the

response varied nonlinearly. The relaxation curve at 20% of yield strain was treated as a master curve and the nonlinear parameters were obtained by shifting this master curve to match with other curves at higher strains using nonlinear curve fitting procedures.

Results: The stress relaxation curves of trabecular bone samples at different strain levels were obtained from series of compressive relaxation experiments and the viscoelastic Prony parameters were determined for each sample. The nonlinear parameters were determined and expressed as a polynomial function of effective stress, Fig. 1(b). The predicted relaxation response from the developed nonlinear viscoelastic model was in good agreement with the experimental data, Fig. 1(c), whereas linear viscoelastic model did not predict the response well and error was around 50%.

Figure:



Caption: Figure 1. (A) Recursive iterative numerical algorithm, (B) Nonlinear stress dependent parameters, (C) Relaxation stress response of a cylindrical trabecular bone sample (diameter = 10.64mm, height = 12.27mm) at two different strain levels.

Conclusion: The time-dependent behaviour of the trabecular bone, observed from the experiments, was significant and the linear viscoelastic models were not sufficient to predict this behaviour. Hence, the more general anisotropic nonlinear viscoelastic material model was developed and was validated with the experiments. The results showed good agreement with the experimental data.

THE FLUID-STRUCTURE MODELLING OF THE HUMAN MITRAL VALVE USING IMMERSED BOUNDARY/FINITE ELEMENT METHOD

Nan Qi [1,*] Hao Gao [1] Xingshuang Ma [2] Colin Berry [3] Boyce Griffith [4] Xiaoyu Luo [1]

[1]School of Mathematics and Statistics, University of Glasgow, Glasgow, United Kingdom, [2]Bioengineering College, University of Chongqing, Chongqing, China, [3]Institute of Cardiovascular and Medical Sciences, University of Glasgow, Glasgow, United Kingdom, [4]Department of Mathematics, University of North Carolina, Chapel Hill, United States

Introduction and Objectives: Dysfunction of the mitral valve (MV) causes significant mortality and remains a major medical problem worldwide. MV has a very complicated anatomical structure. Although there has been significant work on developing computational models of the MV over the past 20 years, due the difficulties associated with both the finite-strain deformational kinematics and fluid-structure interaction (FSI), most MV models that include realistic anatomical geometries and constitutive models consider only the structural mechanics of the valve [2]. In this study, we develop an image-derived patient-specific dynamic model of a human MV using hybrid finite element immersed boundary method (IB/FE), incorporating a FE description of the structural mechanics. This enables us to model FSI while accounting for the nonlinear, anisotropic material response of the MV leaflets.

Methods: The IB/FE approach uses a Lagrangian description of the immersed structure along with an Eulerian finite difference description of viscous incompressible fluid modelled using the incompressible Navier-Stokes equations; interaction between Lagrangian and Eulerian variables is by integral transforms with Dirac delta function kernels [1]. Standard IB methods typically describe the elasticity of the structure using systems of elastic fibers [3]. More recently a version of the IB method that uses elasticity models with FE discretizations has been introduced [4]. Specifically, we use the first Piola-Kirchhoff stress tensor to describe the stresses generated by the immersed structure. It is determined from the passive hyperelastic properties of the leaflets by an invariant-based strain energy functional W. The leaflets of the MV are modelled as an incompressible fibre-reinforced material.

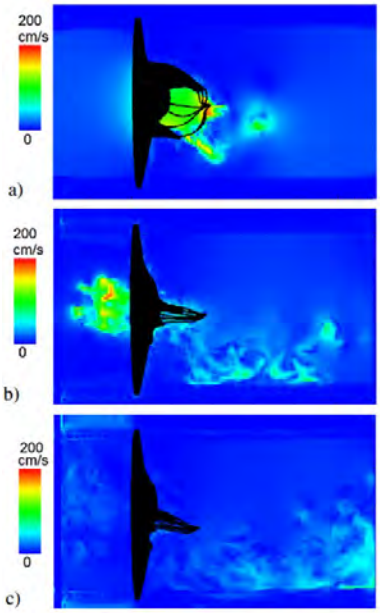
In the simulations, the MV structure is immersed in a 3D fluid box. The valve leaflets, derived from a stack of cardiac magnetic resonance images (MRI), are mounted on a housing and an outer tube that are approximately fixed in place using a penalty method. A typical physiological pressure profile is used in which the pressure waveform is rescaled to match the peak systolic pressure of 150 mmHg of the subject. The simulations employ the open-source IBAMR software framework (https://ibamr.googlecode.com), which provides an adaptive and distributed-memory parallel infrastructure for developing FSI models that use IB method.

Results: The corresponding velocity fields are shown in the Fig.; when the valve is fully opened, just closed and fully loaded at the peak pressure [5]. The valve opens at a driving pressure gradient of around 10 mmHg and we can clearly see a strong jet flow towards the outlet (the left ventricular side). As the MV closes, there is a closing regurgitation across the MV, which is responsible for the first heart sound. The complete closure of the leaflets occurs at a transvalvualar pressure gradient of around 80 mmHg, and then undergoes minor further deformation before reaching the peak transvalvular pressure drop. The opening and closing configurations of the simulated MV qualitatively show good

agreements compared to the corresponding MRI in LVOT view. The flow rate through the valve orifice is also compared, along with the measured flow rate from phase contrast MRI.

The stresses in the anterior leaflet are found to be higher than those in the posterior leaflet and concentrated around the annulus trigons and free edges of the valve leaflets. Those areas are located where the leaflet has the highest curvature. When the MV is fully opened, the fibres of the belly region are stretched, and the stress is higher compared with the trigone regions. Immediate after the MV has closed, the stresses increase in all regions, however, at this point the two trigones experience higher stress levels compared with the belly region.

Figure:



Caption: The in-plane view of the fluid velocity field parallel to the tube longitudinal axis, when the MV is (a) fully opened, (b) just closed and (c) fully loaded at the peak pressure of 150 mmHg.

Conclusion: In this study, we have developed a new human MV model using a hybrid IB/FE approach. This model is a significant step up from our previous work by providing dynamic stress distributions. The model results agree well with the simulated opening and closing leaflet configurations and the flow rate estimated from the MRI measurements. More realistic model is under development by using a more detailed chord structure and patient-specific boundary conditions.

NOVEL METHOD FOR 3D RECONSTRUCTION OF THE CHICK EMBRYO CARDIOVASCULAR ANATOMY FROM NON-INVASIVE ULTRASOUND SCANS FOR LONGITUDINAL STUDIES

Choon Hwai Yap [1,*] Germaine Tan [1] Muhammad Jamil [1] Liang Zhong [2 3]

[1]Biomedical Engineering, National University of Singapore, [2]National Heart Research Institute of Singapore, National Heart Centre Singapore, [3]Duke-NUS Graduate Medical School, National University of Singapore, Singapore, Singapore

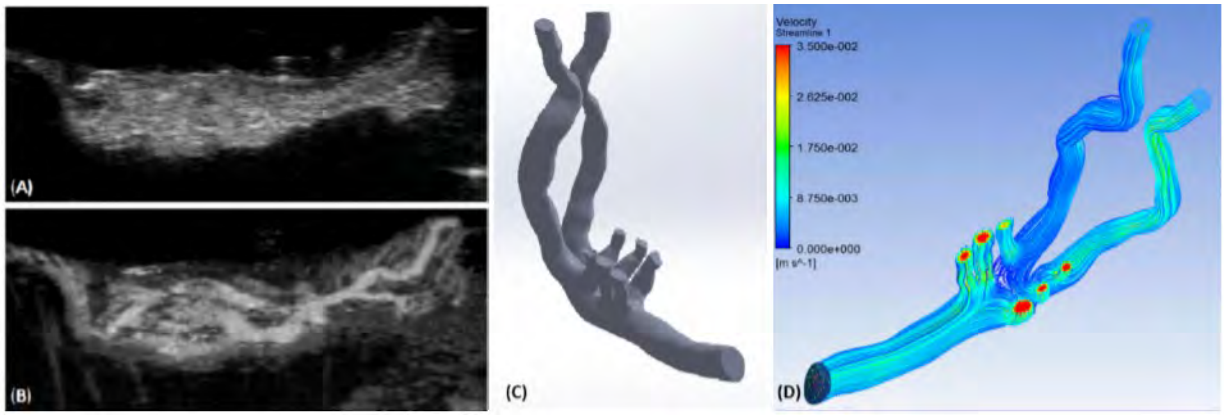
Introduction and Objectives: Congenital cardiovascular defects are the most common type of birth defects, affecting approximately 0.6-1.9% of newborns each year[1]. Recent small animal studies provided evidence that blood flow fluid mechanics may play a role in the pathogenesis of these malformations[2-5]. The imaging of the small animal embryonic cardiovascular anatomy is an important endeavor to support furthering these researches. To date, however, scan techniques are destructive or invasive, rendering it difficult to perform longitudinal studies on the same embryo. In the current study, the aim is to establish such a method to enable serial imaging and 3D reconstruction of cardiovascular anatomy of the chick embryo, based on high-frequency ultrasound. We show that our technique has sufficient resolution to produce geometries for Computational Fluid Dynamics simulations to quantify detailed embryonic cardiovascular fluid mechanics.

Methods: Fertilized eggs were opened at the blunt end to expose the chick embryo, and imaged in 3D over time with high-frequency ultrasound (45MHz), non-invasively. Chick embryos at Hamburger Hamilton stages 21, 25, 27 and 28 were imaged. Motion cancellation algorithms were applied to negate embryonic bodily motion for embryos past the 5th gestation day. Quadratic temporal averaging was performed in order to differentiate blood space from tissue space[6]. The vessels of interest, namely the internal carotid arteries, descending aorta and pharyngeal aortic arches, were obtained by 3D reconstruction through image-based modelling, and the accuracy of the reconstructed model was validated with stereoscopic measurements. Finally, Computational Fluid Dynamics (CFD) simulation using ANSYS Fluent software was used to model fluid flow in the generated construct of a HH27 embryo.

Results: From the raw Cine B-mode images, it was difficult to distinguish between blood and tissue (Fig. 1A), but after taking quadratic mean over time, distinction between the two was clear (Fig. 1B). The motion cancellation algorithm, when applied to the images of embryos past the 5th gestation day, played a significant role in reducing motion artifacts in the image processing. The processed images were successfully stacked and underwent 3D reconstructions of the blood space geometries (Fig. 1C).

CFD simulations show a region of low shear stress and divergent streamlines at the carotid duct, the distal connection between the 3rd and 4th pharyngeal aortic arches[7] (Fig. 1D). We hypothesize that this low shear environment play a role in the natural regression and disappearance of the carotid duct at a later stage (HH28 onwards).

Figure:



Caption: Figure 1: (A) Original UBM still-image of a HH21 embryo. (B) The same image after image processing to highlight blood space. (C) 3D reconstruction of major arteries. (D) CFD simulations of flow in the same arteries.

Conclusion: High frequency ultrasound has the potential of overcoming most limitations presented by the various imaging modalities, being non-invasive and having good scanning depth. We have established a technique for using high frequency ultrasound to obtain 3D anatomic geometry of cardiovascular organs accurately, which can enable downstream CFD analysis. Our technique allows repeated live scans of a single chick embryo, enabling embryo-specific studies of the influence of hemodynamic forces on cardiovascular development.

PARAMETER ESTIMATION OF HUMAN MYOCARDIUM USING IN VIVO CMR

Hao Gao [1,*] Li Cai [2] Colin Berry [3] Xiaoyu Luo [1]

[1]School of Mathematics and Statistics, University of Glasgow, Glasgow, United Kingdom, [2]Northwestern Polytechnical University Xi'an, Xi'an, China, [3]Institute of Cardiovascular & Medical Science, University of Glasgow, Glasgow, United Kingdom

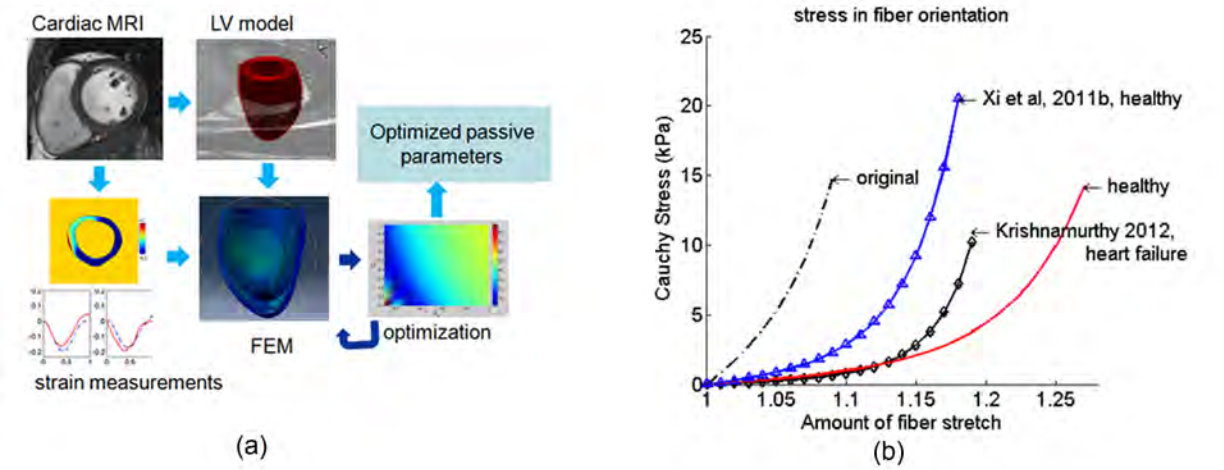
Introduction and Objectives: In general, left ventricular (LV) myocardium is considered as inhomogeneous, non-linearly anisotropic, incompressible, and even time-dependent, with fibre-enforced micro-structure. One of the centre problems in LV modelling is to identify material parameters for the constitutive equations. By employing a structure-based constitutive law [1], which takes into account the complex 3D myofibre architecture of LV myocardium, we tended to identify parameters from in vivo cardiac magnetic resonance (CMR) data.

Methods: CMR was performed on a healthy volunteer. Cine images were used for functional assessment and LV geometry reconstruction. Custom software written using Matlab was used to extract the endocardial and epicardial boundaries at early diastole, when LV pressure is lowest. Hexahedral elements were generated using a linear interpolation from endocardial to epicardial surfaces. A rule-based myocardial fibre generation method was employed to construct the fibre and sheet architecture of the myocardium. The structure-based nonlinear orthotropic constitutive law for passive LV myocardium proposed by Holzapfel and Ogden [1] was used.

Regional circumferential myocardial strain was estimated from early-diastole to end-diastole by using a deformable image registration method from cine images. The LV cavity volume at end-diastole was also calculated from the cine images, and a population-based end-diastolic pressure was assumed (8 mmHg). Material parameters were updated by forming an inverse problem to match the measured regional circumferential strain and LV cavity volume. A sensitivity study showed that there exist close correlations among the material parameters. We therefore adopted a multi-step optimization procedure by reducing the parameter space [2], shown in Figure 1(a).

Results: Myocardial material parameters of the LV model were successfully estimated using the proposed optimization procedure. The simulated regional circumferential strain and LV cavity volume were in good agreement with the measurements from cine images. We also compared the estimated myofibre stress-strain relationship with other studies, although there are necessary discrepancies due to the subject variety and different constitutive laws used, the overall trend of the mechanical response is similar, shown in Figure 1(b).

Figure:



Caption: Figure 1. (a) Schematic illustration of the proposed multi-step optimization procedure; (b) estimated myofibre strain-stress relationship (indicated with 'healthy') and compared with other studies.

Conclusion: In this study, we have demonstrated, for the first time, the feasibility of inversely estimating material parameters in the orthotropic Holzapfel-Ogden constitutive law for passive myocardium by using a multi-step optimization procedure using both strain and pressure-volume data based on in vivo CMR.

CREATING BOUNDARY CONDITIONS FOR NUMERICAL SIMULATIONS OF THE FONTAN CIRCULATION USING HEMODYNAMICS DATA OBTAINED WITH NON-SIMULTANEOUS MULTI-POINT MEASUREMENTS

Masanori Nakamura [1,*] Shinji Goto [1] Keiichi Itatani [2] Shohei Miyazaki [2] Takashi Honda [2] Tadashi Kitamura [2] Tetsuya Horai [2] Masahiro Ishii [3] Kagami Miyaji [2]

[1]Department of Mechanical Engineering, Saitama University, Saitama, [2]Department of Cardiovascular Surgery, [3]Department of Pediatrics, Kitasato University, Sagamihara, Japan

Introduction and Objectives: The Fontan circulation is the final palliative result with a single-ventricle physiology. It has two inlets (superior and inferior vena cava) and two outlets (right and left pulmonary arteries). Hemodynamics in that circulation is influenced by both respiration and heartbeat. Many computational fluid dynamics studies have been implemented so far to better surgery for the Fontan circulation [e.g. 1]. However, adequacy of boundary conditions remains debatable in a sense that the boundary conditions used actually reflect flow fluctuations caused by respiration and heartbeat. Clinically, physiological data are acquired from catheter examinations. However, it is not feasible to implement either simultaneous or synchronized measurements of hemodynamics in the related blood vessels using the catheters. Therefore, it is necessary to establish the way of creating boundary conditions for flow simulations using data measured non-synchronously at multiple locations. This study proposes a method for resynchronizing the measured data for use as the boundary conditions for flow simulations using frequency analyses, and discusses the optimal cut-off frequency to use for differentiating cardiac and respiratory variation in the hemodynamic data in the process of resynchronization.

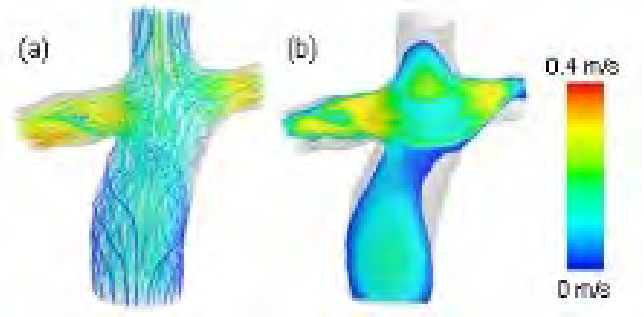
Methods: A Fourier analysis was carried out for pressure and velocity data obtained at four locations, namely, superior and inferior vena cava and left and right pulmonary arteries. After conversion of the data into the frequency domain, a cut-off frequency was placed between two peak spectra which were thought to represent the frequencies of heartbeat and breathing to separate the data affected by heartbeat (cardiac flow) from the ones by breathing (respiratory flow). Then, temporal variations of respiratory and cardiac hemodynamics were separately restored by an inverse Fourier transform, from which representative waveforms of respiratory and cardiac flows were taken. Finally, these representative waveforms were phase-matched in reference to the minimum value of velocity or pressure to synchronize the data obtained at different locations.

Using the synchronized data, we carried out a numerical simulation of the Fontan circulation. A patient was two-year old boy who does not have abnormal collateral circulations and respiratory complications. Flow data were given to the superior and vena cava, while pressure boundary conditions were imposed on the right and left pulmonary arteries. Note that the pressures used for the boundary conditions were corrected, taking account of the characteristic impedance of the Fontan circulation.

Results: From a viewpoint of cyclic repeatability of flow waves, heartbeat effects from respiration effects was optimally separated with the cut-off frequency slightly smaller than the peak frequency of heartbeat effect.

In looking at flow patterns, a remarkable difference was not found in overall flow including velocity and pressure distributions regardless of the cut-off frequency; flow from the superior vena cava and that from the inferior vena cava collided with each other and turned to the left and right pulmonary arteries as exemplified in Fig. 1. A total energy loss during one respiratory cycle in the present geometry showed approximately 3% change for the cut-off frequencies examined. Although the energy loss in the Fontan circulation was quite small (~ 1.6 mJ) compared to that in the whole cardiopulmonary circulation, cumulative energy loss by repeated heart beats would be an indispensable load for a heart, in particular having congenital failure, addressing the importance of properly setting the cut-off frequency to evaluate hemodynamics in the Fontan circulation.

Figure:



Caption: Figure: (a) Streamlines and (b) a velocity contour map at the peak of respiration.

Conclusion: In this study, we propose the way of creating boundary conditions for flow simulations using data measured non-synchronously at multiple locations for the numerical simulation of the Fontan circulation. For separating the cardiac and respiratory flows, it was best to set a cut-off frequency that gave a local minimum in the power spectrum that was slightly smaller than the peak frequency of the heartbeat. Although the overall flow patterns appeared to be similar, the energy loss that is the most important parameter for evaluating the surgery of the Fontan circulation varied with the cut-off frequency.

PREDICTIVE MESOSCALE STRUCTURAL MODELLING OF BONE INFORMED BY MICROSCALE POROELASTIC ANALYSES

Claire C. Villette [1 2,*] Andrew T. M. Phillips [1 2]

[1]Civil and Environmental Engineering, Imperial College London, [2]The Royal British Legion Centre for Blast Injury Studies at Imperial College London, London, United Kingdom

Introduction and Objectives: Bone tissue adaptation is a multi-aspect physiological process driven by interrelated mechanical and biological stimuli [1], which requires the combined activity of several populations of bone cells. Studies suggest that fluid motion in the extracellular space may be involved in cellular mechanosensitivity [2], potentially via the resulting shear stress on the cell walls. In silico studies have implemented these theories in mechanistic models with probant results [3-5]. Phenomenological approaches, based on the empirical relations between mechanical stimulus and bone adaptation are also commonly used. Such approaches are limited in scale and in scope but present tremendous computational efficiency gains.

Previously, the authors developed a mesoscale predictive structural model of the femur using truss and shell elements to represent trabecular and cortical bone respectively, and relying on a phenomenological strain-based bone adaptation algorithm [6,7]. The predicted structure showed good correlation with anatomical observations, with a high computational efficiency. However the use of truss elements was considered as a limitation as only axial strain is considered. In order to introduce a response to bending and shear, the authors considered the use of beam elements, requiring a new formulation of the bone adaptation drivers.

The primary purpose of the study presented here was to isolate phenomenological drivers based on the results of a mechanistic approach, for use in a strain-based bone adaptation algorithm to be used with a beam element representation of trabecular elements in mesoscale structural modelling [6,7].

Methods: Two distinct 2D finite element models of a single trabecula were developed. In one model the trabecula was represented by a single beam element. In the other model, the trabecula was represented by a mesh of poroelastic elements. Each model was subjected to the same selection of uniaxial loading scenarios. 42 load cases were tested, with different angles of load application, varying between 0 and π with respect to vertical, and 3 different load amplitudes.

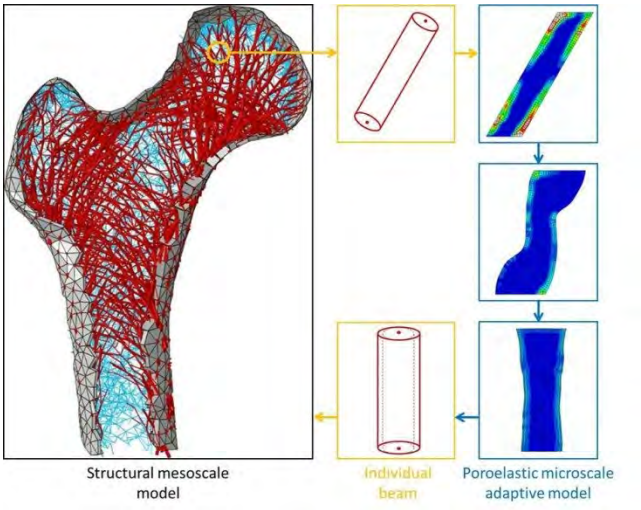
A mechanistic adaptation algorithm was implemented to iteratively remodel the poroelastic trabecula under loading, based on fluid motion velocity through the bone matrix pores. After convergence of this iterative process, the definition parameters of a reoriented beam equivalent to the continuum remodelled poroelastic trabecula were estimated for each load case. The mechanistic adaptation algorithm was initially compared to a published bone adaptation scenario [3].

Figure 1 highlights the relationship between the phenomenological mesoscale and the mechanistic microscale approaches.

Results: Regression analyses were performed based on the initial and converged parameters of the poroelastic model, compared to the initial strain outputs of the single beam model. The ratio of remodelled trabecular thickness over initial thickness was related to the axial strain by a family of linear relationships (R^2>0.998). A fourth order polynomial provided a good fit (R^2>0.98) for the relationship between the ratio of bending strain to axial strain and the change of orientation of the single trabecula axis between initial and remodelled states.

The authors are currently implementing these relations into the phenomenological predictive algorithm for the full mesoscale femur. Challenges include nodal displacement calculation at points of multi beam junction, through weighted average, and generalisation of the derived relationships to the 3D space.

Figure:



Caption: Overview of the combination of modelling techniques used in the study

Conclusion: Phenomenological drivers for predictive mesoscale structural modelling of bone architecture were derived using mechanistic microscale poroelastic analyses. It is expected that the implementation of these relationships into the phenomenological predictive algorithm for the full mesoscale femur will produce a model whose structure and mechanical behaviour are consistent with nature while maintaining a high computational efficiency.

REAL-TIME ESTIMATION OF KNEE JOINT CONTACT FORCES DURING WALKING USING OPENSIM AND A CALIBRATED EMG-DRIVEN NEUROMUSCULOSKELETAL MODEL

Claudio Pizzolato [1,*] Monica Reggiani [2] Luca Modenese [1] David G. Lloyd [1]

[1]Centre for Musculoskeletal Research, Griffith Health Institute, Griffith University, Gold Coast, Australia, [2]Department of Management and Engineering, University of Padua, Vicenza, Italy

Introduction and Objectives: Real-time estimates of joint contact forces and musculotendon unit (MTU) forces can potentially enable rapid patient evaluation and biofeedback for gait retraining. MTU forces can be estimated in real-time using our calibrated electromyography (EMG)-driven neuromusculoskeletal (NMS) model (CEINMS). This uses EMG signals and three-dimensional (3D) joint angles to drive a NMS model that produces instantaneous kinematics and kinetics of individual MTUs [4, 5]. Then, the MTU forces estimated by CEINMS can be used with external joint moments to calculate the knee joint contact forces [3].

While rectified and filtered EMG signals can be directly used as input for CEINMS, joint angles and moments are estimated from motion capture data using inverse kinematics (IK) and inverse dynamics (ID) algorithms in OpenSim [1]. This is time consuming and currently precludes real-time estimation. However, using OpenSim to calculate 3D joint angles is essential to ensure consistency between motion analysis and musculoskeletal models used to estimate MTU kinematics. Furthermore, OpenSim permits personalisation of musculoskeletal models, created from imaging data to reflect an individual's specific anatomy. Therefore, we aimed to i) develop real-time OpenSim IK and ID procedures, ii) integrate these with CEINMS, and iii) compare the real-time estimates of 3D joint angles and moments, and knee joint contact forces to those from offline processing.

Methods: Custom software was written in C++ to read 3D markers trajectories, ground reaction forces (GRF), and EMG signals from a Vicon motion capture system in real-time. GRF, rectified EMG and 3D joint angles were filtered with a 6Hz low pass 4th order Butterworth filter, and processed using OpenSim IK and ID routines, which were modified to run on frame-by-frame. Multiple processing threads were used to increase the data throughput. MTU forces from CEINMS and external joint moments from ID were finally used to calculate medial and lateral knee joint contact forces [3]. CEINMS was calibrated in the background, on additional processor threads, by adjusting selected muscle parameters to reduce the error between joint moments estimated by CEINMS and ID. The real-time outputs were visualised in real-time using a Graphic User Interface (GUI).

From a single subject walking on a treadmill an 8-camera Vicon system collected motion data of a full body marker-set (68 markers) at 100Hz, and GRF and surface EMG signals from 16 muscles of a single leg at 1000Hz. Segmental dimensions and muscle parameters of the OpenSim model were anthropometrically scaled to the subject. The scaled model was then used to compute the set of multidimensional cubic B-splines that characterised the subject MTU kinematics [6] in CEINMS. During the walking trials the real-time software was used to produce and save 3D joint angles and moments from hip, knee, and ankle, and knee joint contact forces. The marker trajectories were also saved for subsequent offline

processing. The real-time and offline pathways were then compared using a modified coefficient of multiple correlation (CMC), which assessed the similarity of waveforms [2].

Results: From 6 consecutive gait cycles we found similar waveforms between the offline and real-time processing for hip, knee and ankle 3D joint angles and moments, with CMCs always greater than 0.95 (Table 1). While the computation time was about 30ms, the use of multiple threads enabled the results to be produced at the same frequency as the marker trajectory data (100Hz). The real-time estimation of knee joint contact forces is now being evaluated.

Conclusion: Our real-time system produced estimates of the 3D joint angles and moments nearly identical to those determined using offline processing. The small variations present were in the filtering and differentiation of 3D joint angles in the offline method that should not affect joint contact forces estimates. This is the first software to calculate, in real-time, 3D joint angles and moments using OpenSim coupled with an individually scaled and calibrated EMG-driven NMS model. Our framework enables real-time estimation MTU and joint contact forces that can be used for gait retraining biofeedback.

Table:

Joint	Joint angle (CMC)	Joint moment (CMC)
Hip FE	0.999	0.981
Hip AA	0.998	0.974
Hip IR	0.998	0.954
Knee FE	0.994	0.960
Knee AA	0.994	0.983
Ankle FE	0.995	0.997

Caption: Table 1: CMC for 3D joint angles and moments between offline and real-time processing from different joints and degrees of freedom (1 subject, 6 gait cycles). FE = flexion extension, AA = adduction abduction, IR = internal rotation.

SS-0072

THE INFLUENCE OF DIFFERENT LOAD CASES IN ORTHOTROPIC BONE ADAPTATION IN THE FEMUR

Diogo M. Geraldes [1,*] Andrew Phillips [2]

[1]Mechanical Engineering, [2]Civil and Environmental Engineering, Imperial College London, London, United Kingdom

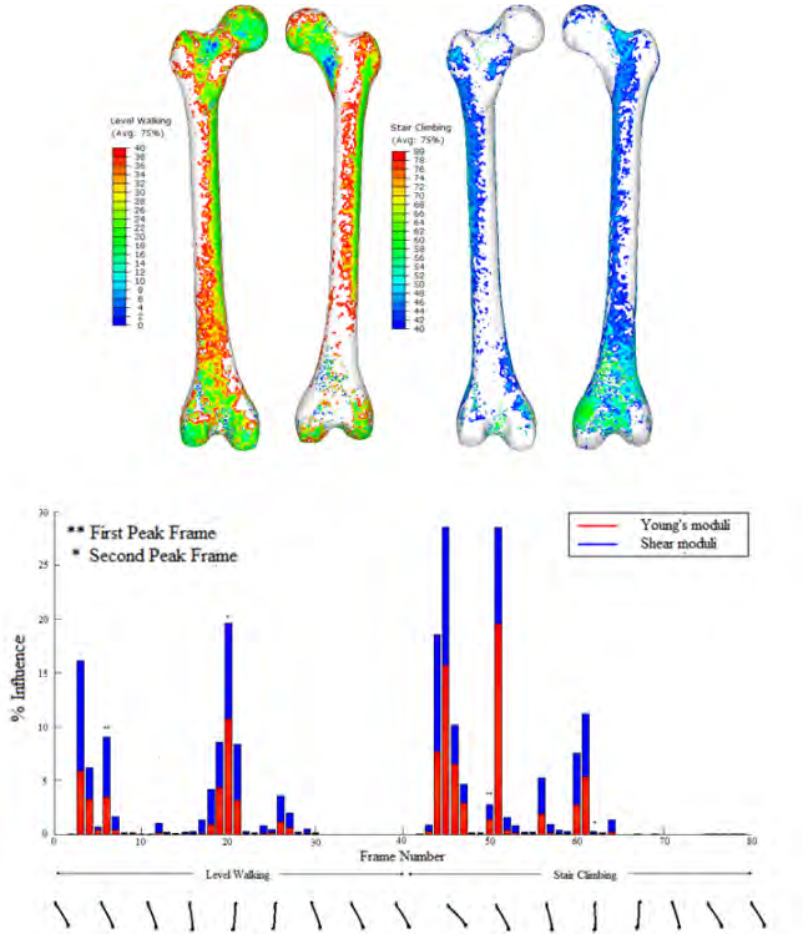
Introduction and Objectives: Osteoporosis is characterised by a reduction in bone mass, degradation of elastic properties and trabecular architecture increasing the risk of femoral neck fractures with an extremely high mortality rate. There is evidence that selected physical activities can increase bone mass density or reduce the rate of bone decay in affected patients [1, 2]. This work describes the importance of considering multiple load cases in bone adaptation and the topological influence of such daily activities on the region-specific material properties of the femur.

Methods: A novel 3D strain-driven orthotropic bone adaptation algorithm was developed and applied to a balanced model of the whole femur utilising physiologically relevant boundary conditions [3]. 80 frames from two different daily activities (40 for level walking and 40 for stair climbing) were considered. At each iteration an envelope containing the maximum driving stimuli was calculated by selecting the strain values for the guiding frame in each element. The guiding frame was defined as the frame in which the highest absolute normal strain value occurred. The orthotropic moduli were updated proportionally to the local principal strains and the material orientations rotated to match the local principal stress orientations. The model ran until the change in material properties and orientation was minimal.

Results: The guiding frames are shown blue to red with red being further through the cycle for each activity modelled, level walking (Figure 1 top, left) and stair climbing (Figure 1 top, right), in order to highlight the topological influence of each of the load cases on the whole femur. The percentage of elements influenced by the different instances modelled in the adaptation process is also depicted (Figure 1, bottom).

It is observed that both load cases contribute to the converged orthotropic material properties. Level walking is shown to influence the regions of the femoral head, inferior part of the femoral neck, greater trochanter, posterior-lateral aspects of the femoral shaft and posterior side of the condylar region. The stimulus produced by the stair climbing activity is shown to be dominant in the mechanical properties of the fracture prone femoral neck region, lesser trochanter, medial aspect of the cortical shaft and anterior side of the distal femur. The material properties of the femoral shaft and the femoral neck seem to be influenced by both activities.

Figure:



Caption: Figure 1 - Topological influence in femur's material properties of different frames for the two activities modelled: level walking (top, left) and stair climbing (top, right); percentage of elements influenced by the different instances modelled in the adaptation process (bottom)

Conclusion: The contribution of multiple frames from both activities to the converged material properties in different regions of the femur is clear. Thus, it is recommended that multiple frames from different activities are considered when predicting bone adaptation, with studies where bone adaptation was predicted by only modelling the peak frames of one of several activities ignoring the significant effect of other frames in influencing bone's material properties.

Stair climbing is highlighted as a potential beneficial non-pharmaceutical preventive intervention to prevent neck of femur fractures resulting from bone deterioration induced by sedentary lifestyles and degenerative diseases.

INTRA-OPERATIVE 3D LASER SCANNING OF TIBIO-FEMORAL JOINTS FOR COMPUTER ASSISTED ORTHOPAEDIC SURGERIES

Shailesh O. Joshi [1,*] Philip Rowe [1]

[1]Biomedical Engineering, University of Strathclyde, Glasgow, United Kingdom

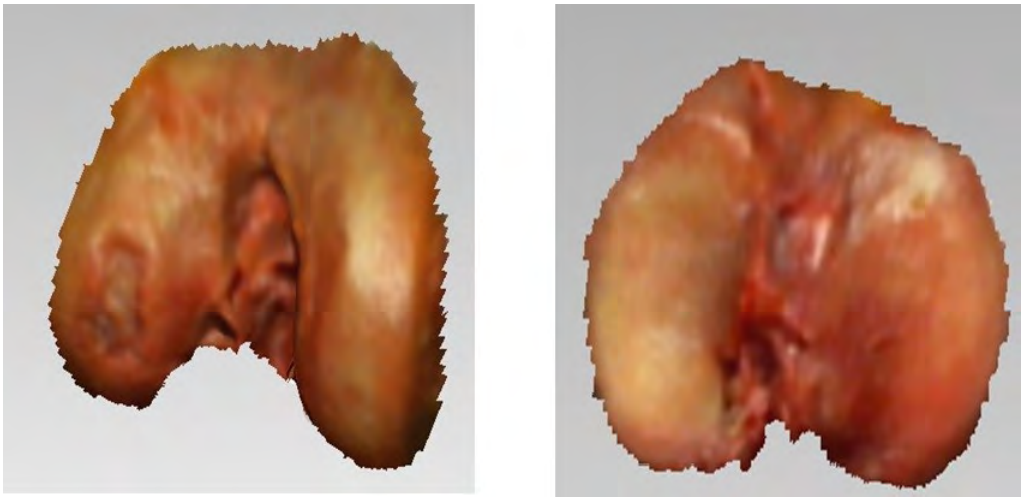
Introduction and Objectives: Over the last decade Computer Assisted Orthopaedic Surgery (CAOS) has emerged particularly in the area of minimally invasive Uni-compartmental Knee Replacement (UKR) surgery. Image registration is an important aspect in all computer assisted surgery including Neurosurgery, Cranio-maxillofacial surgery and Orthopaedics. It is a process of developing a spatial relationship between pre-operative data, such as Computerised Tomography (CT) scans or Magnetic Resonance Imaging (MRI) scans and the physical patient in the operation theatre. For example patient's medial or lateral femoral condyle can be visualised in the pre-operated CT scan as well the same points can be located on the actual patient during surgery using intra-operative sensors or probes. However their spatial correspondence remains unknown until image registration is achieved. Image registration is the process that generates this relationship and allows the surgeon to visualise the 3D pre-operative scan data in-relation to the patient's anatomy in the operating theatre.

Current image registration techniques for Computer Assisted Orthopaedic Surgeries (CAOS) in minimally invasive Uni-compartmental Knee Replacement surgery (UKR) are achieved using a navigated probe and by digitising points on the articulating surface of the knee joint. By using these digitised points a rigid body is formed which is then fitted to the pre-operative scan data using a best fit type minimisation. However, this manual digitisation approach is time consuming and often takes 15-20 minutes and is therefore costly. The rationale for this study was to develop a new, quick, cost effective, contactless, automated registration method which could produce an accurate rigid body model in theatre for registration from the ends of the exposed bones using 3D scans taken intra-operatively by a Laser Displacement Sensor.

Methods: Bespoke and automated 3D laser scanning techniques based on DAVID-Laserscanner were developed and were used to scan surface geometry of the knee joint in 10 cadaveric legs. The lateral compartments of all the knee joints were MRI scanned using 3D FLASH technique and were then segmented using Mimics 12.01 to generate 3D models of the articular cartilages. All the samples were then intra-operatively 3D Laser scanned using a tailored automated technique. The scanning modules were mounted on two different positioner assemblies; A six degrees of freedom haptic robotic arm manufactured by MAKO Surgicals and a customized assembly constructed using aluminium extrusion plates. In addition each sample was scanned through two different incisions; UKA of 9 cm and TKA of 18 cm. The 3D Laser scans were then registered with the corresponding MRI models in the robust digital image software package, Geomagic Qualify®. Average absolute errors between the reference MRI model and the test laser scans were evaluated using Iterative closest point, ICP algorithm. Effects of the independent variables; two setups, two incisions and two surfaces (tibia and femur) on AAE were investigated using three way repeated measures ANOVA. In addition individual effects of the independent variables on the AAE were studied using paired t-test.

Results: Average of the AAE for tibial articular cartilage surfaces ranged from 0.19 mm to 0.26 mm with its standard deviation ranging between 0.30 mm to 0.39 mm. Average of the AAE for femoral cartilage surfaces varied between 0.24 mm to 0.30 mm with a standard deviation between 0.37 mm and 0.49 mm. Repeated measures ANOVA suggested no statistically significant difference ($p>0.05$) between the types of setup used to acquire scans. AAE with TKA incisions was significantly higher than UKA incisions ($p<0.05$), whereas AAE on the femoral condylar surfaces were significantly higher ($p<0.05$) than the tibial condylar surfaces. There was no interaction effect present between the independent variables ($p>0.05$). The effects of the independent variables were confirmed by paired t-test which showed the similar pattern as that of the repeated measures ANOVA.

Figure:



Caption: Textured 3D laser scans of the femoral and tibial condyles of the cadaveric knee joints acquired intra-operatively using developed 3D laser scanning system

Conclusion: We have demonstrated the feasibility of using a novel laser scanning technique where complete 3D models of the tibio-femoral joint in theatre along with their surface texture can be developed which can be registered with the pre-operative scan. The overall time for scanning, post-processing and the registration requires less than 5 minutes and is a non-invasive, cost-efficient approach.

This study has provided proof of concept for a new automated shape acquisition technique with the potential for providing an assessment of the articular cartilage integrity during lower limb arthroplasty.

AUGMENTED REALITY: SHOWING THE WAY IN ORTHOPAEDIC SURGERY

Nicholas Smith [1,*] Philip Riches [1] Vladimir Stankovic [2]

[1]Biomedical Engineering, [2]Electronic and Electrical Engineering, University of Strathclyde, Glasgow, United Kingdom

Introduction and Objectives: Computer Assisted Orthopaedic Surgery (CAOS) techniques are increasingly being applied to the challenge of ensuring accurate implant positioning during Unicondylar Knee Arthroplasty (UKA). Both commercial systems in this field use bulky infrared stereoscopic tracking systems, that restrict patient access, and standard monitors that divide the surgeon's attention away from the patient.

We present a comparison of two prototype CAOS systems which utilise significantly smaller tracking systems and provide surgical guidance through Augmented Reality (AR). AR mixes both real and virtual imagery to offer a non-intrusive and intuitive form of guidance.

Methods: Both systems are based upon six degrees of freedom tracking of fiducial markers using visible spectrum Microsoft Lifecam Studio web cameras, developed under the OpenCV library. The live video used for tracking is augmented in real-time with virtual elements, such as CT models and alignment guides, by a modern OpenGL engine. Passive control is provided by coloured resection models while additional active control is achieved through speed control of the cutting burr.

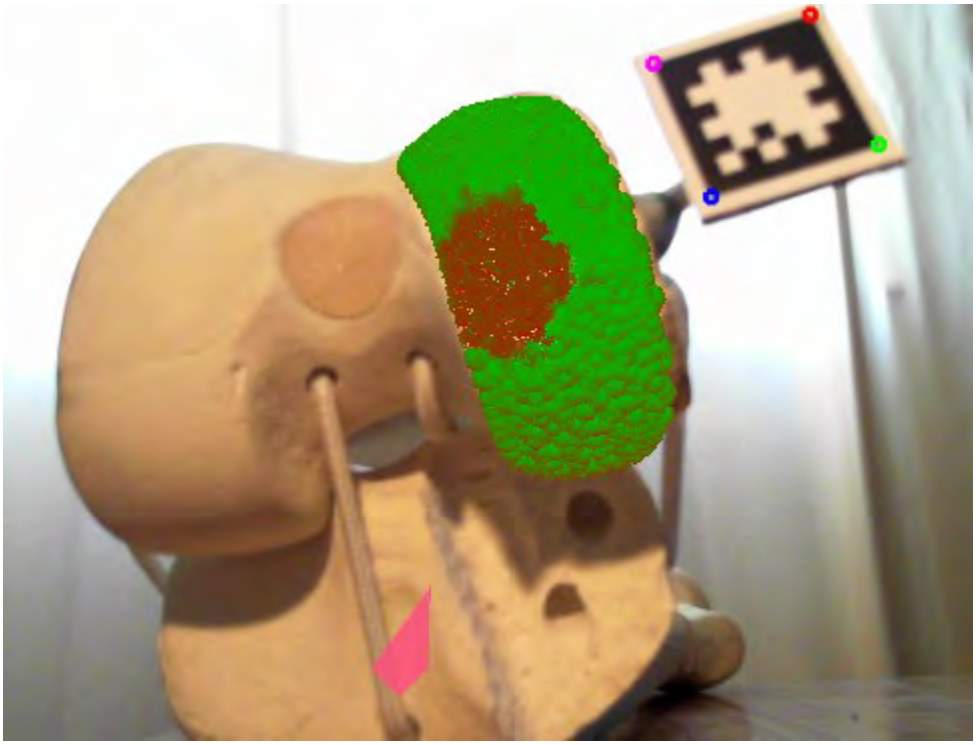
The systems differ in their tracking and display systems. The first system uses a tool-mounted monoscopic camera with the augmented video displayed on a standard monitor. The second system uses a head-mounted stereoscopic camera and a head mounted display (HMD).

The accuracy of both systems was determined by probing 108 known points on a 110x110x50 mm geometry. System latency was also measured, as the time delay between video capture and display of the final augmented frame. Finally the practicality, comfort and intuitiveness of guidance were gauged through user feedback.

Results: The monoscopic and stereoscopic systems produced an accuracy of 1.5±0.3 and 2.1±0.6 mm, respectively. However, the validity of these results is questionable as it was found the test points were inaccurate, particularly in the z axis. The monoscopic system presented an average latency of 263±55 ms compared to 293±15 ms for the stereoscopic system.

Both systems rated well for intuitiveness, with the natural view and 3D display of the stereoscopic system making some instructions clearer. The monoscopic system offered superior comfort. However, tasks such as hip centre location, which required two hands and tracking of multiple markers, were more practical with the stereoscopic system.

Figure:



Conclusion: Due to the inaccuracies of the current target a new 3D printed target is being produced with sub-50 μm accuracy. Based on the results currently available, however, both systems produced accuracies outwith the desired sub-millimetre target. It is felt that this should be reached with several basic modifications. With the advent of USB3.0 cameras, higher resolution images may be streamed at high frame rates. This will allow more accurate marker detection and should therefore improve pose estimation. Additionally, all experiments were performed using small 20 mm markers. Larger markers would provide more data points for detection and a wider point base for pose estimation, both of which offer a potential accuracy boost.

Both systems produced latencies which were not readily perceivable to the user. This is particularly important for the HMD of the stereoscopic system, where large latencies may induce ‘simulator sickness’.

It is felt that the hands-free and natural view offered by the stereoscopic system makes it the superior technology, particularly for use in a surgical environment. This is despite the inherent reduced accuracy resulting from tool to target tracking requiring an additional marker compared to the monoscopic system. If the desired accuracy is achieved it is hoped that the intuitiveness afforded by the augmented guidance will make the system appealing to healthcare professionals by keeping learning curves to a minimum. This will therefore increase the adoption of CAOS technologies.

IN-VIVO PATELLAR TENDON TRACKING IN NAVIGATED TOTAL KNEE ARTHROPLASTY

Claudio Belvedere [1,*] Andrea Ensini [2] Michele d'Amato [2] Paolo Barbadoro [2] Alberto Leardini [1]

[1] Movement Analysis Laboratory and Functional-Clinical Evaluation of , [2] 1st Orthopaedic and Traumatologic Clinic, Istituto Ortopedico Rizzoli, Bologna, Italy

Introduction and Objectives: The appropriate interaction between Tibio-Femoral (TFJ) and Patello-Femoral Joint (PFJ) surfaces and knee soft tissues control joint function [1,2]. Among these soft tissues, the Patellar Tendon (PT) plays important roles within the extensor apparatus [3]. The efficacy of this mechanism is enhanced by the patellar tracking [3]. Alterations at PFJ affecting normal PT functioning, as in case of Total Knee Arthroplasty (TKA), may results in-vivo in knee instability, pain and TKA failure [1,2].

An anatomy-based PT mapping is essential to assess PT functioning during knee motion [3]. PT fiber mapping and lengthening/slackening, both at the native knee and after TKA, have been investigated using several methodological approaches. Unfortunately, these generally did not allow the acquisition of reliable TFJ and PFJ knee motion data, and did not track PT mapping using robust anatomical references [3].

Among possible tracking devices, current knee navigation systems for TKA enable accurate digitization of single bony landmarks or large articular surfaces [1,2], and have the potentials for tracking also PT data.

The purpose of the present study was to evaluate in-vivo PT length and orientation changes throughout knee flexion as observed during TKA, i.e. at the original joint and after knee replacement; this was achieved via original patellar tracking, and with careful patient-specific anatomy-based mapping of PT fibers.

Methods: Ten patients recruited for TKA were implanted with Triathlon® prosthesis (Stryker®-Orthopaedics, Mahwah, NJ-USA). TKA was performed using a surgical navigation system (Stryker®-Leibinger, Freiburg, Germany; 0.5°/0.5mm accuracy).

Marker clusters were pinned onto the femur and tibia; an light cluster was fixed onto patellar anterior aspect [2]. A pointer tracker was used for system control and landmark digitations; TFJ/PFJ anatomical and articular definitions were according to recommendations [3,4] or recent proposals [1,2]. Series of 3 trials of manually driven flexions in a 0°-140° arc were recorded with the knee intact and after TKA [2].

PT fibers were recruited by point digitization along patella-to-fiber origin together with corresponding insertion on the tibial tuberosity [3]. Point strips were also collected along fibers in known anatomical position [3]. Proximal/distal attachment centroids and strips extremities were assumed as fiber origins and insertions, whose length changes over TFJ flexion were calculated and reported in % of maximum fiber length (Lmax) [3]. Fiber orientation was calculated with respect to the tibial proximo-distal axis of the tibia, both on the frontal and sagittal planes.

Results: Patient-specific PT fiber attachments were successfully accessible to the surgeon and resulted in feasible identification and digitization. Repeatable TFJ and PFJ motion patterns were observed together with PT length and orientation changes, both at intact and implanted knees: at the original knee over TFJ flexion-extension, standard

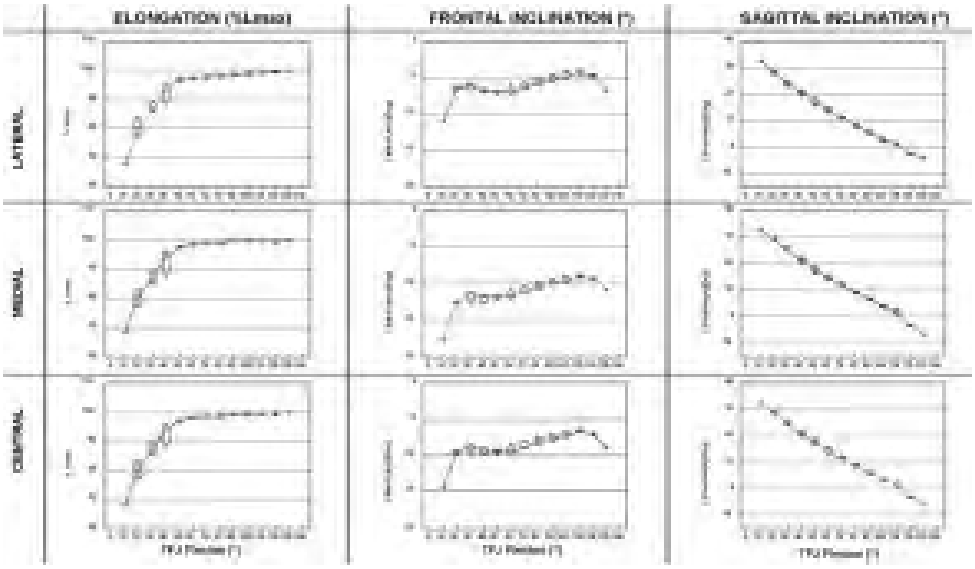
deviation over trials was smaller than 1.0 mm and 1.0° for translations and rotations respectively. Corresponding values over the patients were larger, these being about 7.5 mm and 9.3°.

As for PT lengthening, consistent patterns were observed at the intact knee in the initial 30°±5° of flexion for all fibers (see figure). This was observed also after TKA, although at near full extension all fibers were about 16% tighter than at the intact knee.

As for fiber orientation, all PT fibers at the intact knee were generally laterally and posteriorly tilted of about 12° and 26°, respectively. Further 5°, on average, of lateral and posterior tilt occurred after TKA.

PT length and orientation changes were always significantly correlated to TFJ and PFJ flexion; after TKA, only the frontal plane orientation was also correlated to medio-lateral PFJ translation shift.

Figure:



Caption: Length (elongation in %Lmax) and orientation (frontal and sagittal inclination) changes from a representative patient for the lateral, medial and central PT fibers.

Conclusion: These results show the feasibility in-vivo of patient-specific anatomy-based PT fiber mapping and tracking during TKA. This novel methodology enabled reliable data collection in consistent anatomical-based reference frames. Furthermore, this methodology allows also the possibility to monitor PT functioning intra-operatively during TKA, and this can support the complete restoration of normal knee function.

This study was aimed at contributing to the much controversial knowledge on knee soft tissue recruitment during joint motion. Relevant findings point out the importance of PT fiber recruitment and tracking in TKA.

MUTLI-SOURCE DATABASES, MACHINE LEARNING AND MARKERLESS MOTION CAPTURE: WHY APPLIED SPORTS BIOMECHANICS NEEDS 'BIG DATA'.

Jacqueline Alderson [1,*] Amar A. El-Sallam [2] Andrew Lyttle [3]

[1]Sport Science, Exercise & Health, [2]Computer Science & Software Engineering, University of Western Australia, Crawley, [3]Biomechanics, Western Australian Institute of Sport, Perth , Australia

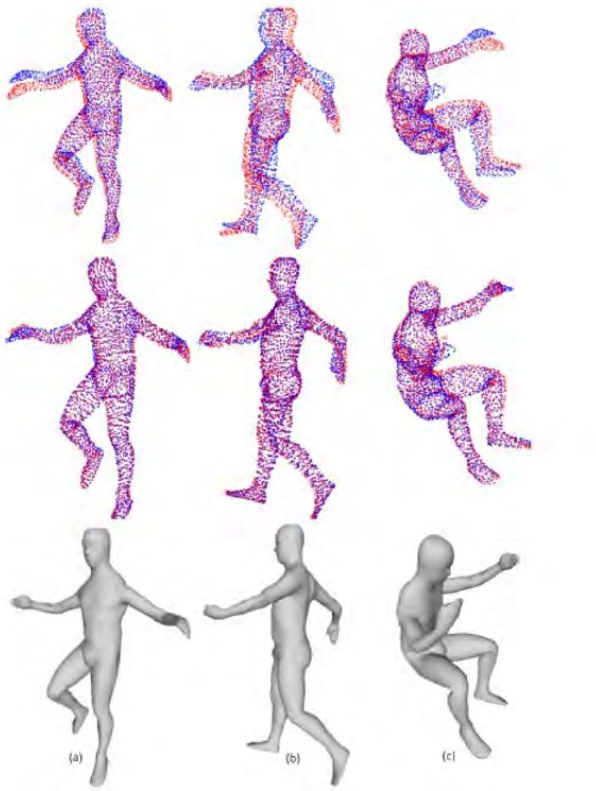
Introduction and Objectives: The sport biomechanist faces a number of unique challenges rarely encountered by those in clinical or lab based biomechanical research that spans research design and data collection, to analysis and reporting. Studies involving athletes are hampered by statistically small cohorts that comprise the entire available 'elite' population and which are regularly criticised for reduced ecological validity given the limitations surrounding collection of high fidelity data during match play. Critically, sporting activities generally occur at high speeds, across multiple planes of motion while utilising all degrees of freedom of the body. Subsequently, the hardware required for the collection of sporting related biomechanical data must be technologically advanced and the collection methodologies appropriate, to accurately and reliably record the unique combination of high speed and complex three-dimensional (3D) motion. The emerging solution to address such hurdles is a 'big data' approach. Though definitional ambiguity pervades the term, the description of [1] who refer to "things one can do at a large scale that cannot be done at a smaller one, to extract new insights or create new forms of value" is particularly relevant when considering its application to the field of sports biomechanics.The ideal 'big data' horizontal framework for biomechanics ideally encompasses multiple input sources such as subject specific motion, medical imaging, musculoskeletal, neurological, physiological and other complementary datasets. For the purposes of this paper we outline a motion capture procedure that fulfils the motion capture component of the framework whereby we markerlessly reconstruct 3D motion from multiple 2D camera views and also merge the dynamically reconstructed 3D visual hull (from the sporting motion) with subject specific 3D body scans.

Methods: This procedure comprises two phases. In an *offline* static phase, a static t-pose of the athlete is acquired using a high resolution 3D video scanner to create a 3D subject specific reference shape. A skeleton consisting of a number of articulated bones and joints is then fitted to the 3D model to create a reference rigged template. In the *online* motion capture phase a number of 2D video cameras are configured and calibrated to capture multi-view videos of the athlete. A background segmentation algorithm is then applied, extracting silhouettes of the athlete and then merged to reconstruct a low fidelity 3D visual hull. A number of optimisation algorithms are then used to extract geometrical data of the visual hull and identify and segment each body part. Global joint kinematics are then estimated by fitting the reference skeleton to the identified body parts of the curve skeleton. Constrained mesh deformation functions are then fed by the global joint kinematics and the resulting error between the surface of deformed model and the visual hull is employed to adapt and refine the accuracy of the initially estimated joint kinematics. A DXA scan is then registered into the final 3D hull to provide subject specific body segment inertial parameters for further application.

Results: The overall mean error between the 3D scan (reference) and the resulting surfaces (absolute mean of the difference between closest points) varied between 12cm to 16cm across three different postures selected for analysis

(Figure 1). This error is reasonable when matching two meshes of 5000 vertices each. Depending on the application or the accuracy, one may run the matching process until a desired error is achieved. GPU implementation could be a faster option for matching and deforming high resolution meshes hence accurate joint kinematics and deformed surfaces can be achieved in a shorter processing time. The overall errors between the aligned reference model and the visual hull confirm that the proposed system is capable of estimating accurate joint kinematics in diverse blind body pose estimation scenarios (i.e. sporting activities).

Figure:



Caption: Top row: VH (blue) and the reference model (red) deformed using the estimated global joint kinematics. Middle row: the deformed reference model after refining the global joint kinematic. Bottom row: 3D meshes of the deformed model.

Conclusion: Like many scientists, sports biomechanists collect copious amounts of numerical data on often small numbers of participants, reduce the data further, to discrete key motion events and run traditional statistical analysis searching for that ever allusive significant difference. A ‘big data’ approach, rather than throwing out this information, implores us to collate our data and our colleagues, all of it, into a shared database, to which we can apply non-traditional analytical techniques to obtain new insights, and importantly manipulate to enhance our current collection, reconstruction and modelling methods.

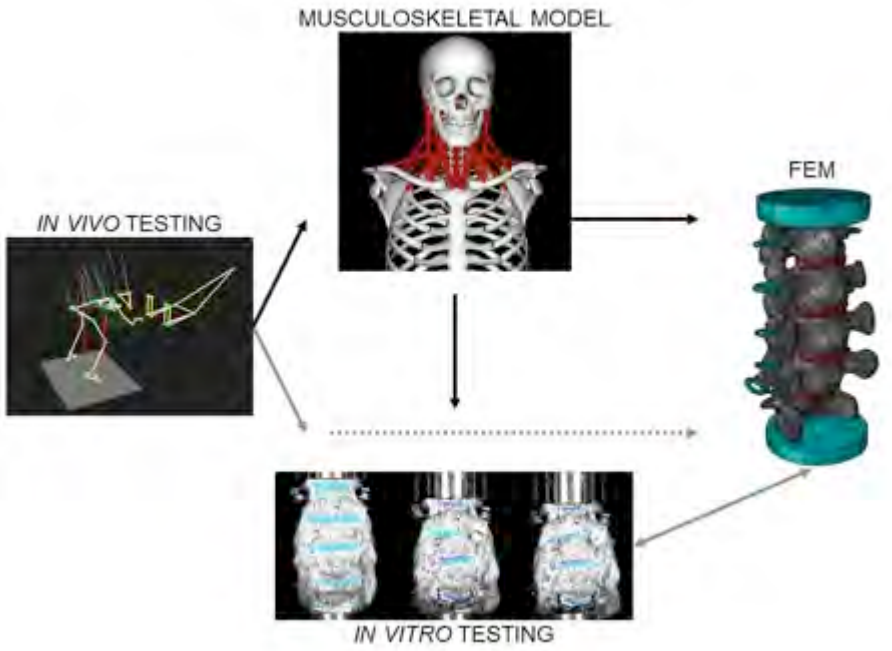
Introduction and Objectives: By generating repetitive high-energy impacts (during the engagement phase) and intense sustained loads (during the sustained push phase) under unstable conditions [1], the Rugby Union scrum has been indicated as a possible risk factor for degenerative spinal injuries for forward players, and has been associated with ~40% of all catastrophic injuries in rugby [2]. However, little is known about how these external loading conditions translate into internal stresses on the spinal structures. The aim of this study was to investigate the biomechanics of cervical spine injury during rugby activities using an integrative approach: in-vivo and in-vitro experiments combined with musculoskeletal modelling.

Methods: Three levels of analysis (Levels 1-3) were integrated. Level 1 was a biomechanical study of scrummaging (N=9 experienced rugby forwards) including motion capture (Oqus, Qualisys, Sweden), force measurement (force plates: Kistler 92876BA, Switzerland; and instrumented scrum machine, [1]), and EMG of neck and trunk muscles (Delsys Trigno, Delsys Inc, USA), carried out to assess the external kinematic and kinetic conditions acting on front row players. The subsequent phases of scrummaging, initial engagament (impact and shock absorption) and sustained push, were observed. Level 2 developed a bespoke musculoskeletal model (Rugby Model, [3]), consisting of 27 anatomical segments, 26 joints, 78 cervical muscles, and 11 torque actuators, in OpenSim (OpenSim 3.2, SimTK, USA). The Rugby Model was driven by the experimental data from Level 1 and was used to estimate joint dynamics, with a specific interest in cervical joint motions and moments. Level 3 performed an in-vitro laboratory experiment to study the injury mechanisms of porcine cervical spines subjected to impact loading conditions similar to those during scrummaging. Load (2 load cells: SLC41/005000, RDP Electronics Ltd, UK) and deformations caused by impacts (mass of 12.86 kg dropped from a height of 250 mm to give an impact velocity of ~2.2 m/s) were measured in a custom made impact rig, and high-speed videos (2 Fastcam SA3, Photron Europe Ltd, UK) were used to investigate the mechanisms of injury through digital image correlation (Vic-3D 2009.1.0, Correlated Solutions Inc, USA).

Results: Results from the biomechanical analysis confirmed that the load acting on the players, especially during the initial engagement, was of a considerable magnitude (~2.8 kN compression force in single-player machine scrummaging). Muscle activation patterns were affected by scrummaging conditions (e.g. machine vs. contested scrummaging; 'Crouch-touch-set' vs. 'Crouch-bind-set' sequence) and phases of the scrum (e.g. pre-engagement vs. engagement vs. sustaned push). For example, the activity of the *erector spinae* was significantly lower (in excess of 65%) in machine scrummaging than in contested scrummaging, and the activation of *sternocleidomastoid* and *upper trapezius* through pre-engagement and engagement were higher in the current 'Crouch-bind-set' technique than in the past 'Crouch-touch-set' one. The computational musculoskeletal model highlighted an antiphase change in movement and loading patterns between the upper and lower cervical levels (i.e. flexion load on the lower vertebrae and extension on the upper vertebrae), and resulted in a "flattening" of the lordotic cervical curve during the impact phase. The present findings do not provide direct evidence for injury mechanisms but seem in line with the patterns of injury that previous authors have described in relation with scrum-related neck traumas [2]. The patterns of strain, load and resulting damages on the cervical structures of the impacted porcine specimens were also similar to those clinically observed in injured players, with the caudal vertebrae (C4-C6) more prone to damages (6 out of 8 specimens) as a consequence of the impact. Fractures resulted from tension in the vertebral bodies due to first order buckling of the cervical spine in extension. The mean maximum load in the cranial and caudal load cells was 5.8±2.0 kN and 6.0±2.1 kN and was reached at a time of 5.1±1.0 ms and 5.6±1.1 ms after impact, respectively.

Figure:



Conclusion: The proposed integrative approach provided novel and more thorough insight into how external loading conditions, muscular activity and body posture affect the internal stresses acting on the cervical spine structures. This understanding will help in elucidating injury factors related to scrummaging and represents a promising framework for future research in the area of impact-related injuries in sports. It will be further developed by including forward dynamics simulations and finite element analysis.

SIMULATION AND PROPHYLACTIC RESEARCH: INTERESTING BEDFELLOWS

Cyril J. Donnelly [1,*] Jeff Reinbolt [2] Gillian Weir [1] Kristin Morgan [3] Jacqueline Alderson [1]

[1]School of Sport Science, Exercise and Health, The University of Western Australia, Perth, Australia, [2]Department of Mechanical, Aerospace and Biomedical Engineering, University of Tennessee, Knoxville , [3]Division of Physical Therapy, University of Kentucky, Lexington, United States

Introduction and Objectives: Modern biomechanics can be dated back to the late 1800's, with the invention of stop-action photography by Eadweard Muybridge [1], which was developed to describe animal motion that could not be observed with the human eye. Later, with the development of the force platform [2], and the application of the Newton-Euler equations of motion, the ability to calculate the forces that cause human motion became possible. With the invention of the programmable computer in the 1950's and the evolution of the silicon processor, our ability to create dynamic simulations has become an apparent reality. Now, over 100 years later, following significant scientific and technological advancements, simulation based research has firmly established its place within the field of biomechanics. The purpose of this manuscript will be to present an applied example of how simulation based research has been used to inform the development of an effective knee injury prevention training protocol.

With the use of the open-source musculoskeletal modelling framework OpenSim, our group has been using simulation based experiments to better understand how specific movements and/or muscle forces during a movement are related to an athlete's lower limb injury risk in sport. Using the residual reduction algorithm, we were able to optimize an athlete's technique to reduce their risk of knee injury during unplanned sidestepping tasks. Through simulation, we showed a causal relationship exists between an athlete's upper body mechanics, knee loading and injury risk during dynamic sporting tasks [3]. We then used computed muscle control to measure and characterize the muscle forces an athlete uses during single-leg landing tasks. Findings from this research showed that the gastrocnemius muscles are used significantly more than the hamstring muscles to stiffen and support the knee during the impact phase of single-leg landing [4]. From these simulation findings and relevant prophylactic research, we have developed and implemented a novel prophylactic training intervention designed to reduce and athlete's risk of knee injury in sport.

Methods: The Australian national field hockey team participated in a novel nine-week body-weight based training intervention. The intended focus of the intervention was to A) improve gluteal muscle strength, increasing an athlete's capacity from attaining 'dynamic-valgus' knee postures, which have been shown to predict anterior cruciate ligament (ACL) injuries in sport [5]. From our group's simulation findings, added foci were to B) improve the dynamic control of the upper body and C) improve the strength of the gastrocnemius muscles. During training, athletes' performed a range of strength, plyometric and balance exercise that continually targeted on or all of the intervention's intended foci. Prior to and following the training intervention, full-body kinematics, lower body kinetics and lower limb muscle activation were collected for 16 athletes during the UWA sidestepping protocol. All experimental methods have been described previously [6, 7].

Results: Following training, athlete's identified as 'high-risk' from their knee moments during unplanned sidestepping (n = 5) significantly reduced their peak valgus knee moments by 28% (p = 0.024), becoming consistent with valgus knee moments observed pre- post training from the 'low-risk' group (n = 11). All athletes (n = 16) were better able to utilize their hip versus their knee to generate their support moment during sidestepping, redistributing the relative contribution of their support moment from their knee to hip (Cohen's d = 0.56). For all athletes (n = 13), total gluteal muscle activation significantly increased by 27% (p = 0.006), while co-contraction of the hamstring muscle group were re-directed from the biceps femoris to the semimebranosus (Δ226%, p < 0.001). It is likely an athlete's capacity to prevent hip internal rotation, which is associated with the 'dynamic-valgus' posture would be improved. Increases in medial hamstring muscle activation would help athlete's support their knee against valgus knee moments, which is a surrogate for ACL injury risk [3, 5, 6]. We are currently analysing further motion capture data from this population to determine if these positive training effects have been preserved following 16-weeks of maintenance training.

Figure:

Figure 1: Depiction of UWA sidestepping protocol.

Conclusion: Simulation research can be used to help inform the development of effective lower limb injury prevention training protocols. The efficacy of a novel hip, trunk and gastrocnemius focused training intervention has been verified among elite level female field hockey players.

THE ROLE OF GENDER ON THE VARIABILITY OF JOINT KINEMATICS AND KINETICS IN UNINJURED ATHLETES DURING A MATCH SPECIFIC LAND-CUT TASK

S Clarke [1,*] I C Kenny [2] A J Harrison [3]

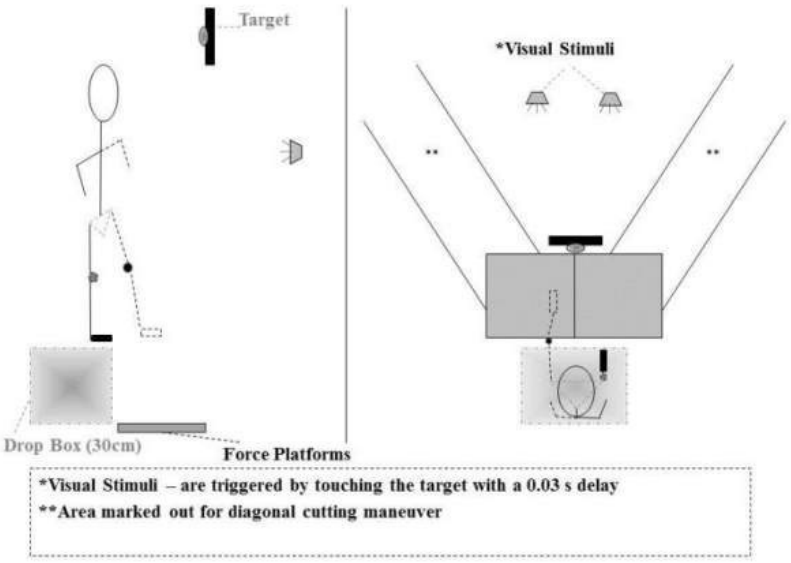
[1]Leeds Beckett University, Leeds, United Kingdom, [2]University of Limerick, Lickerick, [3]University of Limerick, Limerick, Ireland

Introduction and Objectives: Higher levels of movement or coordination variability have been reported to provide flexibility and allow adaptations to complex dynamic sport environments [1]. Decreased movement and coordination variability has been previously been reported in females [2] and proposed as a risk factor for injury. The aim of this study was to compare the variability of hip and knee joint kinematics (movement) variability and lower extremity joint and segment coupling (coordination) variability in healthy males and females during a dynamic landing task. There is a scarcity of information on gender differences in coordination and movement variability during dynamic landing and cutting tasks. This information may provide valuable insight to further explain the gender bias of ACL injury, where lower levels of movement and/or coordination variability may increase injury risk.

Methods: Ten healthy males and ten healthy females were recruited for this investigation. Participants performed a dynamic task (see Figure 1) which involved dropping from a 0.30 m bench, and performing an immediate jump to touch a target and on landing perform a side cut in a randomly cued direction. Five intralimb couplings were calculated using a modified vector coding technique [3]; thigh abduction-adduction leg abduction-adduction, thigh rotation leg rotation, hip abduction-adduction knee rotation, hip rotation knee abduction-adduction, knee rotation knee abduction-adduction. Variability of the normalised coupling and joint angle timeseries was calculated point by point and averaged during the initial 40% of landing and the push off phase of cutting (70-100%). Differences in average variability were assessed using independent t-tests or Mann-Whitney U tests. Cohen's d was utilised as a measure of effect size with a 0.2=small, 0.5=moderate, >0.8=large, scale.

Results: During the initial deceleration period of landing, females demonstrated significantly less movement variability at the knee in the transverse plane on both legs (Table 1) and coordination variability in three of the five couplings examined on the dominant leg (Table 1) when compared to males. During the final push off phase of the cutting movement, females also demonstrated significantly less movement variability at the non-dominant knee and hip in the frontal plane and the dominant and non-dominant hip in the transverse plane (Table 1). No gender differences in coordination variability were noted for either leg during the final push off phase of the cutting movement for any of the examined couplings.

Figure:



Conclusion: These findings may help explain the gender bias in ACL injury incidence. Reduced female coordination variability could also result in less flexible coordination patterns during match situations, with a decreased ability to adapt to perturbations experienced in game play. Poor adaptation to these perturbations may result in an unsafe movement response in females which are associated with the occurrence of an ACL injury. DISCLOSURE: The Irish Research Council for Science Engineering and Technology is acknowledged for its funding of the lead author for the completion of this work. All authors declare no conflict of interest.

BIOMECHANICAL ASPECTS OF TRIGGER FINGER BEFORE AND AFTER PULLEY RELEASE SURGERY

Fong-Chin Su [1 2,*] Szu-Ching Lu [1 2] Li-Chieh Kuo [3] I-Ming Jou [4] Yun-Nien Sun [5] Tai-Hua Yang [2]

[1]Medical Device Innovation Center, [2]Department of Biomedical Engineering, [3]Department of Occupational Therapy, [4]Department of Orthopedics, [5]Department of Computer Science and Information Engineering, National Cheng Kung University, Tainan, Taiwan, Republic of China

Introduction and Objectives: Trigger finger is a common problem in hand clinics. “Triggering” describes the catching and sudden release phenomenon during finger extension movement. The first annular (A1) pulley release surgery has been used to treat trigger finger for over a century. The release is required to extend to the second annular (A2) pulley to completely alleviate the symptoms for certain patients. The pulley release surgery may lead to hand function change. However, the effects of the different extent of pulley release have not been well explored. Therefore, the purpose of this study was to investigate the effects of the different extent of pulley release on the tendon excursion efficiency and the changes of tendon moment arms.

Methods: To understand the effects of the different extent of pulley release, four conditions of pulley integrity were investigated, including pulley intact, A1 pulley release, half A2 pulley release, and complete A2 pulley release. Eight cadaveric hands were used in the experiment, and a total of eight middle fingers were tested. The joint rotation was measured by a motion capture system, and the tendon excursion was measured by linear position sensors. The tendon excursion efficiency was defined as the range of motion of the involved joints per unit of tendon excursion, and the tendon moment arm was determined by the slope of the linear fitting of tendon excursion versus metacarpophalangeal (MCP) joint rotation.

Results: The tendon moment arm with respect to the MCP joint was determined as 11.08mm for the flexor digitorum superficialis (FDS) and 9.29mm for the flexor digitorum profundus (FDP). The tendon excursion efficiency decreased with the increased extent of pulley release. On the other hand, the tendon moment arms increased with the increased extent of pulley release. Significant differences were found among the four conditions of pulley integrity via Friedman's test in all the evaluated parameters, including the FDS tendon moment arm ($p<0.001$), FDP moment arm ($p=0.002$), FDS excursion efficiency ($p<0.001$), and FDP excursion efficiency ($p=0.005$). The results present no significant change between A1 and half A2 pulley release in the FDP excursion efficiency, and the moment arms of FDP and FDS with respect to the metacarpal phalangeal joint.

Conclusion: This study provides the investigations of trigger finger before and after pulley release surgery from biomechanical perspectives. To relieve the discomfort, if necessary, the pulley release may extend to the half proximal A2 for trigger finger patients. Hopefully the biomechanical investigations will improve the understanding of trigger finger, provide suggestions for clinical practice, and further help in developing better assessment and treatment programs.

EFFECTS OF PENNATION ANGLE ASSUMPTIONS ON THE DETERMINATION OF SUBJECT-SPECIFIC MUSCLE MODEL PARAMETERS

Youngho Kim [1,*] Jongsang Son [1]

[1]Biomedical Engineering, Yonsei University, Wonju, Korea, Republic Of

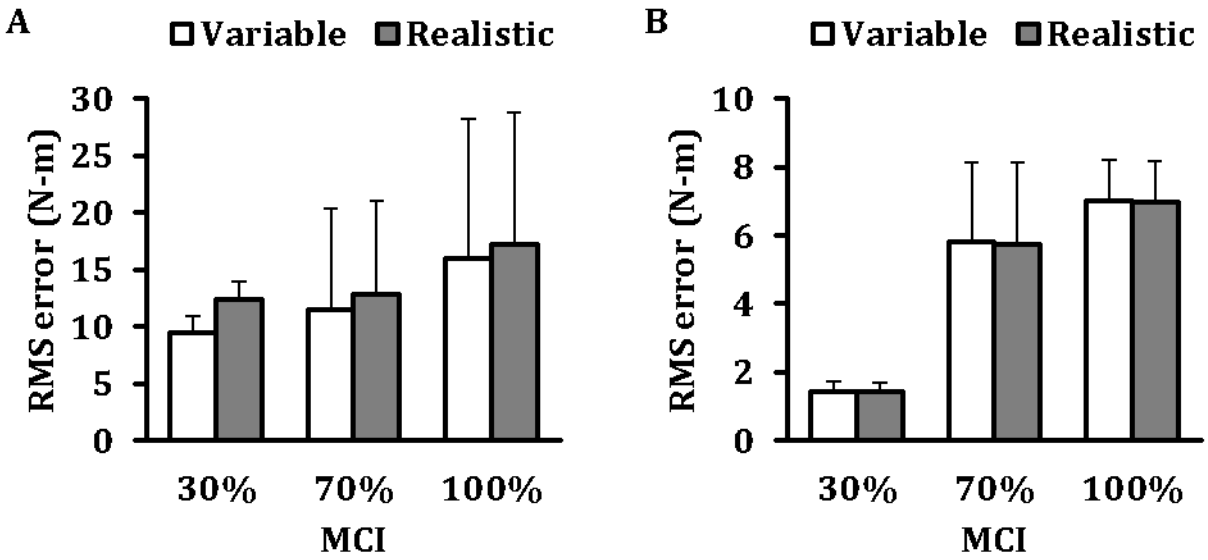
Introduction and Objectives: An EMG-driven model with a Hill-type muscle model is widely used to estimate individual muscle forces and joint moments. It includes some parameters to define muscle properties. In particular, the pennation angle is closely related to the direction of force transfer. To take the pennation angle into account, the variable pennation model has been widely used in the field of muscle mechanics [1], which assumes that (1) the muscle thickness would be constant, and thus (2) the pennation angle would be changed by the fiber length only. However, the muscle thickness varies with the muscle contraction intensity (MCI) [2]. It implies that the variable model might not be sufficient to reflect the real muscle. Therefore, this study was aimed to develop realistic pennation models of the major ankle muscles as a function of both the ankle joint angle and MCI, and to investigate effects of the developed model on the determination of subject-specific muscle model parameters.

Methods: Ten adult subjects (26.7 ± 2.1 yrs.; 70.3 ± 4.2 kg; and 172.5 ± 5.5 cm) with no history of musculoskeletal injury participated in this study. Each subject's right foot was firmly attached to the Biodex dynamometer with the knee joint at 30° flexion. The ankle joint was fixed at 15° dorsiflexion (-15°) and 0°, 15° and 30° plantarflexion. Four EMG sensors were attached to the belly of major ankle muscles (tibialis anterior, TA; gastrocnemius medialis, GCM; gastrocnemius lateralis, GCL; and soleus; SOL). For each condition, the subject was required to perform 0, 30, 70 and 100% of their maximum voluntary isometric plantar- and dorsiflexion. To measure the pennation angles, longitudinal sonography images were taken with a brightness mode real-time ultrasonic apparatus during the tests [3]. The pennation angle surface model was developed using the 'Poly22' fitting algorithm in MATLAB with average values of the measured pennation angle data corresponding each condition. Then, our EMG-driven model [4] was applied to investigate effects of the developed realistic pennation model on the determination of subject-specific muscle model parameters by comparing those of the existing variable pennation model.

Results: As a result, pennation angles increased with increases in MCI for all four major ankle muscles. The pennation angle of TA decreased as ankle plantarflexed, while the pennation angle of plantarflexors (GCM, GCL, and SOL) increased. Interestingly, the pennation angle has linear relationship with ankle angle, but nonlinear with MCI. When using the EMG-driven model with the existing pennation model, the root mean square (RMS) error between the measured and modeled joint moments was 9.41 ± 1.35, 11.44 ± 7.85, and 15.97 ± 10.79 N-m in isometric plantarflexion movements with 30, 70, and 100% MCI at neural position (0°), respectively (Figure 1A). However, the EMG-driven model with the developed pennation model showed the RMS error of 12.33 ± 1.49, 12.79 ± 8.02, and 17.18 ± 10.88 N-m in the same condition. After determined the subject-specific parameters, the existing model showed that the RMS error was considerably decreased by 1.43 ± 0.29, 5.82 ± 2.25, and 7.03 ± 1.27 N-m, but the developed model gave better results

with the decreased RMS error of 1.41 ± 0.30, 5.75 ± 2.19, and 6.97 ± 1.47 N-m in 30, 70, and 100% MCI, respectively (Figure 1B).

Figure:



Caption: Comparison of root mean square (RMS) error at each muscle contraction intensity (MCI) between the variable and realistic pennation models. RMS errors were considerably decreased after determined the subject-specific parameters (B) compared with before (A).

Conclusion: These results implied that the existing model could better estimate joint moments compared with the realistic model when using muscle model parameters that are typically based on cadaveric studies, but the realistic model might be better for the determination of subject-specific parameters. Nonetheless, it is hard to conclude that the realistic model would be as an alternative of the existing model, because this study was simply considered the isometric condition. Indeed, the realistic pennation model was developed from the previous observation that the pennation angle is related to the joint angle and MCI. Therefore, further studies would be required to investigate the effects of the realistic model on the performance in various dynamic movements such as gait.

APPLICATION OF TRANSCRANIAL DIRECT CURRENT STIMULATION AND BRAIN-COMPUTER-INTERFACE-CONTROLLED ORTHOSIS FOR HAND REHABILITATION OF STROKE PATIENTS

Ming-Shaung Ju [1,*] Ko-Chieh Chao [1] Wen-Chuan Chang [1] Chou-Ching Lin [2]

[1]Mechanical Engineering, [2]Neurology, National Cheng Kung University, Tainan, Taiwan, Republic of China

Introduction and Objectives: EEG-brain-computer-interface training can modify brain potentials and change connectivity of cortical circuits. The transcraninal direct-current stimulation (tDCS) can impose stimulation on central nervous system. In our previous study [1], the power ratio of μ band in C3 and C4 was used for the BCI and the accuracy was improved using the common spatial pattern (**CSP**) method [2]. The goal of this study is to integrate tDCS and a BCI-controlled orthosis for hand rehabilitation of stroke patients. Functional magnetic resonance (fMRI) and multi-channel EEG brain connectivity analysis were used to validate effectiveness of the new method.

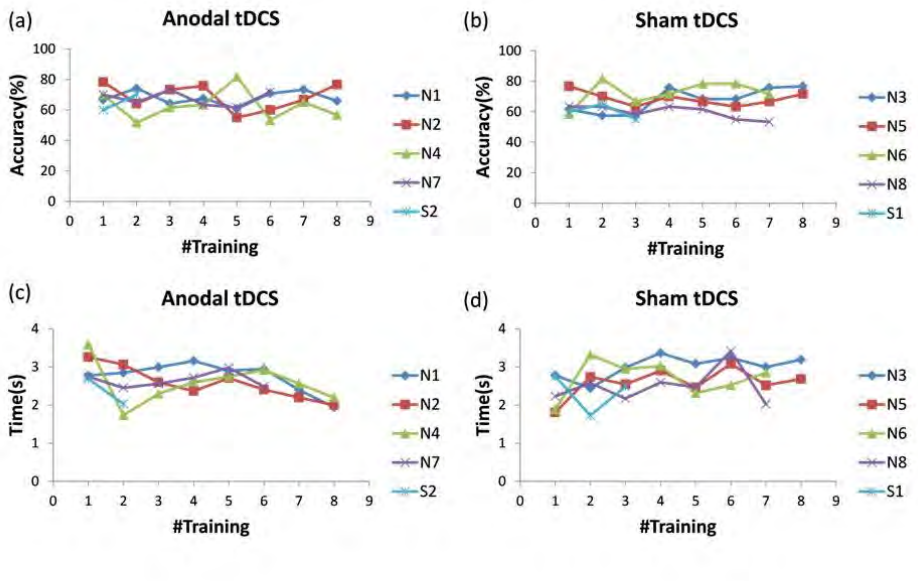
Methods: 8 healthy subjects (averaged age 24 years, 6 right-handed and 2 left-handed) with no history of neurological diseases and 2 stroke patients (a 35-year-old man with left hemiparesis and a 56-year-old woman with right hemiparesis) participated in this study. 19 channels of EEG signals were recorded according to the international 10-20 system. The EEG signals were band-pass filtered between 8 and 30 Hz. The CSP method was employed to extract event-related EEG features when left and right hand imagery movements were performed by the subjects [3]. A command generated according to the features was used to control right or left movement of a cursor on a screen or to drive left or right orthotic hand to extend middle and index fingers of the subjects. After a BCI pre-training session, tDCS followed by BCI training was performed twice a week for consecutive 4 weeks. The anodal tDCS (strength 2mA, ramp 5s) was applied for 20 min through 35cm^2 rectangular saline-soaked sponge electrodes. The position of anodal electrode was determined through induction of largest MEPs by using transcranial magnetic stimulation over the motor cortex area, and cathodal electrode was placed over lateral supraorbital area. 5 out of 10 subjects were randomly selected to take the sham tDCS as the control group. For the sham tDCS, the current was applied only for 30 seconds to mimic the sensation at the beginning of actual tDCS without producing any effect on the brain. The accuracy of BCI control, reaction time, and changes of brain connectivity of each session were analyzed. The cross-spectrum and phase slope index between EEG signals, within four bands, were computed. Five indices for brain connectivity, namely, global degree, global coupling strength, global efficiency, clustering coefficient, and in/out-degree were computed[4, 5].

Results: 4 healthy subjects and a stroke patient participated in anodal tDCS, and the other 5 subjects including another stroke patient participated in the sham tDCS. **Fig. 1** shows the control accuracy and reaction time of all subjects. The accuracy of anodal-tDCS group fluctuated at an average of 70% during the training and that of the sham-tDCS group increased slightly from 65% to 72%. The averaged reaction time of anodal-tDCS group decreased from 3.2s to 2.1s and that of the sham-tDCS group increased from 2.2s to 2.9s. The results showed anodal tDCS did not enhance accuracy of controlling the BCI. However, it can improve the reaction time. The brain connectivity depends on the bandwidth of EEG even for same right- or left- hand imaginary movement. Compared with the sham tDCS group, the anodal-tDCS group has higher global degree and global efficiency in latter stage of training, showing that they have more connections of nerve

signal. The anodal-tDCS could shorten the distance between the senders and recipients. The anodal-tDCS group has higher global coupling strength than the sham-tDCS group in the latter stage which means anodal-tDCS can enhance coupling strength between main nodes of signal transmission. The anodal-tDCS group has a higher clustering coefficient than the sham-tDCS group before the 6th training and get lower in the last 3 trainings.

Although BCI-control cursor training integrated with anodal tDCS does not enhance accuracy of using BCI but the reaction time does reduced after the training. Shorter reaction time implies increased transmission rate of cortex neuron signals which is consistent with the brain connectivity analyses.

Figure:



Caption: Fig. 1 Accuracy and reaction time

Conclusion: An EEG-based BCI was successfully integrated with tDCS and applied to cursor control training of healthy subjects and stroke patients. fMRI and brain connectivity analyses reveal that direct stimulation of the central nervous system do induce change of the activation of neurons in the cortex. On-going work is the control of orthotic hand to stretch the index and middle fingers of chronic stroke patients. The results will be presented and discussed in the congress.

MORPHOMETRIC ANALYSIS OF THE THORACIC INTERVERTEBRAL FORAMEN OSSEOUS ANATOMY IN ADOLESCENT IDIOPATHIC SCOLIOSIS USING LOW DOSE COMPUTERIZED TOMOGRAPHY.

Thorbjorn J. Loch-Wilkinson [1,*] Maree Izatt [1] Robert Labrom [1] Geoff Askin [1] Mark Pearcy [1] Clayton Adam [1]

[1] Paediatric Scoliosis Research Group, Science and Engineering Faculty, Queensland University of Technology and Mater Health Services, Brisbane, Queensland, Australia

Introduction and Objectives: The dimensions of the thoracic intervertebral foramen in adolescent idiopathic scoliosis (AIS) have not previously been quantified. During posterior approach scoliosis correction surgery pedicle screws may occasionally breach into the foramen. Better understanding of the dimensions of the foramen may be useful in surgical planning. This study describes a reproducible method for measurement of the thoracic foramen in AIS using computerized tomography (CT).

Methods: In 23 pre-operative female patients with Lenke 1 type AIS with right side convexity major curves confined to the thoracic spine the foraminal height (FH), foraminal width (FW), pedicle to superior articular process distance (P-SAP) and cross sectional foraminal area (FA) were measured using multiplanar reconstructed CT. Measurements were made at entrance, midpoint and exit of the thoracic foramina from T1/T2 to T11/T12. Results were correlated with potential dependent variables of major curve Cobb Angle measured on X-ray and CT, Age, Weight, Lenke classification subtype, Risser Grade and number of spinal levels in the major curve.

Results: The FH, FW, P-SAP and FA dimensions and ratios are all significantly larger on the convexity of the major curve and maximal at or close to the apex. Mean thoracic foraminal dimensions change in a predictable manner relative to position on the major thoracic curve. There was no significant correlation with the measured foraminal dimensions or ratios and the potential dependent variables. The average ratio of convexity to concavity dimensions at the apex foramina for entrance, midpoint and exit respectively are FH (1.50, 1.38, 1.25), FW (1.28, 1.30, 0.98), FA (2.06, 1.84, 1.32), P-SAP (1.61, 1.47, 1.30).

Conclusion: Foraminal dimensions of the thoracic spine are significantly affected by AIS. Foraminal dimensions have a predictable convexity to concavity ratio relative to the proximity to the major curve apex. Surgeons should be aware of these anatomical differences during scoliosis correction surgery.

Introduction and Objectives: Aortic walls have long been assumed to be uniform in the circumferential direction in most of the studies on blood vessel wall biomechanics. However, it gradually becomes clear that they are heterogeneous in the circumferential direction in humans [1] and rabbits [2]. Sugita et al. [2] observed the deformation of an aortic segment during inflation in the longitudinal direction to find that the wall of rabbit thoracic aorta is more compliant in the ventral side than the dorsal. This indicates that cyclic deformation of aortic wall during heart beat is higher in the ventral side than the dorsal, which may cause difference in the properties of smooth muscle (SM) cells not only in biomechanical but also in biochemical aspects. In this study, we observed the dorsal-ventral (DV) difference in the SM contractility and RNA expression levels with a microarray analysis in rabbit thoracic aortas.

Methods: *DV difference in the biomechanical properties:* Thoracic aortas were obtained from matured male Japanese white rabbits weighing 2.5–3.0 kg. The aortic segments were stretched to their in vivo length and pressurized to 80 mmHg in an aerated Krebs-Henseleit solution at 37°C. Four small needles were stuck perpendicularly into the aortic wall at almost equal intervals on a circumference. Displacement of the needles during pressurization from 0 to 200 mmHg and during isobaric SM contraction at 80 mmHg induced with norepinephrine (NE) was observed in the longitudinal direction with a CCD camera and laterally with two digital cameras placed in an opposite direction across the aorta. The images taken by the cameras were used to identify the point at penetration of each needle. Circumferential length between the needles was obtained assuming that the aortic segment had circular cross section.

SM contractility at cellular level: SM cells isolated from dorsal or ventral quarter of rabbit thoracic aortas with enzymatic digestion were used. Length of the isolated cells was measured in an aerated Ca2+-free Krebs-Henseleit solution at 37°C before and after contraction induced with 2.3mM of CaCl2 and 10-5M of NE.

DNA Microarray analysis: To study the dorsal-ventral difference of SM cells in biochemical properties, dorsal and ventral quarter of aortic segments were analysed with a Rabbit Gene Expression Microarray (G2519F, 020908, Agilent) based on the manufacturer's standard protocols. Microarray expression data was validated by real-time PCR.

Results: Circumferential stretch ratio at 120 mmHg in reference to length at 40 mmHg was significantly lower in the dorsal side (1.3±0.1, mean±SEM, n=5) than in the dorsal (1.6±0.1), indicating that thoracic aortas are stiffer in the dorsal side than in the ventral as shown in the previous study [2]. The circumference of the aortic specimens contracted significantly more in the ventral side (24±4%, n=5) than in the dorsal (16±3%) upon SM contraction. Similar results were obtained for isolated cells. The amount of contraction was 37±4% (n=20) for cells isolated from the ventral side and was significantly

higher than that of the dorsal side (22±2%). These results indicate that the more compliant side of the aorta is more contractile.

In the microarray analysis, there were 392 genes of 43,603 found to express more than twice in the ventral side as much transcript as in the dorsal side, besides 296 genes were found to express less than half as well, indicating that gene expression profile is also different between dorsal and ventral sides. Several genes with DV difference were confirmed by real-time PCR, including osteopontin with higher expression in the dorsal side and actin with higher expression in the ventral. Osteopontin stimulates DNA synthesis of SM cells [3] and actin is one of the most important contractile proteins. Thus, SM cells in the dorsal side may have more synthetic phenotype and those in the ventral side more contractile.

Conclusion: DV difference in the smooth muscle contractility and gene expression profile may be explained by the DV difference in the mechanical properties. Higher compliance in the ventral side causes higher cyclic strain during a cardiac cycle. Such higher mechanical stimulation may induce higher contractility to the SM cells, i.e., more contractile phenotype in this side. However, the reason for the DV difference in the mechanical properties remains unknown. The ventral side of the thoracic aortas is connected with the vertebral column via collagen fibers. This might induce accumulation of collagen fibers in the dorsal side. Since collagen fibers are much stiffer than other components in the aortic wall, accumulation of collagen fibers may induce wall stiffening.

THE SKINNY ON OSTEOARTHRITIS -- DOES BODY FAT AFFECT QUADRICEPS MUSCLE COMPOSITION?

K H Collins [1,*] R A Seerattan [1] W Herzog [1]

[1]University of Calgary, Calgary, Canada

Introduction and Objectives: Western-type diets, high in fat and sugars, often lead to obesity. Obesity in turn is associated with chronic inflammation thought to be a risk factor for the onset and increased rate of progression of metabolic osteoarthritis (OA) in joints [1]. Aside from affecting bones and cartilage, obesity-induced metabolic OA may affect muscle structure and function, causing weakness, thereby increasing risk for OA development [2]. However, the relationships between diet-induced obesity, muscle structure and weakness, and OA remain poorly understood. The purpose of this study was to determine these relationships in a pre-clinical model of metabolic OA.

Methods: Thirty-two male rats (8-12 weeks) were randomized into a high fat/high sucrose diet (DIO) (n=21, 40% fat 45% sucrose) or control (n=11 lean chow (LFD, 13.5% fat) group. After a 12-week obesity induction period, DIO animals were stratified into Obesity Prone (DIO-P, Top 33% of animals by change in body mass over twelve weeks, n=7), Obesity Resistant (DIO-R, bottom 33% n=7). Animals were euthanized after a total of 28 weeks when all outcomes were measured: body fat (Dual Energy X-Ray Absorptiometry), knee OA severity (Modified Mankin score) [3], and vastus lateralis muscle (VL) mass (g) and intramuscular fat infiltration (LFD n=6). Vastus lateralis muscles were frozen, stained with Oil Red O, imaged and quantified under 10x magnification using a custom MatLab program. Kruskal-Wallis tests and Spearman correlations were performed at $\alpha=0.05$.

Results: DIO-P and DIO-R animals had increased body fat when compared to LFD (DIO-P: 56.7±1.7%, DIO-R: 42.8±1.5%, LFD: 29.5±2.5%, $p<0.001$). However, DIO-P animals were heavier than both DIO-R and lean animals (DIO-P: 1207±66g, $p<0.001$), but DIO-R and lean animals had similar mass (DIO-R: 896±43g, LFD 823±19g, $p=0.25$). All DIO animals had greater Modified Mankin scores than LFD (Median and {Interquartile range}: DIO: 50 {40-63}, LFD: 26 {22-38} $p=0.002$). Despite being heavier, DIO-P and DIO-R animals had similar Mankin Scores ($p=0.805$). Conversely, DIO-R animals had more joint damage than LFD animals, (DIO-R: 47{40-64}, LFD: 26{22-38}, $p=0.004$). There was a strong positive relationship between body fat and Modified Mankin score ($r=0.6$, $p=0.001$), but not body mass. All DIO animals had decreased VL mass compared with LFD (2.1±0.05g, 2.3±0.07g), and despite having similar body mass, DIO-R had decreased VL mass compared with LFD (2.0±0.06g) ($p<0.05$). VL intramuscular fat was increased in DIO animals (DIO: 22.7±1.3%, LFD: 3.3±0.9%) and despite having similar body mass, DIO-R animals had increased VL intramuscular fat compared with LFD (DIO-R: 20.7±0.8%) ($p<0.001$).There was a significant negative relationship between body fat and VL mass ($r=-0.50$, $p=0.03$) and Modified Mankin Score and VL Mass ($r=-0.40$, $p=0.04$). Positive relationships were calculated between body fat and VL fat ($r=0.80$, $p<0.001$), and Modified Mankin Score and VL fat ($r=0.45$, $p<0.05$).

Conclusion: Body fat is associated with increased intramuscular fat accumulation in the vastus lateralis muscle. Quadriceps intramuscular fat is a novel link between systemic inflammation, muscle composition and metabolic OA. This work is a first step towards understanding the crucial mechanical and inflammatory signatures of metabolic OA in skeletal muscle.

USING ADVANCED MRI TECHNIQUES FOR ESTIMATING STRAIN DISTRIBUTIONS ALONG MUSCLE FIBERS DURING ISOMETRIC PLANTAR-FLEXION ACTIVITY OF HUMAN MEDIAL GASTROCNEMIUS, IN VIVO

Agah Karakuzu [1,*] Uluc Pamuk [1] Burak Acar [2] Can A. Yucesoy [1]

[1]Institute of Biomedical Engineering, [2]Electrical and Electronics Engineering, Bogazici University, Istanbul, Turkey

Introduction and Objectives: Magnetic resonance imaging (MRI) enables identifying orientation of muscle fibers through coupled implementation of diffusion tensor imaging (DTI) [1]. MRI analyses also allow quantifying 3D local tissue deformations in human muscles, in vivo [2]. These analyses combined are capable of determining deformation along muscle fibers. This is physiologically highly relevant information. Previously it was shown that skeletal muscle is not independent from its surroundings, because myofascial connections provide linkages from the muscle belly to adjacent muscular and non-muscular structures [3]. Finite element modeling designed to study mechanics of activated skeletal muscle within the context of a fascial integrity suggests presence of inhomogeneous deformations along the muscle fibers indicating sarcomere length heterogeneity [3]. Using MRI and DTI analyses our aim was to quantify fiber direction deformations in human subjects, in vivo, and to test the hypothesis that sustained plantar-flexion activity of the medial gastrocnemius causes heterogeneous length changes.

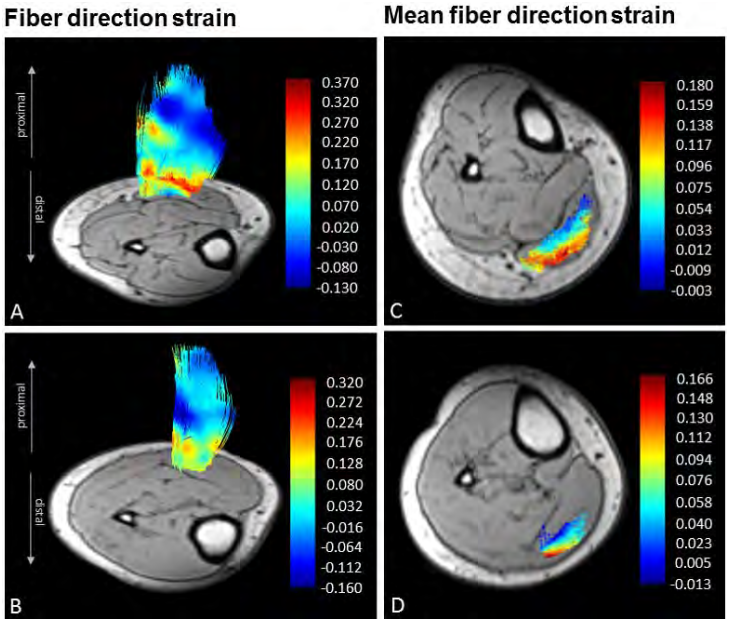
Methods: Five healthy female subjects (age=26±3 years, height=162±7 cm, mass=51±5 kg) participated in this study. The subjects were positioned prone in a 3T clinical MRI scanner with their right leg constrained using a custom design apparatus: the ankle was fixed at 90° and the knee was kept extended (175.6°±3.3°) (reference state). Maintaining these positions, the subjects were asked to sustain isometric plantarflexion activity corresponding to 15% maximum voluntary contraction (MVC) with the help of a visual feedback (deformed state). DTI and high-resolution 3D MRI anatomic image sets were acquired in both states, separately. To quantify tissue deformations occurring in global coordinates due to such contraction, the image sets were registered using non-rigid Demons algorithm [4]. DTI data were denoised [5] prior to Split and Merge Tractography [6]. Streamline integration using 4th order Runge-Kutta algorithm allowed determining muscle fiber tracts of the medial gastrocnemius. Strain transformation from global coordinates to local muscle fiber direction was used to quantify deformation along muscle fibers. Undeformed state images were also transformed by a synthetic rigid body motion (10˚ rotation in the axial, 3˚ rotations in coronal and sagittal planes and 4mm translation axially) imposed. Resulting fiber direction strains calculated were used as estimates of error strains.

Results: For the pooled data of all subjects, mean fiber direction strains (16.0±9.3% for lengthening and 4.0±3.7% for shortening) calculated were significantly greater than mean strain errors (1.9±1% for lengthening and 1.8±0.9% for shortening). The figure shows for two subjects, examples of “serial” strain distributions along muscle fibers (panels A-B) and “parallel” strain distributions as mean fiber strain of groups of muscle fibers represented by each tract (panels C-D). The serial strain distributions indicate that along the same tract, shortening and lengthening (up to locally 108.9% and 23.6%, respectively) occurs simultaneously. Mean fiber strains of different tracts are non-uniform (e.g. in panel D they range from -0.01 from to 0.16; among all subjects from -0.02 to 0.33). Therefore, parallel strain distributions within axial

sections of the muscle are also heterogeneous. These findings confirm our hypothesis and are in concert with the expectations from the previous studies of our research group [3].

At reference state, extended knee position conceivably imposes stretch on the medial gastrocnemius proximally. On activation at 90° of ankle angle, shortening along the muscle fiber direction is plausible. However, instead of such uniform strain distributions, our findings indicate that locally along groups of muscle fibers represented by each tract, lengthening occurs at parts, whereas shortening occurs at different parts and at varying amplitudes. This is explained by epimuscular myofascial loads acting on the muscle belly via the muscle's connections to the surrounding muscular and non-muscular structures and further mechanical interaction between neighboring muscle fibers [3].

Figure:



Caption: Serial (A-B) and parallel (C-D) distributions of fiber direction strains. + and – values indicate lengthening and shortening, respectively.

Conclusion: MRI and DTI analyses combined provide a powerful tool for quantifying deformation along activated human muscle fibers, in vivo. Estimating length changes of bigger groups of sarcomeres is quite relevant for characterization of the muscle's contribution to joint mechanics.

EFFECTS OF BOTULINUM TOXIN TYPE A ON MUSCULAR MECHANICS APPEAR TO BE MUCH MORE INVOLVED THAN KNOWN SO FAR

Can A Yucesoy [1,*] Ahu N Turkoglu [1] Filiz Ates [1]

[1]Bogazici University, Istanbul, Turkey

Introduction and Objectives: Botulinum toxin type A (BTX-A) is widely used in treating cerebral palsy (CP) patients. Partial muscle paralysis helps blocking the hyper-excitable stretch reflexes. This also decreases active force production. Therefore, through reduced spasticity and decreased muscle tone BTX-A is considered to improve function by acting against an agonist-antagonist force imbalance and increasing joint range of motion. Although this mechanism can reflect positively on function, a comprehensive understanding of the effects of BTX-A requires more critical and specific testing. (I) BTX-A is not contained only within the muscle injected and (II) active force reduction is not invariable for different muscle lengths [1]. (III) BTX-A is considered to decrease passive resistance to stretch via the mechanism described however, its effects on muscle passive forces and tissue structural properties need to be studied. (IV) If BTX-A actually increases muscle length range of force exertion should be assessed. (V) Intra-operative tests on CP patients show that spastic muscle activated alone has a regular muscle force-joint angle relationship [2]. However, if an antagonistic muscle is co-activated, the muscle's mechanics become representative of the patients' joint movement disorder [3]. This suggests that intermuscular mechanical interaction [4] is improper in CP patients. Therefore, it is important to test whether BTX-A affects such interaction. In order to address these issues, a broader scale than just the injected muscle should be considered. Active and passive forces of neighboring muscles should be measured simultaneously and at various muscle lengths and positions. Keeping the target muscle compartment intact allows preserving intermuscular interactions. The goal was to quantify the effects of BTX-A accordingly.

Methods: The tibialis anterior (TA), extensor digitorum longus (EDL) and extensor hallucis longus (EHL) muscles of the intact anterior crural compartment of the rat were studied 5 days post injection. 0.1U BTX-A in 20μl of saline (BTX-A group) or only 20μl of saline (control group) was injected into the mid-belly of the TA. (i) The TA was lengthened (BTX-A, n=8, body mass 312.5±14.6g; control, n=8, body mass 318.5±12.5g). (ii) The EDL was lengthened both proximally and distally and, (iii) the relative position of the EDL was changed (BTX-A, n=8, body mass 315.0±6.3g; control, n=8, body mass 300.0±6.9g). In (i) and (ii) muscles other than the one lengthened and in (iii) all muscles were kept at constant length. Gomori trichrome stain was used to assess intra- and intermuscular connective tissue content histologically.

Results: (1) Substantial force decreases (peak force drops range from 47.3% to 85.6%) for all compartmental muscles indicate spread of BTX-A. (2) Force reductions are length dependent and more pronounced at shorter lengths (e.g., for the TA, force reductions increase from 46.6% to 55.9% with decreasing length), (3) BTX-A does not increase muscle length range of force exertion, but can decrease it (for the EDL both proximally and distally, by up to 26.1%), (4) BTX-A causes increased passive forces (for all lengthened muscles, minimally three-fold). (5) Unlike the sizable intermuscular interaction effects shown in the control group, EDL forces of the BTX-A group measured at the most proximal position did not change significantly with the muscle's position changes and proximo-distal force differences vanished. This shows

compromised intermuscular interactions. Histological analyses show an increased intramuscular collagenous tissue content and a contrasting decrease in intermuscular connections. Spread of BTX-A and length dependent force reduction implies complex nature of effects on joint mechanics. Narrowed length range of active force production suggests that BTX-A can worsen already limited joint range of motion of CP patients. Increased passive forces can compromise intended reduction in passive resistance to stretch as obtained by reduced hyper-excitable stretch reflexes. These effects are contraindicated. Highly diminished intermuscular mechanical interactions is remarkable and can be clinically relevant if in future studies the role of such interaction on mechanics of spastic muscle can be further established.

Conclusion: BTX-A does not increase the length range muscle produces force, but can reduce it. Moreover, it causes increased muscle passive force, but diminished intermuscular mechanical interactions. In sum, our experiments reveal remarkable new effects of BTX-A worthwhile further testing in clinically representative conditions.

PEAK FORCE AND HYSTERESIS IN ACTIVELY AND PASSIVELY LENGTHENED SKELETAL MUSCLE MYOFIBRILS AT VERY LONG SARCOMERE LENGTH.

Tim Leonard [1,*] Jens Herzog [1] Azim Jinha [1] Walter Herzog [1]

[1] University of Calgary, Calgary, Canada

Introduction and Objectives: The molecular spring titin is a giant protein found in muscle sarcomeres and is the primary source of passive force in myofibrils [1]. The extensible region of titin contains spring-like domains arranged in series with visco-elastic properties that come into play in a prescribed sequence with increasing sarcomere length (SL). Within the physiologically relevant SL range, sarcomeres that are lengthened will initially align and straighten the Ig domains, followed by stretching the PEVK region. These two events are known to be essentially elastic. Beyond the physiological range (> 3.5μm), Ig domains unfold, and this unfolding is thought to be highly visco-elastic. Active muscle lengthened not only from SL of 1.8μm to 4.0μm but also beyond 4.0μm (region of loss of myofilament overlap) will produce more force than passively lengthened muscle at the same SL [2].We hypothesize that the rate of Ig domain unfolding in titin is increased with higher force. If so, then activated myofibrils will exhibit greater hysteresis during stretch-shortening cycles (SSC) compared to passive myofibrils because the increased force for the actively stretched myofibrils will cause a greater number of Ig domains to unfold compared to passively stretched myofibrils.

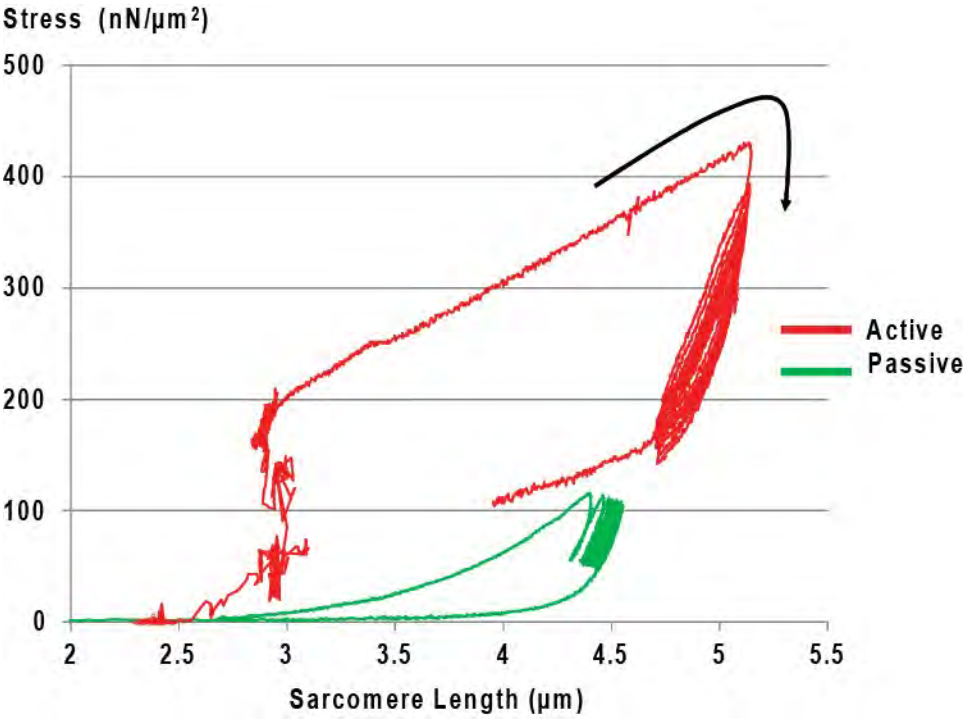
Methods: Rabbit psoas myofibrils were used for these experiments, activated and lengthened (n=6) and passively lengthened (n=5). Single myofibrils with an initial mean sarcomere length (SL) of 2.8μm were either actively (pCa+2=3.5) or passively (pCa+2=8) lengthened to approximately 4.5μm and then immediately subjected to 10 small amplitude SSC of 0.5μm/sarcomere before returning to SL of 1.8μm. All length changes were done at 0.1μm/sarcomere/second. Forces are expressed as stresses so that comparisons between myofibrils of different diameters can be made. Materials and apparatus are reported elsewhere for brevity [2]. All descriptive results are reported as mean ± standard deviation Institutional ethics approval was obtained for these experiments. The primary outcomes measures reported here are: 1.Peak force at the end of the initial lengthening to 4.5μm, or at the stretch segment of the SSC for each subsequent cycle. 2. The hysteresis measured for each of the small amplitude SSC, calculated as stretch energy -- return energy in units of nN*μm. 3. The percent energy loss calculated as (energy returned-energy input)/energy input x100.

Results:

Mean 1st peak force (force achieved at the end of the initial stretch to 4.5μm) was higher in active versus passive myofibrils (see Figure 1) at 339±137nN/μm2 versus 103±17nN/μm2, as expected. Mean peak force for each subsequent SSC fell continuously from the 2nd to the 10th cycle in active, while the peak force stabilized in passive tests by the 4th cycle. Hysteresis was greater in the active tests; mean 1st SSC hysteresis was 18±1nN*μm (active) versus 4±2nN*μm (passive). By the 10th SSC, the hysteresis in active was still 9±4nN*μm while in passive it was only 0.4±0.3nN*μm The mean percent energy loss per cycle was initially high for both test conditions; active = 26±14% versus passive = 28±8% and by the end of the 10th cycle, active was 17±4% while passive was only 5±4%. The mean energy loss across all 10 SS cycles for active was 18±11% and for passive 11±8%.

Figure 1: Stress as a function of sarcomere length for two different conditions. One exemplar active (red) and passive (green) experiment are shown here. The black arrow shows the direction of the trace with respect to time. The active data shows initial activation and then a stretch to about 5 μm and then the 10 small stretch-shortening (SS) cycles. The forces are much higher in the active experiment than the purely passive lengthening experiment.

Figure:



Conclusion: Hysteresis was greater for active compared to passive SSC and while the hysteresis was reduced by the 10th cycle, it remained higher in absolute and relative terms for active compared to the passive tests, indicating that higher forces promote greater Ig domain unfolding, resulting in a more visco-elastic (and less elastic) behaviour of titin. The much higher active force beyond myo-filament overlap (> 4μm) can only be attributed to titin [2] and a stiffer (possibly due to a shorter) free region of titin results in greater Ig domain unfolding at long sarcomere length, producing a greater hysteresis compared to passively lengthened myofibrils. The continuous drop in peak force across the 10 SSC in active is not seen in the passive tests, indicating that the higher force in active results in the recruitment and unfolding of new Ig domains during the entire test. The large hysteresis in active at the 10th SSC (at 50% of the 1st SSC) was not seen in passive (only 10%) indicating that the passive myofibrils exhibited a more elastic behaviour by the end of the tests, compared to the active samples.

APPLICATION OF A PSEUDO-INVERSE METHOD FOR THE ESTIMATION OF INDIVIDUAL MUSCULO-TENDON FORCES CONTRIBUTIONS TO THE GROUND REACTION 3D FORCE AND MOMENT AND TIBIOFEMORAL CONTACT FORCES

Florent Moissenet [1,*] Laurence Chèze [2 3 4] Raphaël Dumas [2 3 4]

[1]CNRFR - Rehazenter, Laboratoire d'Analyse du Mouvement et de la Posture, Luxembourg, Luxembourg, [2]Laboratoire de Biomécanique et Mécanique des Chocs, IFSTTAR, Bron, [3]Université Claude Bernard Lyon 1, Villeurbanne, [4]Université de Lyon, Lyon, France

Introduction and Objectives: Besides giving access to an estimation of individual musculo-tendon forces (iMTFs), musculoskeletal (MS) models now allow studying interactions between the different MS structures [1,2]. In this sense, the study of iMTFs contribution to forces and accelerations is possible during different tasks and may provide insights about either pathologic gait patterns or the progression of joint disorders (e.g., osteoarthritis). However, to estimate the contributions of iMTFs, most of the studies require a high computational time since they are based on a forward dynamics approach with an induced acceleration analysis [3] or a perturbation analysis [4]. Recently, Lin et al. [5] proposed an inverse dynamics approach with the use of a pseudo-inverse. Yet, even if inverse dynamics was used, a 5-point rigid contact was used to model contact forces between the foot and the ground. The aim of this study was thus to extend this approach to estimate the iMTFs contributions to the ground reaction 3D force and moment (GRFM) at the centre of pressure. The procedure was applied to a 3D lower limb MS model during gait, and the contributions of iMTFs to the GRFM and to tibiofemoral contact forces (TBCF) were computed and compared to the literature.

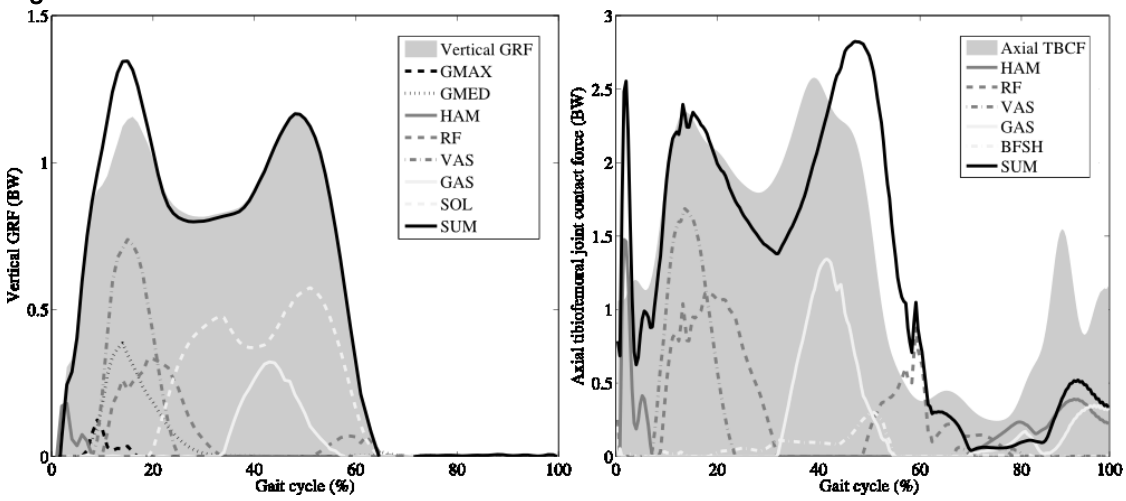
Methods: A previously described 3D lower limb MS model [1], consisting of pelvis, thigh, patella, shank and foot segments and 43 muscular lines of action was used. The following procedure was then applied on one gait cycle provided in the dataset of the "First Grand Challenge Competition to Predict in Vivo Knee Loads". For details relating to the subject and dataset, see [6].

The dynamics equation of the whole lower limb was used, introducing the iMTFs and Lagrange multipliers standing for the bone, contact and ligament forces [7]. The iMFTs were first estimated by a static optimization procedure [1]. In order to estimate the iMTFs contributions to the GRFM, a parameter reduction was applied in order to cancel all Lagrange multipliers [7,8]. The GRFM due to each iMTF were then computed using the pseudo-inverse approach [5] by setting all other iMTFs to zero. For that, the ground reaction 3D moment was replaced by six equivalent forces [9]. Similarly, for the iMTFs contribution to TBCF, a partial parameter reduction [1] was applied in order to cancel all the Lagrange multipliers except the ones standing for the contact forces. The same pseudo-inverse was used with the unique, above-mentioned, iMTF, and the corresponding contribution to GRFM as well as to the segment accelerations.

Results: The contributions of iMTFs to the GRFM obtained meet the estimations reported by Lin et al. [6]. Similarly, the contributions of iMTFs to the axial, medial and lateral TBCF are close to the estimations reported by Pandy et al. [2]. A selection of these results is reported in Figure 1.

In each case, the sum of the contributions of all iMTFs (SUM) obtained from the proposed pseudo-inverse method was near to the magnitude of the measured GRFM and TBCF (i.e., the root mean square errors were respectively 0.06BW and 0.54BW). This was expected for the GRFM that are one of the inputs for the MS model. Conversely, while the TBCF is an output of the model, the sum of the contributions matches reasonably well, especially at the first peak, the prosthetic measurement.

Figure:



Caption: Left: Contribution of gluteus maximus (GMAX), gluteus medius (GMED), hamstrings (HAM), rectus femoris (RF), vastii (VAS), gastrocnemii (GAS), soleus (SOL) and the sum of all musculo-tendon forces (SUM) to the measured vertical ground reaction force (GRF) expressed in body weight (BW). Right: Contribution of RF, VAS, GAS, biceps femoris short head (BFSH) and SUM to the measured axial tibiofemoral contact force (TBCF) expressed in BW.

Conclusion: This study confirms that the iMTFs contributions to different forces in the lower limb can be obtained through an inverse dynamics and static optimisation procedures using a pseudo-inverse. Moreover, a rigid foot contact model is not required. The contribution to the GRFM can be directly computed at the centre of pressure.

Thanks to the proposed MS model and the partial parameter reduction [1], it is now possible to analyse the contribution of iMTFs to many different forces in the lower limb (e.g., ligament, patellar contact) and to better understand the interactions into the MS system.

SPEED-ACCURACY TRADE-OFF IN GOLF DRIVING: A KINEMATIC AND PERFORMANCE ANALYSIS OF A GROUP OF LOW HANDICAP GOLFERS

Dr Susan Brown and Michael Davidson

Edinburgh Napier University

UK

Introduction: Research studies which consider kinematics within golf driving are numerous, although differences in data collection and processing methods can directly influence findings. Researchers have investigated the role of major segments such as the pelvis and torso (presented and analysed as a single segment), using the principle of the X-Factor (the separation of the pelvis and torso/shoulder segments) albeit used differently across studies. It is argued that an increase in club head speed can be attributed to an increased X-Factor which has a positive impact on driving performance [1]. However, the methods used for trial selection are also inconsistent, for example using a single measure of club head or ball speed to determine suitability for inclusion [1,2,3]. Recently researchers demonstrated the effect of different parameters on accuracy in driving confirming the interaction between club head and ball launch conditions as being paramount in driving success [5]. Furthermore, driving accuracy has been shown as a more robust predictor of scoring average than driving distance [6,7].

Objectives: To identify specific pelvis and torso segment differences when participants were asked to drive the ball for distance and for accuracy; to determine if driving for distance has an impact on driving accuracy; and if driving for accuracy caused a significant decrease in driving distance.

Methods: A 12-camera, 3D motion capture system operating at 500Hz (Oqus 3+, Qualisys AB) was used to capture 20 drives from 15 low handicap golfers (mean (±SD) self-reported handicap 0.7±1.76 strokes) using a TrackMan™ Pro radar (Trackman A/S) to directly measure club head and ball data set up according to the Manufacturer's guidelines. There were two randomly ordered conditions; driving distance and driving accuracy using analogies of hitting the longest drive down a par 5 wide fairway and hitting the fairway on a tree-lined par 5 respectively. 37, 19mm diameter retro-reflective markers were used following the definitions presented within the Qualisys Project Automation Framework (PAF) reduced marker set for golf analysis to identify each segment coordinate system (SCS) (head, pelvis, torso, left upper arm, left lower arm, left hand, right and left feet, club shaft and club head). Mean (±SD) data were extracted after processing (Visual 3D™, C-Motion Inc. through PAF) for both conditions for the following: peak X-Factor (z-component of torso orientation with respect to the pelvis); peak X-Factor rate of change (z-component of angular velocity of the torso relative to the pelvis, expressed within the pelvis SCS); peak angular velocity for the pelvis and torso (with respect to the GCS). TrackMan™ data was extracted for club head and ball speed, spin rate, smash factor (ratio of ball to club head speed), carry distance (distance) and side distance (accuracy). Paired sample t-tests were used to identify differences between the conditions.

Results: See Table 1. Comparison between the two conditions showed a significantly greater peak pelvis–torso separation (X-Factor) when hitting for distance compared to accuracy but no significant differences for peak X-Factor angular velocity, peak pelvis or peak torso angular velocity. Significant differences were seen for club head speed, ball speed, carry distance and side distance with all variables greater for the distance condition ($p<0.05$). **Conclusion:** The analysis

demonstrates a speed-accuracy trade-off within the golf drive in terms of the performance outcome, with greater carry distance, but an increase in side distance or in other words, a reduction in accuracy. There is a certain amount of sense in this given a shot hit with spin could deviate further offline the further it travels. Within this study, the golf drives for accuracy generated 95.8% of the carry distance of those which were struck under the speed/distance condition. This is in contrast to previous studies which found a decrease of around 15-20% in ball velocity during kicking for speed and accuracy [8,9,10]. The increase in driving distance may be attributable to the increase in peak pelvis-torso separation (X-Factor) as previously described. It would seem that where other studies have shown an important performance related reduction in accuracy with an increase in segment speed, this may not apply to the same extent in golf.

PERFORMANCE DIFFERENCES BETWEEN BLADE AND CAVITY BACK 5-IRONS

Tom Corke[a,b,*], Eric Wallace[a], Steve Otto[b]

[a]Sport and Exercise Sciences Research Institute, Ulster University, Northern Ireland

[b]R&A Rules Ltd, St Andrews, Scotland

[*]Presenting author

Introduction and Objectives: The topic of 'perimeter weighting' was discussed half a century ago [1], which entailed positioning of a clubhead's discretionary mass so as to maximise moment of inertia (MOI) about specific axes, and thus its resistance to twisting. The cavity resulting from this design gave rise to the archetypal 'cavity back' iron, which is commonly perceived to offer different performance characteristics to the more traditional 'blade' iron. Whilst efforts have been made to understand the effect of relocating this discretionary mass [2,3], the effect of mass distribution on shot outcome has generally remained confined to modelling [4,5,6]. These factors motivated the current study to experimentally determine the performance differences between a blade and cavity back 5-iron.

Methods: Representative blade and cavity back 5-iron clubhead models were chosen based on their physical properties. The clubs were matched for clubhead mass, overall length, static loft and static lie. Inertia properties and centre of gravity (CG) location were determined manually relative to a hosel coordinate system. Three motion tracking cameras were used to track opto-reflective passive markers positioned on the clubheads at 1000Hz; a bespoke clubhead tracking system [7] was used to process this data, returning clubhead presentation variables at the point of first contact with the ball. Developments were made to the system to include tracking of the leading edge of the club face. The two studies discussed herein involved a golf robot and a sample of 96 participants, comprising both male and female golfers ranging in ability from touring professional to high-handicapped amateurs. Stereoscopic and Doppler radar launch monitors were used to measure launch conditions for robot and player tested respectively. The robot testing was designed to measure the relative performance of irons when impact location was systematically varied, whilst the sample of golfers – each performing 12 shots from natural turf with both irons – established whether any observed differences remained tangible once human variation had been introduced. A paired *t*-test was used to determine whether within-player differences between club medians differed significantly from zero.

Results: The robot testing indicated that the effective loft with which the cavity back was presented to the ball was 1.56° greater than that of the blade, even though the static lofts were matched. This agreed in principle with research concerning shaft bending [8] and the relative CG locations of the two clubheads. Vertical launch angle and total spin were 0.27° and 390 rpm greater for the cavity back relative to the blade respectively. Comparable differences arose from the player testing, as can be seen in Table 1. Dependency of ball launch variables on impact location yielded further differences. A greater disparity in horizontal launch angle between toe and heel shots was evident for the blade relative to the cavity back. Figure 1 illustrates the change in spin axis tilt as horizontal impact location is varied. Although relatively weak, the positive relationship exhibited by the cavity back is consistent with the 'gear effect' as observed in driver studies [5,6], whereas an 'angle effect' [9] appears to dominate for the blade. Figure 1 also shows a more rapid decay in efficiency

(ball speed normalised to clubhead speed) for eccentric impacts with the blade; indicating that missing the location of peak efficiency on the club face by 5 mm in the horizontal direction will cause the blade to lose 0.43 mph of ball speed, whereas the cavity back will lose only 0.34 mph, at a clubhead speed of 90 mph. Due to the non-linearity of this relationship, a miss of 15 mm in the same direction equates to a larger disparity: a loss of 3.85 mph for the blade and 3.04 for the cavity back. The higher average efficiency of the cavity back (Table 1) for the player testing suggests that this difference may be tangible to the golfer, and was further supported by the cavity back's more consistent efficiency ($p < .05$), as indicated by subsequent analyses.

Conclusion: The cavity back 5-iron tested as part of this study was found to consistently launch higher, and with greater total spin than the statically-matched blade 5-iron. Both effects could, to some extent, be attributable to the greater effective loft of the cavity back at impact. Robot testing revealed that ball launch variables such as efficiency and launch angle varied less with impact location for the cavity back than the blade. Relationships supporting the likely presence of the 'gear effect' in cavity back impact mechanics were also observed, although strength of association was relatively weak. Although average performance differences between the club types were found at the group level for the player tests, inspection of differences at the participant level indicated that the relative performance of the clubs was far from universal.

ANALYSIS OF THE DELIVERY PLANE IN THE GOLF SWING USING PRINCIPAL COMPONENTS

Morrison, A, McGrath, D, Wallace, E

SESRI, Ulster University, UK

Introduction and Objectives: Although the swing plane has been a popular area of golf biomechanics research, the movement of the club relative to the swing plane has yet to be shown experimentally to have a relationship with performance. Recent studies have shown that only the trajectory of the clubhead near impact can fit to a single plane, while the remainder of the swing deviates from this plane (Kwon et al., 2012; Morrison et al., 2014). As many popular golf coaching texts advocate keeping the club either on or parallel to a particular plane, the movement of the club relative to the delivery plane needs to be explored further.

This study used principal components (PC) and multiple regression analysis to investigate the relationship between the movement of club relative to the delivery plane, and the impact conditions between club and ball. As a delivery plane was calculated for every shot, it was the route by which the club arrived at the plane that was under investigation.

Methods: Fifty-two male golfers of handicap between+4 and 18 participated in this study (handicap 6.6±6.9). Twelve Oqus 300 cameras operating at 1000Hz through Qualisys Track Manager were used to collect and calculate 3D coordinate data (Qualisys AB, Gothenburg, Sweden). Five markers were attached to the face of the club for static capture, and were referenced to 3 dynamic markers attached to the crown of the club. Two pieces of retro-reflective tape 20cm apart were attached near the top of the shaft. Participants hit 40 shots with their own driver into a net situated 10m away from the player, onto which a fairway was projected. The clubhead model was identical to that of Betzler et al (2012), and had been previously validated.The delivery plane was defined as per Morrison et al (2014), and was calculated for every shot. The perpendicular distance of the club face centre from the delivery plane was calculated at specific swing events, along with the angle the two shaft markers formed with the delivery plane. The swing events used were takeaway, mid-backswing, late backswing, top of the backswing, early downswing and mid-downswing (Kwon et al., 2012). Maximum and minimum values of the displacement and angle of the shaft to the plane within each swing were also included in the PC analysis. Diagnostics were carried out and outliers and highly correlated variables were removed according to recommendations by Field (2009).The PCs extracted from the data were then used as predictor variables in a multiple regression analysis. A total of 16 impact related outcome variables were used along with handicap. The impact variables were the same as those used by Betzler et al (2012), in addition to impact location of the ball relative the mean impact location of the player. A further 8 regression models were created for the median absolute deviation (MAD) values of these impact variables. Statistical analysis was carried out using SPSS (Release 22, IBM).

Results: Three PCs were extracted which accounted for 84.7% of the variance in the original data, with individual components accounting for 42.8%, 26.8% and 15.1% respectively. Using the rotated component loadings (fig. 1), the PCs appear to group the variables by swing phase. PC1 appears to represent variables from the top of the swing and the downswing, while PC2 represents the backswing. PC3 appears to account for the remaining maximum and minimum values.

The multiple regression analysis suggested that the PCs account for the most variance in the impact location related variables. Interestingly, it was the variability in impact location rather than the distance from the club face centre that was most highly correlated (table 1).

Conclusions: The movement of the golf club relative to the delivery plane during the golf swing was investigated in relation to the impact characteristics. The results suggest that when the club makes fewer deviations during the swing to arrive at the final trajectory, the precision of ball striking improves. Simplicity in the route and alignment of the club to the final trajectory are important in better ball striking, and should be considered by coaches in their analysis.

Table: Coefficients for multiple linear regression fits between principal components and selected output variables and R2 values for the models

Outcome variables	Constant	PC1	PC2	PC3	R^2
Handicap	6.440	2.630	-3.617	2.376	53.2%
Distance from face centre (mm)	12.666	1.605	-2.232		32.7%
Distance from impact cluster centre (mm)	9.315	1.299	-1.433	1.024	55.9%
Horizontal impact location MAD (mm)	6.720	1.007	-1.404		57.4%
Vertical impact location MAD (mm)	5.113	0.709	-0.680	0.503	43.5%
Distance from face centre MAD (mm)	4.910	0.492	-0.869		34.6%
Distance from impact cluster centre MAD (mm)	4.304	0.533	-0.667	0.466	45.5%

Figure: Graph of the data from the rotated component matrix with variables ordered chronologically through the swing (correlations with a magnitude below 0.4 have been removed) (MBS = mid backswing, LBS = late backswing, Top = top of the backswing, EDS = early downswing, MDS = mid downswing)

BIOMECHANICAL CONSIDERATION FOR IVD TISSUE ENGINEERING

Puay Yong NEO, James C H GOH
Department of Biomedical Engineering
National University of Singapore

The intervertebral disc (IVD) can be found between two vertebrae bodies and consists of i) the gelatinous nucleus pulposus (NP) in the central region, ii) the fibrous annulus fibrosus (AF) surrounding the NP, and iii) the endplates interfacing the disc with the adjoining vertebral columns. During loading conditions, the IVD absorbs and disperses loads - an ability that is intimately related to its capability to absorb and release water. While the interconnected network of collagen and elastin provide the elasticity and general morphology of the NP, the proteoglycans maintain the osmotic pressure, and in turn confers compressive strength, stiffness and viscoelasticity properties to the IVD as a whole. During loading, lateral expansion of the NP is confined by the surrounding AF through i) tension of the AF in the circumferential direction, and ii) compression of the AF in the radial direction.

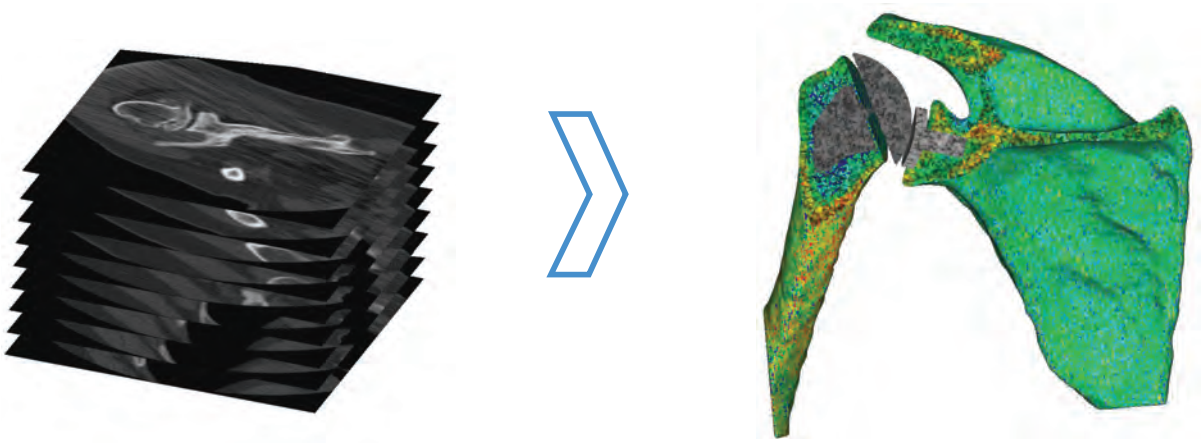
Tissue engineering (TE) offers a promising treatment alternative for degenerative disc disease (DDD) as current options do address the pathophysiology of the clinical problem. With a TE approach, the biology and structural architecture of the IVD can be taken into consideration and perhaps mimicked. Eventual success in clinical translation of a TE strategy for IVD is in turn heavily contingent upon recapitulating not only the structure and composition of the healthy IVD, but in particular its mechanical properties. For example, the AF experiences complex loading conditions, and possesses residual stresses even when the spinal column is unloaded. Hence AF TE strategies not only should target mending the damaged AF to prevent disc herniation and further AF degeneration, but take into consideration the biomechanical compatibility of the TE AF with the native IVD tissue. Another case in point would be TE of the NP. Given the role of the NP in the native IVD, a TE NP strategy considering the relevant mechanical properties such as swelling pressure and confined compression modulus would be paramount in determining its eventual success in clinical translation.

The native IVD is a composite tissue with complex mechanical requirements. For eventual success at the bedside, TE strategies targeting the repair of the IVD as a whole disc or its individual components (NP, AF) not only have to consider the biochemical and mechanical properties of the biomaterials used, but also should take into consideration the appropriate mechanical properties and biomechanical compatibility of the TE construct when integrated with the native IVD tissues.

Mimics® Innovation Suite

Software & Services for Engineering on Anatomy™

With 25 years of expertise, Materialise offers software and services for patient-specific treatment and biomedical research. The Mimics Innovation Suite allows researchers to quickly segment even the most complex anatomical structures. This results in an accurate 3D model which can be used to simulate orthopaedic interventions, optimize your FEA or CFD mesh or prepare musculoskeletal simulations, and all of this within the same software package.



Key Advantages:

- **High geometrical accuracy:** Benefit from the accurate and consistent segmentation in the Mimics Innovation Suite, used by leading researchers
- **Flexible:** Customize the modular software to your unique R&D needs
- **Product quality:** Enjoy the comfort of working with validated, stable software
- **User-friendly:** Segment, measure, design and model directly on your anatomy of interest within one software suite
- **Technical support:** Access our experts for training and further optimizing your workflow

Regulatory Information:
The Medical Edition of the Mimics Innovation Suite consists of the following medical device software components: Mimics Medical version 18.0 and 3-matic Medical version 10.0 (released 2015). Mimics Medical is intended for use as a software interface and image segmentation system for the transfer of imaging information from a medical scanner such as a CT scanner or a Magnetic Resonance Imaging scanner. It is also used as pre-operative software for simulating /evaluating surgical treatment options. 3-matic Medical is intended for use as software for computer assisted design and manufacturing of medical exo- and endo-prostheses, patient-specific medical and dental/orthodontic accessories and dental restorations.The Research Edition of the Mimics Innovation Suite consists of the following software components: Mimics Research version 18.0 and 3-matic Research version 10.0 (released 2015). Mimics Research is intended only for research purposes. It is intended as a software interface and image segmentation system for the transfer of imaging information from a variety of imaging sources to an output file. It is also used as software for simulating, measuring and modeling in the field of biomedical research. Mimics Research must not be used, and is not intended to be used, for any medical purpose whatsoever. 3-matic Research is intended for use as a software for computer assisted design and engineering in the field of biomedical research. 3-matic Research must not be used, and is not intended to be used, for the design or manufacturing of medical devices of any kind. NUMERICAL ANALYSIS OF THE RESIDUAL STRAIN IN ARTERY WALL

Tongtong Guo [1,*] Xueming XIAO [1]

[1]Nature Science Department, Harbin Institute of Technology Shenzhen Graduate School, SHENZHEN, China

Introduction and Objectives:

There exist residual strain in artery wall, which can avoid stress concentration under blood flow and be decided by the vascular material actually. In this paper, we considered the impact of the residual strain and blood pressure in our arterial model, discussed the mechanical response of the arterial wall in different mechanical parameters.

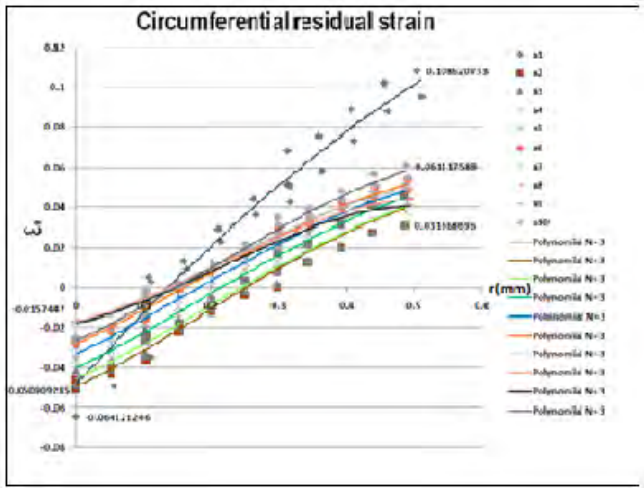
Methods:

We firstly established the three layers anisotropic elastic artery model with fiber reinforced(G.A.Holzapfel, 2000). By applying the displacement boundary conditions, the distribution of the residual strain was simulated under different opening angles; Then altering the two material parameters, C10 and k1, to explore the impact to the residual strain, so do the circumferential stress after loading blood pressure.

Results:

With the addition of the two material parameters under the same opening angle, the residual strain increased as well; As C10 and k1 increased 3 times, the maximum residual stress value increased 2.58 times, the maximum residual strain increased 17.48%(Figure 1). Circumferential residual strain curve along radial direction of artery wall behaved as quasi-linear distributions, taking cubic polynomial fitting, R2=0.943; Keep the parameter abiding to a value, with the increment of opening angle, both of the residual stress and strain increased; The circumferential stress of arterial wall with residual strain varied slowly and deliberately after loading blood pressure, which got in line with the physiological characteristics of the real arterial wall, As C10 and k1 increased 30 times, the circumferential stress of the inner layer increased 1.38times, outer wall is 17.2.

Figure:



Caption: Figure 1

Conclusion:

The material parameters of the arterial wall have a significant effect on the residual strain, which mainly due to the larger p arameters reflect the bigger strain energy value. The study shows that individual differences tremendous impact on arteria l mechanical environment.

REQUIREMENTS AND LIMITS OF A PERSONAL REHABILITATION DEVICE FOR UPPER LIMB

Federico Casolo [1,*]

[1]Dipartimento di Meccanica, Politecnico di Milano, Milan, Italy

Introduction and Objectives: The functional motor recovery is a fundamental pillar for the rehabilitation[1]. The evolution of cognitive disorders, as well as other pathologies directly affecting muscle mechanics, can be profitably countered by intensive physiotherapy or assisted recovery of physiological movements[2].Only personal devices may allow patients intensive care at reasonable costs, psychological and economic. The present work aims to identify clinical-functional requirement of a device for the neuro-motor rehabilitation of the upper limb and to propose a prototype of a simple multifunctional robotic system suitable to equip a standard wheelchair. The project is mainly focused on the needs of neuromuscular patients, but the robotic device may have a much wider field of use. Until now it has been tested by two patients affected by Duchenne muscular dystrophy who collaborate in the research. Assistive devices can be classified as exoskeletons or end-effectors depending on whether they are connected to the arm: at several points or at a single location. The basic requirements of a personal assistive device are: ease of use, set-up and wear, avoiding to overstress natural joints, limited dimensions and cost. Only end-effector devices can fulfill these conditions. Our prototype is an end-effector where a robotic arm is connected to a point of the subject forearm, constraining 3 d.o.f. . A consequence of this architecture is the impossibility to place each segment at any arbitrary position but it is a minor problem because the arm segments always reach physiological positions[3]

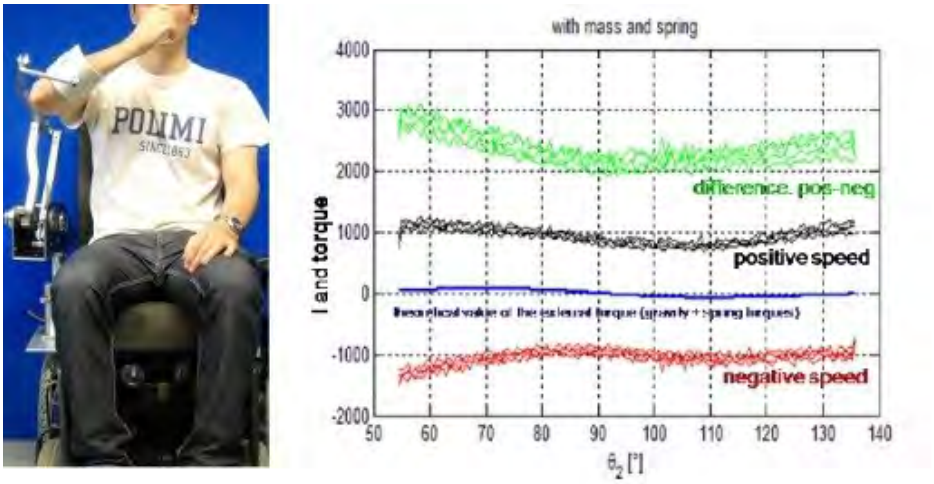
Methods: In order to minimize complexity and cost, only three axes of the system, are active. A dynamical model of the whole system hallows to use the gravitational forces of the limb to obtain the correct arm posture. The device is equipped with three brushless motors powered by four electronic boards appositely designed and communicating via I^2C protocol; one board works as master for the other three, which have simpler tasks. Most of the driving software has been developed with Matlab and the code has been translated into C++. To save weight and volume two of the little flat motors have been coupled with harmonic drives and the other with a planetary gear; a cable transmission is also used. For the same reason a system of spring and cables working against gravity helps to minimize the torque needed and consequently motors size and weight.

The working principle of the device is related to the enabled working model (w.m.) A first w.m. helps the patient to repeat a stereotyped action and is mainly used for physiotherapy, if the subject cooperate his effort is measured and used to monitor the the disease evolution. A second w.m. actively compensates the gravity in order to facilitate autonomous arm movement of weak subjects. With a third w.m. the device helps the subject during the activities of daily living (ADL). For the first and the third w.m.s a mechanical impedance control have been implemented to smoothly follow the hand target. One of the most difficult problems for the second w.m. is related to the efficiency of the transmissions that oppose different resistances at start and during motion. Since it is not possible to predict in which direction the subject would like to move, to compensate the resistance of each transmission in that direction, a new algorithm has been implemented in the control software: it basically applies harmonic torques varying between the values of the two opposite resistance to

the motion until the system start moving and than torques related to the velocity ranges are applied. On the other hand the third w.m. requires to interpret the patient intention to move the upper limb. A simple solution of this problem requires to add force sensors at the arm-machine interface and moreover requires a patient able at least to vary even slightly the force exchanged with the robotic armrest of the wheelchair. Since those sensors are not present in the prototype, the problem has been solved linking the hand motion to the head movement. Some of the already tested algorithms to connect hand target to head kinematics can solve the problem, but their suitability changes subject by subject and can be judged according to the subjects learning curves

Results: Look up tables have been built with many experimental test [fig] to compute the extra torque required to the motors - and the resultant I - in order to balance the resistance of the transmissions to be moved from any angular position, in both directions and with a wide range of possible loads. Some learning curves built for few subject highlight the subjective attitude to drive the hand target with the different algorithms implemented for the third w.m

Figure:



Caption: data to build lookup tables

Conclusion: All three w.m. have been positively tested but the third requires to be refined adding new force sensors

MOTION ANALYSIS OF SIT-TO-STAND ASSISTED BY A WEARABLE ROBOTIC EXOSKELETON IN PATIENTS WITH SPINAL CORD INJURIES

Hsing-Po Huang [1,*] Wu Cheng-Hua [2] Ting-Ming Wang [3] Mao Hui-Fen [4] Jia-Da Li [1] Hong Shih-Wun [1] Hu Jwu-Sheng [2] Tung-Wu Lu [1 3]

[1]Institute of Biomedical Engineering, National Taiwan University, Taipei, [2]Institute of Electrical Control Engineering, National Chiao Tung University, Hsinchu, [3]Department of Orthopaedic Surgery, School of Medicine, National Taiwan University, [4]School of Occupational Therapy, National Taiwan University, Taipei, Taiwan, Republic of China

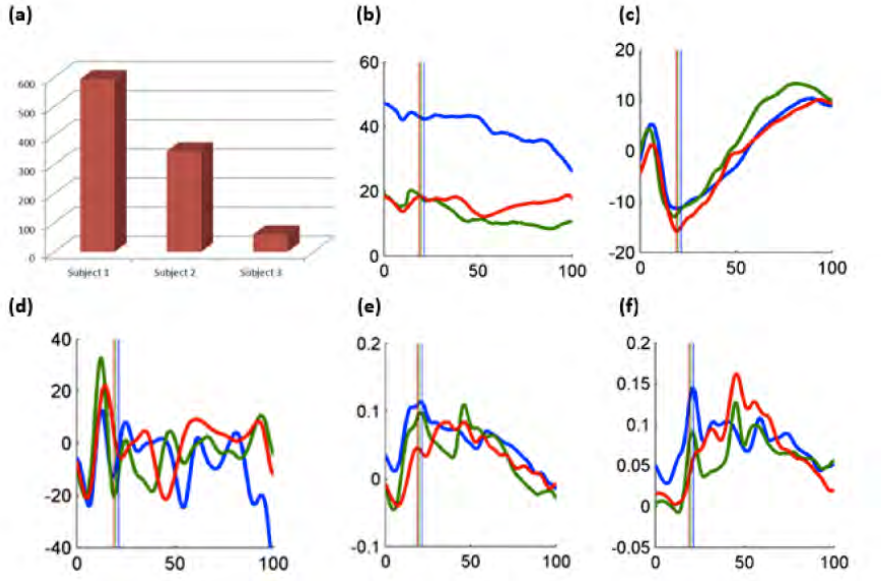
Introduction and Objectives: Decreased or loss of mobility in people with spinal cord injuries (SCI) is a key factor associated with their quality of activities of daily living, and the impact on patients is enormous, including their participation in social, vocational, and recreational activities. Sit-to-stand (STS) is a prerequisite to locomotion, recovery of the function of sit-to-stand will help patients with SCI gain their ability to walk [1]. Patients with SCI need assistance to stand up, either by the great effort of the upper extremities or by other people [2]. Wearable robotic exoskeletons have been proposed to provide assistance to patients with SCI in walking but the performance of such devices in assisting STS has not been documented. Motion analysis has been used widely in the study of human motion and the assessment of assistive technology. The purpose of the current study was to study STS assisted by a wearable robotic exoskeleton in patients with SCI by motion analysis techniques.

Methods: Three patients with complete SCI below T4 participated in the current study with written informed consent as approved by the Institutional Research Board (Table 1). A wearable robotic exoskeleton (WRE) developed by Mechanical and Systems Research Laboratories, Industrial Technology Researcher Institute, Taiwan was used to provide controlled torques to the hip and knee joints to assist STS in patients with SCI (Fig. 1). Thirty-nine retroreflective markers were used to track the motions of the body segments and the WRE, and measured using 8-cameras motion analysis system (Vicon T-40S, Oxford Metrics Group, UK), and measuring the ground reaction forces with 3 forceplates (AMTI, U.S.A.). Ninety degree of hip initial angles and 1400 rpm of angular velocity of WRE were selected. The hip, knee and trunk joint angle and angular velocity was acquired by camera, and internal joint moments of hip and knee normalized to body weight were calculated using inverse dynamics analysis. The energy consumption was calculated by summation of potential energy related to center of mass, translational kinetic energy and rotational energy [3]. The time-varying COP positions were measured by two forceplates during quiet standing. The sway area of the COP was described by an equivalent ellipse, the two principal axes of which were obtained by using principal component analysis [4]. The center of mass position was acquired by the data of Dempster's coefficients.

Results: There were no significant differences of extensor moments of the hip and knee among the SCI subjects (fig. 1e and 1f). Greater sway area of the COP was found in the patient with higher injury level of SCI (S1). The S1 subject also showed greater trunk flexion during sit-to-stand (fig. 1b). In addition, greater trunk angle angular velocity were also found in the S1 subject. The patient who were unexperienced with the wearable robotic exoskeleton showed greater posterior COM related to COP motion during sit-to-stand (fig. 1c). The patient with a higher injury level (S1) had larger COP

traverse (580), whereas patients with lower injury level (S2, S3) had smaller COP traverse (320, 53) (fig. 1(a)). The higher level (S1) can complete the task by a trunk flexion compensatory strategy (fig. 1(b)). Patient with no previous powered HKAFO using experience (S3) had a backward position of COM than S1 and S2 (fig. 1(c)). Greater trunk angle angular velocity were found in S1 (fig. 1(d)).

Figure:



Caption: (a) The 95% confidence ellipse area of the traverse of center of pressure of quiet standing. (b) The trunk flexion angle during sit-to-stand (Blue line: S1/ Green line: S2/ Red line: S3). (c) The inclination angle of COM-COP during sit-to-stand. (d) The trunk angular velocity during sit-to-stand. (e) The hip joint moment during sit-to-stand. (f) The knee joint moment during sit-to-stand.

Conclusion: The results of the current project could help the therapist for designing the training plans for the patients who would use the powered HKAFO. In addition, it was suggested that a subject specific training program is needed according to the patient's physical ability, including the injury level, balance reaction and muscular strength. The adjustment of trunk angle and angular velocity of the powered HKAFO was also helpful for the efficiency of sit-to-stand.

Table:

Code	Height	Weight	Age	Medical history	ASIA level	Injury level	Onset years	Muscle tone	HKAFO training
S1	170	60	36	Force impact	A	T4-7	4.83	Hypotonic	yes
S2	180	59	37	Force impact	A	T10-12	2.5	Hypotonic	yes
S3	170	68	35	Force impact	A	T10-12	1	Hypotonic	none

NEUROMUSCULAR ELECTRICAL STIMULATION TOLERANCE DURING AN EIGHT-WEEK TRAINING PROTOCOL IN ELDERLY WITH KNEE OSTEOARTHRITIS

Matias Fröhlich [1,*]Matheus Joner Wiest [2]Fábio Juner Lanferdini [1]Alexandre Mayer [1]Marco Aurélio Vaz [1]

[1]Neuromuscular Plasticity, Federal University of Rio Grande do Sul, Porto Alegre, Brazil, [2]University of Alberta, Edmonton, Canada

Introduction and Objectives: Neuromuscular electrical stimulation (NMES) is largely used in knee osteoarthritis (OA) treatment aimed at preserving and/or improving knee extensor muscles strength [1-5]. However, NMES treatment effectiveness shows large variability mainly due to the different stimulus parameters used, especially NMES intensity or amplitude. Increases in NMES amplitude are necessary to maintain target muscle strength levels in order to produce the desired muscle adaptions during NMES training. However, increases in NMES amplitude often result in increased discomfort or pain. Knowing the optimal NMES amplitude is important to increase its effectiveness in knee OA treatment. The purpose of this study was to determine the tolerance to increases in stimulation amplitude during eight weeks of NMES training in adults with knee OA.

Methods: Sixteen knee OA patients (♀=14, ♂=2; age = 59.13±8.47 years) participated of an eight-week knee extensor NMES training program. A portable stimulator delivered a symmetrical biphasic current with a frequency of 80 Hz and pulse width of 400 µs to the knee extensors motor point. NMES protocol started with 10 s stimulation trains, with 50 s intervals between stimulation trains. Inter-train interval was reduced in 10 s every two weeks. Treatment time was set at 18 min in the first training week and two minutes per session were added per week up to a total of 32 min. Treatment frequency was set to three times per week. Patients were seated with the knee flexed at 90°. The ankle joint was fixed to the legs of a chair by a strap, allowing for isometric knee extensor contractions during NMES. NMES amplitude was set at the maximum level tolerated based on subject's comfort level, and was increased throughout the session by the subject. The stimulator recorded the mean NMES amplitude values during each session. The mean and standard deviation NMES amplitude (mA) values were calculated for each treatment week.

Maximal isometric knee extensor torque was recorded before and after the NMES training program on an isokinetic dynamometer. Subjects performed three 5 s maximal voluntary isometric knee extensor contractions at 60° of knee flexion (full knee extension=0°). A 2-min interval was used between contractions. Maximal torque was determined from the highest absolute torque achieved during the three contractions. Peak torque values were reported as a percentage increase from pre-training values.

Mean weekly NMES amplitudes were compared using a one-way ANOVA, with a Bonferroni *post hoc* test to identify specific differences (significance level = 5%). Baseline and post-training torque values were also compared with a two-tailed T-Test.

Results: No between-weeks differences were observed for the NMES amplitude for the first four weeks ($p \geq 0.153$), but NMES amplitudes increased from week 4 to week 8 ($p \leq 0.048$; Figure 1A). A 46.47 ± 26.07% increase in NMES amplitude

was observed from the beginning to the end of the NMES training program. The torque showed a 17.02 ± 31.58% increase after the NMES training program (p=0.0001; Figure 1B).

Conclusion: Eight weeks of NMES training increased knee extensor torque by 17%. These results are in agreement with a previous study that evaluated the effects of NMES training on knee extensors torque production capacity [3]. This torque increase is evidence that the stimulation parameters and protocol were adequate and can be used in future NMES training protocols aimed at increasing or maintaining muscle strength.

The accommodation time-course to the NMES amplitude of weeks 1-4 was probably due to skin pain receptors activation and/or afferent neurons adaptive adjustment during the first four training weeks. The 46% increase in NMES amplitude from weeks 4-8 is probably related to increase in pain threshold due to activation of endogenous pain inhibitory systems, generally by local spinal mechanisms, according to the gate control theory [6]. Endogenous opioids, such as dynorphins, enkephalins and endorphins, working mainly at the end-receptors, are among the mediators suggested to play a key role in hypoalgesia during NMES [7].

EVALUATION OF CENTER-OF-PRESSURE DISPLACEMENT IN A STANDING POSITION WITH EYES OPENED AND CLOSED IN OLDER ADULTS

Lindomar Mineiro[1], Suzane K. Martello[2], Elisangela V. Rodrigues[1], Luiza H. Gallo[1], Liliana L. Rossetin[1], Eduardo M. Scheeren[2], Anna R. S. Gomes*[1]

[1]PPGEDF, Universidade Federal do Paraná, [2]PPGTS, Pontifícia Universidade Católica do Paraná, Curitiba-PR, Brazil

Introduction and Objectives: Senescence is associated with a general deterioration of many biological systems, mainly in the locomotor system [1]. Some studies have reported that older adults have greater difficulty in detecting the direction and magnitude of disturbances and they are more dependentof visual input. It limits the generation of appropriate neuromotor action to keep the balance when compared to youngers [2]. Thus, alteration in the visual input is considered an important factor for risk of fall and fractures in aged [3]. Understanding the changes in the postural control of older individuals is important to prevent the loss, reduction, or reverse specific age-related impairments and improve reactive postural control [4]. The aim of the present study was to investigate the visual input in the postural control displacement of female community-dwelling elderly.

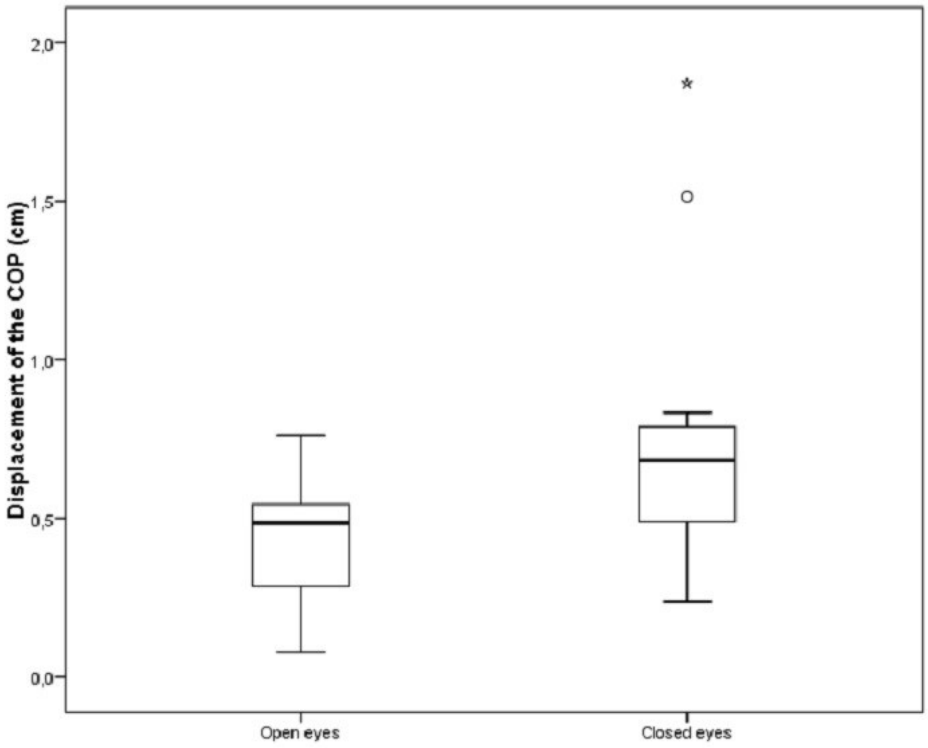
Methods: The study sample consisted in 12 elderly women (74.25 ±5.46 years old) from local community. The postural control was assessed by the center-of-pressure (COP) displacement with the participant in a static standing position through a force plataform (AMTI, OK6-7-2000) [5]. It was performed two experimental conditions, in a standard standing position: the first with eyes opened (EO), looking forward to a fix point 3 m from the plataform; and the second with eyes closed (EC). The participants were oriented to stay in a quite standing position for 30 s. The signals were sampled at 100 Hz and were low-pass filtered using a fourth-order dual-pass Butterworth filter at 10 Hz prior to processing.

It was used MatLab (v.7.10.0) software to calculate COP displacement. Shapiro-Wilk's test revealed data were not normally distributed, considering non-parametric. Wilcoxon was used to compare the two experimental conditions. A significance level of $p < 0.05$ was adopted for all statistical procedures, which were performed using SPSS (v.20.0).

Results: The COP trajectories showed an increase in the displacement when eyes were closed in comparison with opened eyes (0.771±0.476 cm *vs* 0.437 ± 0.203 cm, p=0,041). The data are demonstrated in the Figure 1.

The mean values of COP with eyes opened found in the present study were similar to those described in literature for community-dwelling elderly. However, in the condition with eyes closed the mean values of the present study were under that reported by the literature, showing a better postural control, probably because they presented moderate level of physical activity [6].

Figure:



Caption: Figure 1 - COP displacement with open eyes and closed eyes.

Conclusion: It can be concluded that when eyes were closed the absence of visual input impaired the control of standing balance which increased center-of-pressure displacement for female community-dwelling elderly.

PO-0007

THE EFFECTS OF CORE STABILITY TRAINING ON DYNAMIC BALANCE IN HEALTHY YOUNG STUDENT

Yenting Wang [1 1,*] Alex, J. Y. Lee [2]

[1]Graduate Institute of Athletics and Coaching Science , National Taiwan Sport University, Taoyuan City, [2]Department of Physical Education, National HsinChu University of Education, HsinChu City, Taiwan, Republic of China

Introduction and Objectives: Core stability is the ability to control the position and movement of the central portion of the body. Greater core stability may benefit sports performance by providing a foundation for greater force production in the upper and lower extremities [1]. Core stability training (CST) targets the muscles deep within the abdomen which connect to the spine, pelvis and shoulders, to assist in the maintenance of good posture and provide the foundation for all arm and leg movements [1,2]. On a more significant note, muscle power is derived from the trunk region of the body and a properly conditioned core helps control that power, allowing for smoother, more efficient and better coordinated movement in the limbs.

Methods: Twenty-four healthy collegiate female students (height: 162.3 ±6.0 cm, weight: 54.1 ± 16.3kg, age: 20.1 ± 1.4 yrs) from university participated in this study. All participants completed a self-report health history questionnaire and signed a written informed consent before testing.

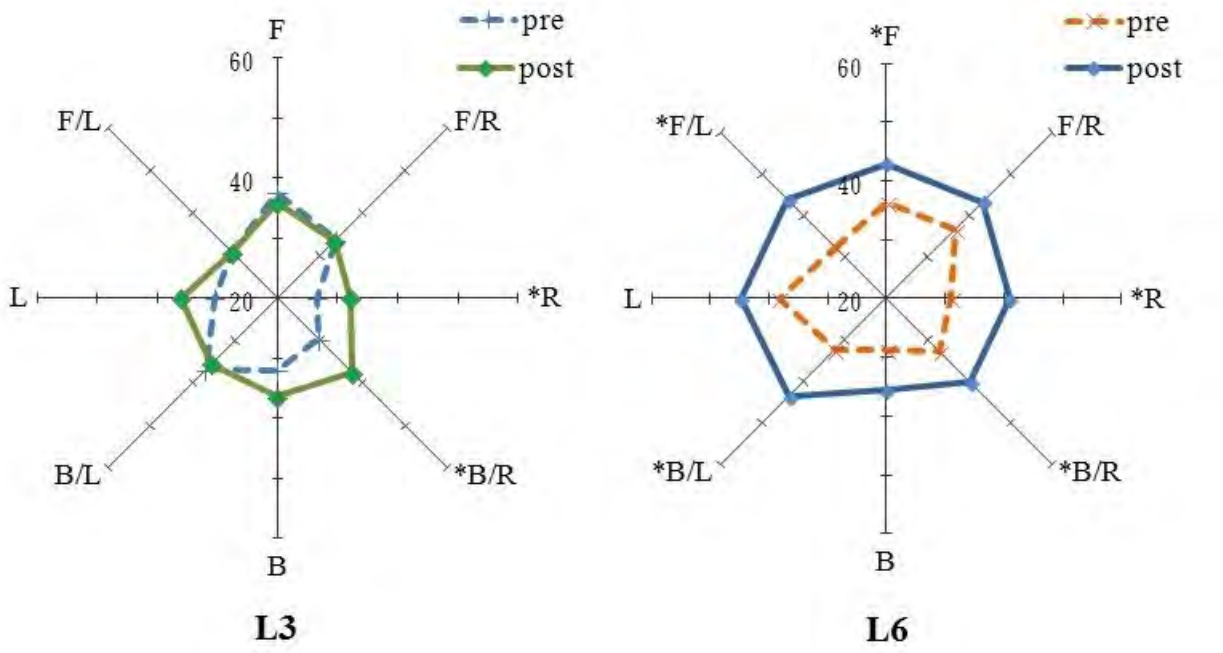
The CST was combined the pilates and Swiss ball exercise altogether in ninety minutes, twice per week, for six weeks. Guidelines from the United States aerobic fitness association was followed, including warm-up exercise, the main movement along with three phases in order promote a progressive manner, and impose different intensity at different stages of the training protocol as well as strengthen the abdominal muscle strength and lower limb muscle strength.

The dynamic balance was evaluated by the 8-direction limits of stability (LOS) test. Subjects were tested bilaterally at two levels of difficulty: 3 and 6. To control for the learning effect and fatigue, the order of the tests was randomly assigned. The subject was instructed to start moving the cursor which accurately moves the display toward the flashing target at eight different directions. The LOS score was calculated for each direction according to the percentage between the straight line distance to target and the number of samples.

Repeated-measures t test were used to examine the differences in each parameter before and after training. For all analyses, the level of statistical significance was set at $P < .05$.

Results: The LOS performance in right (26.6 ± 14.4 vs. 32.1 ± 14.2) and backward-right (29.8 ± 14.7 vs. 37.5 ± 17.0) directions at level 3 was significant improved in post-training than pre-training. Furthermore, The LOS performance in overall (27.7 ± 9.2 vs. 38.9 ± 11.3), right (30.9 ± 12.3 vs. 40.9 ± 13.3), forward-right (32.3 ± 12.4 vs. 43.9 ± 14.3), backward-right (32.9 ± 9.6 vs. 40.2 ± 14.5), and backward-left (32.5 ± 12.7 vs. 43.4 ± 17.3) directions at level 6 was significant improved in post-training than pre-training (Figure 1)

Figure:



Caption: Comparisons of the LOS scores in each direction between groups before and after training.

Conclusion: Finding of this study showed significant improvement in the overall performance on the stable, level 6 LOS test indicates that a 6-week period of Core training can improve dynamic postural stability. This study provided support for this hypothesis, since it showed that CST could facilitate voluntary active postural and lower extremity corrections during the unstable LOS test.

The CST appears to be effective in improving flexibility, dynamic balance in healthy young students.

PO-0008

COMPARISON OF THE EFFECT OF NEUROMUSCULAR BALANCE TRAINING AND EXTERNAL ANKLE SUPPORTS ON BALANCE PERFORMANCE IN NETBALL

Alice Fisher-Edwards [1] Saeed Fayaz [1] Dawn Ridgway [1] Eddie J. Bradley [1,*]

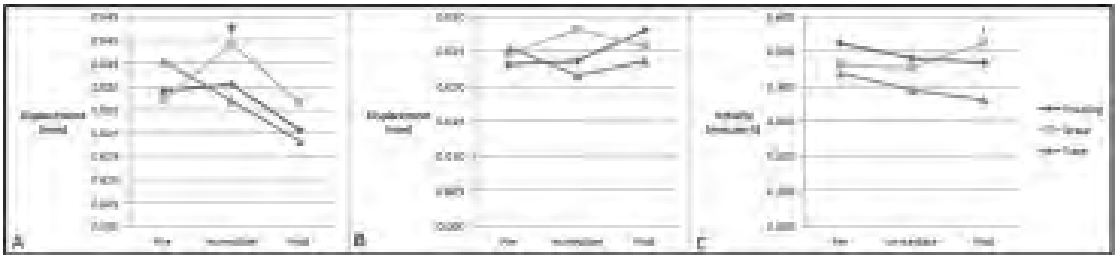
[1] Sport, University of Sunderland, Sunderland, United Kingdom

Introduction and Objectives: Netball is a fast-paced goal-scoring ball sport with a demand for high-intensity movements such as running, jumping, passing, and shooting. The game is characterised by rapid changes in acceleration to break free from the opposition or to change direction suddenly. As such, netball has a high injury rate. McManus et al [1] reported an incidence of 14 injuries per 1000 player hours with an overall lower limb injury rate of 92.4%. Between 30% and 84% of injuries sustained by elite netball players occurred in the ankle [1-3], with 34% to 71% being ligamentous injuries. The application of prophylactic ankle devices are commonplace in netball, usually a semi-rigid brace or tape, that are designed to increase stability at the ankle by restricting range of motion[4,5] and improving proprioception [6,7]. The benefit of proprioceptive training in reducing injury incidence in previously injured athletes has been identified [8] but it is not known if it has the same effect in netball players with no history of ankle injury. Balance training is an effective way of improving stability and can easily be incorporated into regular training sessions. The aim of the study was to determine if balance training was effective as routinely used prophylactic ankle devices in maintaining stability in a group of netball players.

Methods: Experimental cross-sectional design. 15 previously uninjured female university netball players (aged 18-21) were randomly assigned to a training, semi-rigid brace or tape group (each n=5). The participants in the training group completed a six-week balance training regime, three times a week on a Biodex Balance Trainer. The training consisted of a unipedal postural stability test, an athlete single leg stability test, a bipedal limits of stability test, and maze test that increased in dificulty over the six-week period each session. Participants in the device groups were instructed to wear a semi-rigid brace or zinc oxide tape in a figure of 8 technique on the weaker ankle, identified using a Lafayette Manual Muscle Tester, during normal training and matches. Antereo-posterior (AP) and mediolateral (ML) displacement and centre of pressure velocity (CoPVel) measures were recorded on a Pasco force platform pre, immediately following application of brace or tape or after the first training session, and at the end of the six-week training program. Differences in balance measurements were compared between ankle stability conditions and time periods using a two-way ANOVA (ρ=0.05).

Results: No significant differences were found for AP sway or CoPVel between the groups at any time period. Mediolateral sway improved in the tape condition, however this was not significantly lower than the training group after six weeks (Figure 1).

Figure:



Conclusion: The use of tape and braces is routine in netball but the current literature is undecided on its effectiveness, especially in previously uninjured players. This study compared the effects of a neuromuscular balance training program with common prophylactic ankle supports on balance performance in an uninjured sporting population. The training group displayed similar changes in stability as both the brace and tape groups over the six week period. The findings of this study are similar to the 10% improvement in Star Excursion Balance Test (SEBT) composite scores after an eight-week neuromuscular training program applied to a group of female soccer players [9]. While Ozer et al [6] identified that neuromuscular balance performance, including single leg balance and proprioception assessment, were similar between bracing, tape, and barefoot conditions in a group of non-sporting males, balance was exclusively used as a measurement tool and no neuromuscular training was involved. The six-week training program provided similar proprioceptive and mechanical benefits around the ankle joint as the brace and taping, resulting in comparable improvements in balance performance. In conclusion, a six-week proprioceptive training program was as effective in improving balance as the application of tape or brace in a cohort of netball players and the necessity of such devices, especially if previously uninjured, should be reconsidered.

PO-0009

ANALYSIS OF BALANCE CONTROL BY MEANS OF COM AND COP FLUCTUATIONS DURING SUSTAINED SWISS PRESS HAND STAND MOVEMENT

Kazuo Funato [1,*] Hisashi Mizutori [2] Yu Kashiwagi [1] Noriko Hakamada [3] Tsuyoshi Nobukuni [4]

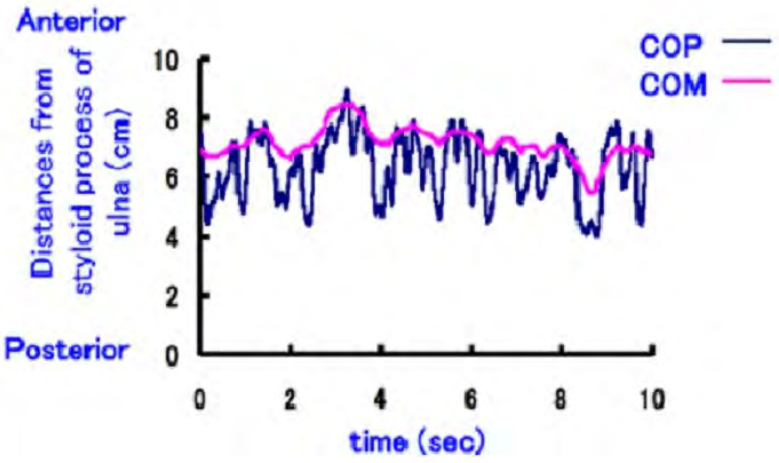
[1]Graduate School of Training Sciences, Nippon Sports University, Tokyo, [2]Keio University, Fujisawa, Kanagawa-pref, [3]Japan Institute of Sports Sciences, Tokyo, [4]Hiroshima Senior High School, Hiroshima-city, Japan

Introduction and Objectives: Hand stand Swiss press movement is one of the fundamental and important techniques in gymnastics. This study was designed to examine how to get stable balance during isolated Swiss press by comparing Japanese world class and junior national gymnasts. As one of the research on the balance control of hand stand, frequency analysis on center of mass (COM) during hand stand indicated the greatest power spectrum existed below 1Hz (Clement and Rezette, 1985). This study focused on the balance control by means of COM as well as center of pressure (COP) fluctuations in the A-P direction during 10s sustained hand stand movement.

Methods: Hand stand movement was performed on a force platform (9287B, Kistler Co., sampling rate: 1 kHz) and was recorded with high speed camera (A602fc-2, BASLER, H6x8- 1.0, SPACE Inc., 100fps). X-Y coordinates of COP was recorded from force platform as long as sagittal plane X-Y coordinates of COM from video analysis. Reflective makers were positioned on the left side of the subject. Body segment angle (thigh, trunk, and forearm), joint angle (shoulder and hip), center of mass (COM), center of pressure (COP), moment arm of COM, and moment around COM were calculated. COM was calculated by Winter's method based on Dempster (1955) body segment data. Subjects were male Japanese junior high class gymnasts (n=44, age: 15.4 +/- 1.9 years old, height: 154.3 +/- 11.5cm, weight: 48.7 +/- 10.4kg). Each subjects performed twice sustained hand stand movements for 10 seconds, one of two trials was taken for the analysis. Frequency analysis in A-P fluctuations of COP and COM were examined by Fast Fourier Transform (FFT) methods.

Results: Skilled subjects had larger trunk segment angle, larger shoulder joint angle, smaller hip joint angle, and smaller moment around COM than unskilled subjects. COM of skilled subjects positioned upon COP vertical line even at the beginning of toe-off phase. This could be suggested that enough flexibility of shoulder and hip joints, as well as sufficient muscle strength to keep the stretched position might essential to stabilize the Swiss press. Mean frequency in maximum power spectrum in COP and COM were shown at around 0.47 +/- 0.36 Hz and 0.30 +/- 0.15 Hz, respectively. Whereas mean frequency in COP fluctuations have characterized as another high power spectrum at around 1.21 +/- 0.51 Hz. This result was similar to previous study by Clement and Rezette (1985) describing the COP fluctuation around 3.0Hz during hand stand. Higher frequency component in COP might contribute to minimize the fluctuation of COM.

Figure:



Caption: Typical example of COP and COM fluctuations during Swiss press hand stand in A-P direction.

Conclusion: It was estimated that the high power spectrum frequency band of COP might contribute to control the balance during sustained hand stand movement. Wrist strategy as well as high flexibility of shoulder and hip might be stressed in order to keep the balance in stable during hand stand Swiss press.

CHRONIC EFFECT OF FLEXIBILITY TRAINING ON POSTURAL BALANCE IN ELDERLY WOMEN PRACTITIONERS WATER AEROBICS

Elciana D. P. L. Vieira [1,*] Flávia Porto [2] Edmundo Drummond Alves Júnior [1] Jonas Lírio Gurgel [1]

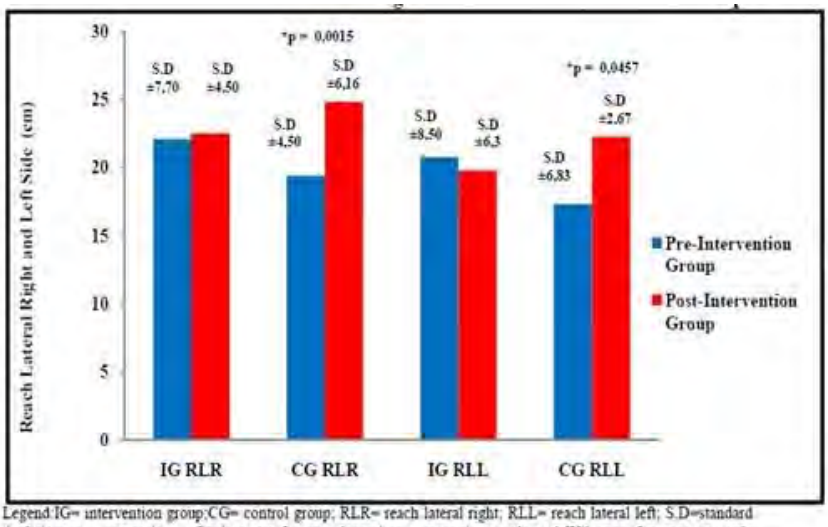
[1]Physical Education, Federal Fluminense University, Niterói, [2]Physical Education, University in the State of Rio de Janeiro, Rio de Janeiro, Brazil

Introduction and Objectives: The aging process involves a series of changes that may lead to impairment of performance of daily activities and increase the risk of falling. Among the various risk factors, weakness of postural balance and the loss of flexibility were chosen for study because of a possible relationship between them. This study aimed to examine the chronic effect of flexibility training on postural balance in elderly women practitioners of water aerobics belonging to the Prev-Quedas Project. The other objective was to identify correlations between the values of Δ goniometric those concerning testing of postural balance in both groups.

Methods: The subjects consisted of participants only in a water aerobics program, selected from non-probabilistic way meeting the eligibility criteria. Were excluded those with diseases, diagnosed by a doctor, that compromised postural balance. Also were excluded from the study participants who had two or more consecutive missing sessions weekly on proposed training without replacement had occurred in the same week or at least on week after missing. Two groups were formed: the intervention group (IG) comprised of 25 elderly women who participated in a program with flexibility exercises, in addition to water aerobics and the control group (CG) comprised of 21 elderly women who underwent only in water aerobics. The flexibility training lasted three months, with a weekly frequency of two non consecutive days. The static range of motion exercises involving trunk and lower limbs. The two groups underwent an evaluation: anthropometric (body mass index and circle measures of chest, waist, abdomen and hip), cognitive capacity, handgrip strength, the ability of functional and lateral reach, static stabilometry, the time spent on one foot and maximum range of motion of trunk, hip and ankle joints (goniometry). Both groups were assessed before the intervention began (pre-intervention) and after (post-intervention). Shapiro-Wilk test was used to analyze the normality of data. To compare the two groups, Student t test for paired and independent samples (parametric data) or Mann-Whitney and Wilcoxon for nonparametric data were used. Pearson correlations were used to correlate for the parametric and Spearman for nonparametric data. The level of significance was $p \leq 0,05$ for all tests.

Results: The IG showed significant improvement in the maximum range of motion of the hip and ankle joints, before and after the intervention, when compared to CG who got the same result only in the ankle joint. However, the CG demonstrated significant improvement in the ability to reach for both sides beyond the average speed and total displacement of the COP in the anteroposterior axis (COPy) with eyes open. However, the same group showed a reduction in the time spent on one foot. Also, no significant correlations were found between the values of Δ goniometric for those regarding testing of functional and lateral reach, static stabilometry and one leg support for both groups.

Figure:



Legend:IG= intervention group;CG= control group; RLR= reach lateral right; RLL= reach lateral left; S.D=standard deviation; p = comparison t Student test for two dependent parametric sample and Wilcoxon for nonparametric sample; * p ≤ 0,05.

Conclusion: Therefore, flexibility training associated with the practice of water aerobics not had significant results on postural balance in elderly women, although promoted increases on the maximum range of motion on the hip and ankle joints. According to the results of this study, the water aerobics exercises appears to contribute for improvements of postural balance and increases the range of motion on ankle joints.

TWENTY MINUTES SEEMS TO BE NOT ENOUGH TO RECOVERY QUADRICEPS MUSCLE FATIGUE FOR WALKING

Fabio A. Barbieri [1,*] Stephannie Beretta [2] Victor Beretta [2] Lucas Simieli [2] Diego Orcioli-Silva [2] Paulo Santos [2] Jaap van Diëen [3] Lilian Gobbi [2]

[1]Physical education, Univ. Estadual Paulista - Bauru - Brazil, Bauru, [2]Physical education, Univ. Estadual Paulista - Rio Claro , Rio Claro, Brazil, [3]MOVE Research Institute Amsterdam, Faculty of Human Movement Sciences, VU University Amsterdam, Amsterdam, Netherlands

Introduction and Objectives: Quadriceps muscle fatigue reduces gait stability [1,2] by changes in the spatial-temporal [1-4], kinetics [3-4] and muscle activity [4,5] parameters. Around 23 to 30% of falls in the job occur because the fatigue [6]. Given the negative effects of muscle fatigue on gait, it is important to understand the recovery period of spatial-temporal, kinetics and electromyography parameters after muscle fatigue. The aim of the study, therefore, was to investigate the effect of different recovery periods after quadriceps muscle fatigue on gait in young adults.

Methods: Forty individuals aged between 20 and 40 years old (age: 28.85±5.00 years old; body weight: 78.61±14.00 kg; body height: 1.76±0.06 m) participated in this study. The participants performed the following tasks: i) walking in regular environment: the participants performed 3 trials at preferred velocity and walked 8 meters on each trial, ii) maximal isometric voluntary contraction protocol (MVC): 2 trials in each period performed on a Leg Press instrument; iii) fatigue induction protocol: quadriceps muscle fatigue was inducted by repeated sit-to-stand task until voluntary exhaustion; iv) the first and second items were repeated after muscle fatigue, and after 5, 10 and 20 minutes of passive rest. The spatial-temporal (stride length, stride duration, stride velocity, step width and double support time), kinetic (braking and propulsive anterioposterior impulses) and electromyography (root mean square of vastus lateralis and biceps femoris of the right limb) parameters were analyzed before and after the muscle fatigue protocol and after 5, 10 and 20 minutes of passive rest. These parameters were measured in the central stride on each trial. Data were compared by ANOVA with repeated measures for time periods (before muscle fatigue X after muscle fatigue X 5 minute of rest X 10 minutes of rest X 20 minutes of rest).

Results: The MVC decreased after muscle fatigue protocol ($p<0.001$) and after the 5, 10 and 20 minutes of recovery compared with before muscle fatigue protocol. For gait parameters, step width ($p<0.001$) and RMS of biceps femoris ($p<0.05$) increased immediately after muscle fatigue and remained increased after the recovery periods – 20 minutes (Table 1). In addition, for the stride duration ($p<0.001$) there was a decrease in the value immediately after fatigue induction when compared with the period before muscle fatigue and 10 and 20 minutes of rest. The anteroposterior propulsive impulse ($p<0.001$) was also decreased after the muscle fatigue protocol and remained low after 5, 10 and 20 minutes of rest.

Conclusion: We concluded that 20 minutes is not enough to recover the gait parameters, especially parameters related to gait stability. The findings indicate that the modulations of gait, caused by muscle fatigue, are quite persistent and may be an effect of the persistent decline of muscle strength.

Table: Table 1. Means and standard deviations of the spatial-temporal, kinetics and electromyography parameters before (BF) and after (AF) muscle fatigue and after 5 (AF5), 10 (AF10) and 20 (AF20) minutes of rest. * - before fatigue is significantly different the other muscle fatigue period; # - before fatigue is significantly different the after fatigue and 10 and 20 minutes of rest.

PO-0012

PRE-IMPACT FALL DETECTION WITH THE REMOVAL OF GRAVITY EFFECT

Soonjae Ahn [1,*] Isu Shin [1] Jaesung Ryu [1] Youngho Kim [1]

[1]Department of Biomedical Engineering, Yonsei University, Wonju, Korea, Republic Of

Introduction and Objectives: Falling is a major cause of injuries and deaths in older adults [1]. Even though most falls produce no serious injury, 20-30% of fall-related patients will suffer moderate to severe injuries. Furthermore, some of them require hospitalization to continue living in community and have an increased risk of death [2]. As for intervention strategies, one of the important problems in preventing or reducing the severity of injury in the elderly is to detect falls in its descending phase before the impact [3, 5]. Many studies have been performed to detect pre-impact falls using accelerometers [3-5], but did not remove gravity effect, since the gravity can some errors.

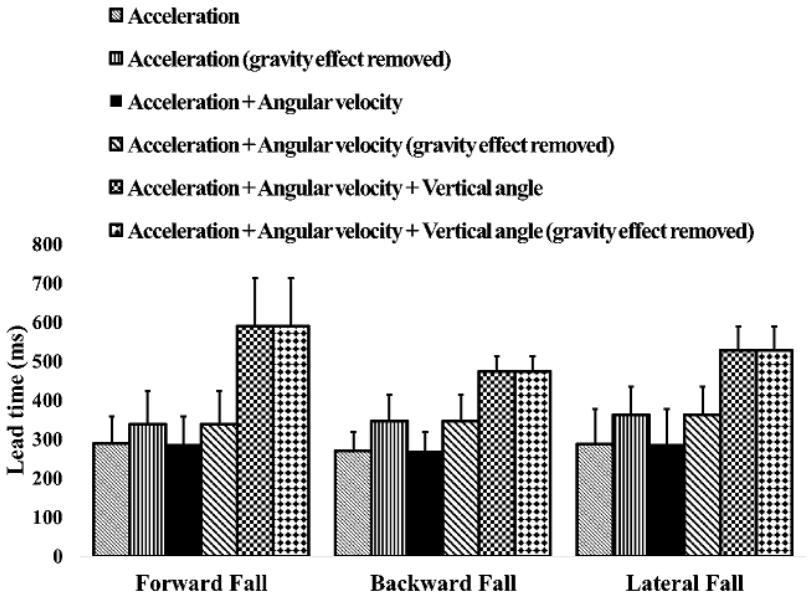
In this study, six different protocols based on different sensor configurations and with/without the gravity removal were tested in order to detect falls before impact. Three different protocols used acceleration with gravity effect removed. Then, lead time, sensitivity and specificity were also compared among different protocols.

Methods: Forty healthy male volunteers (23.4 ± 4.4 years, 68.7 ± 8.9 kg, 172.0 ± 7.1 cm) participated in the present study. In faint fall simulations, the subjects were told to stand on the floor beside the mattress. Then they fell by simply relaxing to the front, back, and lateral. All falls were conducted on the soft foam mattress for five times respectively. A chair and the mattress were used for ADL trials (sitting, sit–stand transitions, walking, stand–sit transitions and lying). Each activity was conducted for three times.

MPU-9150 (Invensens®, USA) containing a 3-axis accelerometer and a 3-axis gyro sensor was used for the pre-impact fall detection sensor module. It was attached on the middle of the left and the right anterior superior iliac spines. Data was sampled at 100Hz. Totally six different protocols were tested: acceleration, acceleration (gravity effect removed), acceleration + angular velocity, acceleration + angular velocity (gravity effect removed), acceleration + angular velocity + vertical angle, acceleration + angular velocity + vertical angle (gravity effect removed). To remove the gravity, the algorithm proposed by Moe-Nilssen [6] was applied to the raw acceleration signal. This algorithm is based on a simple trigonometric computation and transforms. When using raw acceleration signals, the detection threshold was set 0.4g, but 0.6g when the gravity effect was removed. When acceleration and angular velocity were used, thresholds of acceleration and angular velocity were set to 0.4g, 30°/s but 0.6g when the gravity effect was removed. When acceleration, angular velocity and vertical angles were used, thresholds of acceleration, angular velocity and vertical angle were set to 0.9g, 30°/s and 30° respectively.

Results: Table 1 showed the sensitivity and the specificity for six different protocols. Most false-positive errors occurred during stand-sit transition without considering vertical angle. However, when considering vertical angle, results showed 100% sensitivity and 100% specificity. Means and standard deviations of lead times for three types of falls were shown in Figure 1. When the vertical angle was not considered, with gravity effect removed, the longer lead time was observed. When using vertical angle, the lead time was the longest and no effect was found for gravity removal.

Figure:



Caption: Lead time

Conclusion: In this study, six different protocols based on different sensor configurations and with/without the gravity removal were tested in order to detect falls before impact. For a long lead time, it is necessary to use acceleration and to remove gravity effect in pre-impact fall detection. 100% sensitivity, 100% specificity and the longest lead time were found when vertical angle data was used in addition to acceleration and angular velocity data. Consequently, for the faster and more accurate detection, vertical angle data is required.

PO-0013

THE RELATIONSHIP BETWEEN DYNAMIC AND STASIC ABILITY OF POSTURAL STABILITY AND BODY COMPOSITION IN JAPANESE OBESE CHILDREN

Noriyuki Yamamoto [1,*] Yoshiya Ito [1] Sharon Hanley [2] Hitoshi Yanagi [3] Tadashi Wada [4] Fumiko Takenoya [5] Yukinori Shintaku [6]

[1]Japanese Red Cross Hokkaido College of Nursing, Kitami, [2]Hokkaido University, Sapporo, [3]Kitami Institute of Technology, Kitami, [4]Kokushikan University, [5]Hoshi University, Tokyo, [6]Biwako Seikei Sport College, Ohtsu, Japan

Introduction and Objectives: Overweight in children leads to decreased ability to balance the body. In childhood and adolescence fractures of the distal forearm (wrist) are extremely common, affecting 1% of the pediatric population aged 3–15 years annually [1]. A previous study has shown that overweight children and adolescents have a greater risk of sustaining these fractures than leaner children [2]. Although neural regulation of the plantar flexor muscles is essential in the control of postural sway as mentioned above, the muscle properties, such as muscle volume and strength, around the ankle joint can also affect postural stability as the muscle is the effector of the neural command. Studies have shown that muscle strength is associated with the incidence of falls [3,4], and that the muscle strength of the plantar flexors is correlated with the limit of stability [5]. However, the relationship between postural stability during quiet standing and muscle volume in obese children has not been explored at all. The purpose of this study was to investigate relationship between dynamic and static ability of postural stability and body composition in Japanese obese children.

Methods: Twenty-two obese children (male:16, female:6, age 8-12yrs, height 141.0±9.9cm, body weight 46.8±10.4kg, BMI 23.2±2.6kg/m^2, %fat 33.0±6.0%) subjects participated in this study. Before the experiment, all procedures and any potential risks were explained to each subject, and an informed consent document was signed previous to participation. This study was approved by Japanese Red Cross Hokkaido College of Nursing Review Board for Health Sciences Research Involving Human Subjects. The body composition of the subjects was measured by bio-impedance method (BC-612, TANITA, Tokyo, Japan). Postural sway was recorded by detecting the body's center of gravity continuously with a force platform equipped with a data processor (Gravicorder G-5000, Anima, Tokyo, Japan). Subjects were requested to stand on the platform with their feet parallel, gazing at a target, a black circle with a diameter of 10cm on a white background, fixed at a 2.0m distance and at the height of each subject's eyes. This arrangement of the visual target produced a visual angle of 5°. The body sway of each subject was recorded for 30 seconds, first with the eyes open ($EO_{two\ legs}$) and next with eyes closed ($EC_{two\ legs}$). Similarly, the subjects were asked to keep one leg on the platform and the other leg elevated, aligned with the contralateral malleolus and with the hands placed on the waist. The subjects were instructed to stand as still as possible, first with the eyes open ($EO_{one\ legs}$) and next with eyes closed ($EC_{one\ legs}$). The one leg task was recorded duration of the first contact to grand and contact times during 30 seconds. During each task, the foot center of pressure (COP) position and horizontal ground reaction force were measured. The path length of COP and area of body sway were registered. All data are expressed as means ± SD. Correlation analysis was also performed between the variables with the subjects to investigate the effect of body composition on a wider range of postural stability. Significance level was set at the $p < 0.05$.

Results: A significant negative correlation was found between the skeletal muscle volume and the path length of COP in $EC_{two\ legs}$ ($r = -0.590$, $p < 0.05$). In contrast, there was no significant correlation between the skeletal muscle volume and the path length of COP in $EO_{two\ legs}$. A significant negative correlation was obtained between the skeletal muscle volume and the path length of COP in both eye condition of one leg task ($EO_{one\ leg}$: $r = -0.574$, $p < 0.05$, $EC_{one\ leg}$: $r = -0.654$, $p < 0.05$). Therefore, there was found a significant negative correlation between the %fat and the path length of COP in $EC_{one\ leg}$ ($r = -0.547$, $p < 0.05$). On the other hand, there was no significant correlation between %fat and the path length of COP in $EC_{two\ legs}$, $EO_{one\ legs}$, $EO_{one\ legs}$.

Conclusion: The present study compared postural sway measures, such as the path length of COP and area of body sway during one leg and both feet standing, and the correlation between postural sway and body composition in Japanese obese children. The main findings were that the muscle volume was negatively correlated the path length of COP in $EC_{two\ legs}$, $EO_{one\ legs}$, $EC_{one\ legs}$. However, as the correlation does not necessarily indicate a causal relation, further physiological studies are required. In the present study, we indicated that one leg and both feet standing ability of the obese children depends on the skeletal muscle volume. The present study suggested a high risk of fall into the obese children during the exercises.

EFFECT PROPRIOCEPTIVE TRAINING IN THE POSTURE BALANCE OF GYMNASTICS RHYTHMIC ATHLETES

Rodrigo F. D. Oliveira [1,*] Deise A A Pires-Oliveira [1] Larissa D Bertin [1] Stheace K F Szezerbaty [1] Juliana Serpeloni Almeida [1] Ana Claudia S. Hirata [1]

[1] Centro de Pesquisa em Ciências da Saúde, Universidade Norte do Paraná - UNOPAR, Londrina, Brazil

Introduction and Objectives: Rhythmic gymnastics (GR) is a sport that Brazil has gained significant results, a process of expansion in international competitions in the last years[1], [2]. The good results are coming from the organization and implementation of a multidisciplinary approach, which aims at the harmonious development of the gymnast, as well as the adaptation of his body to the requirements of modality.[1,2]

Physical demand movements, lack of concentration, poor posture and insufficient or incorrect physical preparation can cause great risk of injury to athletes. The higher incidence of injuries in GR are the joint, knees, ankles and some cases in hand ends. Lesions also vary according to their severity and can occur from tendonitis (tenosynovitis) to a more serious injury with ligament ruptures and fracture[3].

The proprioceptive re-education aims to develop joint protection through conditioning and reflective training, one of the final steps of the whole rehabilitation process and fundamental in functional recovery. Studies show that instability and imbalance are related to this type of training situations and are essential in order to have activation of proprioceptors, and result in a muscular response to the reorganization and posture stabilization. [4, 5]

Due to the increasing number of sports injuries and mainly the high incidence of injuries in the ankle joint GR practitioners athletes, evolving into frames of joint instability, there is a need for evaluation programs and proprioceptive intervention.

The objective of the project is to evaluate the influence of proprioceptive training on postural balance Rhythmic Gymnastics athletes - GR.

Methods: Nine subjects participated in this research, female, mean age between 13 to 16 years, from the GR team UNOPAR, Londrina / PR. Subjects were excluded undergoing surgical procedures or who had musculoskeletal injuries in the lower limbs and / or who were in clinical and physical therapy.

After the explanation and signing the Consent and Informed by the legal guardian of each athlete, began the exercise protocol. The protocol was performed twice in the week prior to GR training in order preventing any muscle fatigue.

The first parameters in the force platform BIOMEC400 (EMG System of Brazil, SP Ltda) were measured; called pre-intervention. Then the application of a specific proprioceptive protocol lasting 4 weeks, and reviewed in force platform called post intervention.

The protocol consisted of a circuit with the following devices: step down; balance beam; bosu; proprioceptive inflatable disc, trampoline, slide. Where the athletes performed the sport movements under appliances

Results: When evaluated the COP area, the three tested positions, it was observed that after the intervention there was an improvement in the balance of one leg right and onde leg left positions, as well as bipedal balance also showed a significant improvement. According to the results, we can see that according to the variables analyzed, there was an

improvement of proprioceptive mechanism after 4 weeks of intervention in the area of the COP and Vel AP and ML, noting that the lower the values found, the better the result.

All statistical procedures were performed using the SPSS 17.0 has been established at the 95% confidence interval and 5% significance level software for all tests (P <0.05). We used the Shapiro-Wilk test to establish the normality of the sample, T Wilcoxon test was used to compare the two times for the same individual. The respective data are presented as median and the quartiles.

PO-0015

THE EFFECT OF BAREFOOT COBBLESTONE WALKING ON PATTERNS OF LIMB MOVEMENT

Bruno G. Straiotto [1,*] Darren C. James [1] John P. Seeley [1]

[1]School of Applied Science, London South Bank University, London, United Kingdom

Introduction and Objectives: Understanding how individuals adapt their gait when walking over different surfaces can have important implications in relation to locomotion generally and for individuals whose movement is compromised by disease or ageing. The objective of this study was to examine body segment coordination of human gait for movement over two different surfaces. This was achieved using standard kinematic analysis techniques and through application of principal component analysis (PCA) to the data obtained.

Methods: Eight subjects (2 females, 6 males; age 33±5 years; mass 76±14 kg; height 1.7±0.1 m (mean±SD)) performed barefoot walking trials across a flat surface (FS) and a destabilizing cobblestone surface (CS). Movements in each condition were recorded in three dimensions from a set of reflective markers placed over 35 anatomical landmarks. Marker positions were recorded using an eight-camera, motion-capture system at 60 Hz. The walking data were normalized to a constant gait cycle using a standard method ("normalized to 101%"). The marker coordinates were interpreted as 105-dimensional posture vectors. These vectors were centred and re-scaled to unit variance for each trial and submitted to PCA to identify the principal movement components (PMCs) for each condition.

Results: The first four principal components covered approximately 90% (FS) and 92% (CS) of data variability. The PMC eigenvalues in % were as follows (FS then CS): PMC1, 46.4±2.1, 52.6±4.9; PMC2, 22.6±4.9, 21.7±5.1; PMC3, 14.2±2.2, 12.4±2.5; PMC4, 9.1±2.1, 7.2±1.9 (mean±SD). PCA decomposition of the main movement patterns of gait allowed identification of significant differences in PMC1 ($p=0.02$), PMC3 ($p=0.04$) and PMC4 ($p=0.01$) between FS and CS. The eigenvector coefficients provided information about the contribution of different body segments to particular movement components. For both conditions, several of the PMCs were related to forward movement, and for CS bodily adjustments in relation to posture and balance were recorded.

Conclusion: In this study, the spectrum of eigenvalues that quantify the strength of individual movement components in the data set provided only limited insight into the changes in movement patterns. Different PMCs were used by the subjects as means to control their stability for movement over the destabilizing surface. The approach of PCA has theoretical benefit as the PMCs describe the behaviour of the whole system without use of pre-selected variables and may access "hidden variables" inherent to the body's movement patterns. There were differences in PMCs associated with the subjects' strategies to control their stability when the system was affected by external factors - in this case the uneven nature of the cobblestone surface. In this study it appeared that eigenvalues were somewhat insensitive to movement change.

THE EFFECT OF AGE ON THE SOMATOSENSORY, VISUAL AND VESTIBULAR CONTRIBUTIONS TO THE MAINTENANCE OF POSTURAL EQUILIBRIUM

Lisa Alcock [1,*] Thomas O'Brien [2] Natalie Vanicek [3]

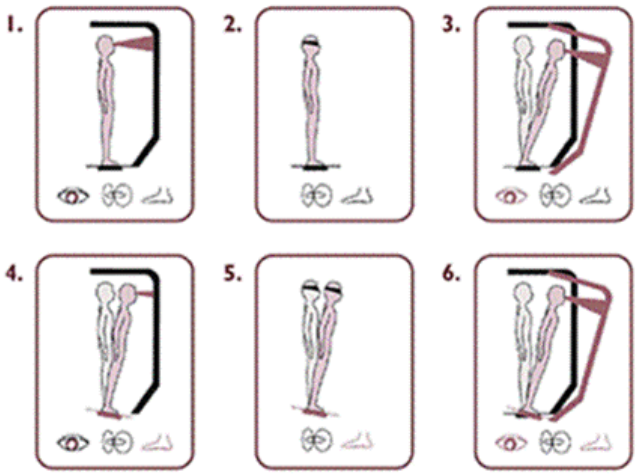
[1]Institute of Neuroscience, Newcastle University Institute for Ageing, Newcastle upon Tyne, [2]School of Sport and Exercise Sciences, Liverpool John Moores University, Liverpool, [3]Department of Sport, Health and Exercise Science, University of Hull, Hull, United Kingdom

Introduction and Objectives: Adequate postural control relies on maintaining equilibrium and correct orientation relative to three dimensional space and time[1]. Age-grouped comparisons have indicated increased latency in response to external perturbations and increased sway in older adults when visual, somatosensory and vestibular input where removed or inaccurate[2-4]. However, little is known about the accumulative changes that occur with older age. Postural sway of older women is particularly increased when support surfaces are unstable or when multiple balance systems are challenged, compared to males[4], making them more vulnerable to postural unsteadiness and falls[5]. Understanding the nature of this decline will help to guide timely intervention and the development of balance strategies. Therefore, the aim of this cross-sectional study was to quantify the postural responses of older women across an age-continuum using the NeuroCom EquiTest®.

Methods: Postural control was assessed from 39 non-falling community-dwelling women [Age 71.9(±7.2)y, range 60-83 years]. The relative contribution of systems responsible for balance was assessed across six conditions on the Sensory Organisation Test (Figure 1) and the *Equilibrium (EQ) score* (angular difference between measured anterior-posterior sway limits and the theoretical maximum sway limit) and *Composite score* were calculated. The ability to respond to unexpected perturbations that were graded in magnitude was evaluated using the Motor Control Test during which *response latency* and *weight symmetry* were evaluated. Linear regression quantified the changes in balance that occurred with older age.

Results: Significant yearly declines in *EQ score* and *Composite score* were estimated for conditions when somatosensory information was inaccurate (Conditions 5 and 6 on the Sensory Organisation Test; Table 1). The largest annual change was estimated for Condition 5 when somatosensory information was inaccurate and visual input was also removed. From the Motor Control Test, annual increases in response latency were observed with older age across all conditions, however only line gradient for the medium backwards translations were significant (R^2=16%, B=0.76, p=.013). Analysis of correlations between *weight symmetry* and age (data not presented) revealed small positive relationships (r≤0.33) for all backwards and forwards translations with the strongest, significant correlation for the medium backward translation (R^2=11%, B=0.28, p=.044).

Figure:



Caption: Figure 1: Schematic illustrating the SOT conditions. Condition 1: control condition. Condition 2: restricted visual input. Condition 3: inaccurate visual feedback (sway-referenced surround). Condition 4: eyes open, inaccurate visual feedback (sway-referenced surround). Condition 5: eyes closed and inaccurate somatosensory cues (sway-referenced support). Condition 6: eyes open and inaccurate visual and somatosensory cues (sway-referenced support and surround).

Conclusion: The magnitude of postural sway increased throughout older age in a cohort of women particularly when visual input was removed and somatosensory cues were inaccurate. This indicated that with advancing age, women were less able to utilise vestibular feedback to maintain balance, and increasingly relied on visual input and somatosensory information even when inaccurate. Increased asymmetric weight loading, as observed during the Motor Control Test, indicated that participants distributed their body weight unilaterally in preparation for a perturbation. This may be considered an anticipatory mechanism prior to initiating a stepping strategy needed to compensate for age-related increasing response latency. Participants were informed prior to the Motor Control Test that they would experience a perturbation to balance and anticipatory responses may have been elicited. Balance disturbances are generally unknown and may be multidirectional thus anticipatory responses are not always possible. The unexpected nature of postural disturbance would increase the motor planning and response complexity, and therefore the Motor Control Test may underestimate the motor responses executed.

Table:

Condition	1	2	3	4	5	6	Composite Score
Mean EQ score [SD]	95.0 [2.4]	89.8 [4.0]	87.1 [9.2]	81.0 [9.7]	41.5 [21.4]	36.1 [22.1]	65.5 [10.7]
Pearson's r correlation	-0.10	-0.30*	-0.08	-0.23	-0.46**	-0.34*	-0.43**
R^2 (%)	-	9	9	5	21	11	18
Line gradient	-	-0.17	-0.20	-0.31	-1.37	-1.01	-0.63

PO-0017

DETERMINATION OF AN OPTIMAL THRESHOLD LEVEL FOR A THRESHOLD-BASED FALL DETECTION METHOD

Jongsang Son [1,*] Soonjae Ahn [1] Isu Shin [1] Jeseong Ryu [1] Jongman Kim [1] Baekdong Cha [1] Eunkyoung Choi [1] Youngho Kim [1]

[1] Biomedical Engineering, Yonsei University, Wonju, Korea, Republic Of

Introduction and Objectives: Fall-related injuries can cause a long-term hospitalization which may lead to a loss of independence, morbidity and mortality [1]. For these reasons, the automatic (pre-impact) detection of a fall could be a promising approach to prevent the fall-related injury. To accomplish this aim, many researchers have been interested in specific changes in the acceleration of a human segment under a fall condition, and generally used a wearable sensor to measure the acceleration data due to its great portability. Most fall detection algorithms are typically based on the threshold of the acceleration, and show a possibility of application to the related-field [2]. Although the threshold could directly result in the performance of the sensitivity and specificity, it has been less studied in determining the threshold which is empirically done before [3]. In this study, a novel method determining an optimal threshold level is introduced to suggest a guide for a threshold-based fall detection.

Methods: Total twenty healthy male (23.4 ± 1.3 yrs.; 176.1 ± 7.6 cm; and 69.3 ± 9.5 kg) participated, who have no clinical history of musculoskeletal injury. They were categorized into two different groups performing: (1) typical activities of daily living (ADLs) such as normal gait, sit-to-stand, stand-to-sit, and stand-to-lying (6 subjects); and (2) simulated falls to the front, back, and side (14 subjects). All ADLs were conducted for five times, and all falls on soft foam mattress for three times. The experimental protocol was approved by the Yonsei University Research Ethics Committee (1041849-201308-BM-001-01). During the tasks, three-axis accelerations were obtained from the middle of two anterior superior iliac spines at the sampling rate of 100 Hz, and then the signal vector machine (SVM) was calculated from the measured acceleration data. By using the SVM data, an optimal threshold was determined from the optimization based on the maximum sensitivity and specificity criteria subject to the constraint that the lead time is equal to or longer than the pre-defined time. Because the longer lead time would be favorable to take an action to prevent fall-related injuries before the contact. To investigate changes in the sensitivity and specificity according to the lead time, the pre-defined time was arbitrarily set with 100, 200, 300, 400, or 500 ms.

Results: Table 1 shows the changes in the sensitivity and specificity according to the pre-defined lead time. The optimal threshold values increased as the pre-defined lead time decreased. The sensitivity and specificity were the best (100%) with the lowest optimal threshold value (i.e., 0.41 g), and were decreased with the increase in the optimal threshold value. These results suggested that the performance of the threshold-based algorithm might have a trade-off relationship between the sensitivity/specificity and the lead time. This means that the longer lead time, the lower sensitivity and specificity in our database at least.

Conclusion: The purpose of this study was not to develop an automatic pre-impact detection algorithm, but to develop a quantitative determination algorithm of a threshold for a guidance to a threshold-based detection algorithm. Indeed, it might be insufficient to expect a perfect fall detection algorithm with only accelerations, because the acceleration signal is sensitive to an external impact. Therefore, many researchers have tried to combine other sensors such as gyro sensor or

inclinometer to improve the sensitivity and specificity [4]. In this regard, we expect that the developed algorithm would be useful to determine the threshold satisfying a desired lead time.

Acknowledgment: This research was financially supported by the Ministry of Education (MOE) and National Research Foundation of Korea (NRF) through the Human Resource Training Project for Regional Innovation (No. 2013H1B8A2032194).

Table:

Lead time (ms)	Optimal threshold (g)	Sensitivity (%)	Specificity (%)	Accuracy (%)
100	0.41	100	100	100
200	0.52	100	94.7	97.1
300	0.70	100	64.7	80.8
400	0.81	100	50.7	73.2
500	0.87	100	35.3	64.9

MUSCLE CONTRIBUTIONS TO CENTER OF MASS ACCELERATION DURING BALANCING AGAINST EXTERNAL PERTURBATION.

Shinya Ogaya [1,*] Koutatsu Nagai [2] Yusuke Okita [3] Koji Nonaka [1] Satoshi Fuchioka [1]

[1]Physical Therapy, Osaka Prefecture University, Habikino, [2]Physical Therapy, Hyogo University of Health Sciences, Kobe, [3]Physical Therapy, Kyoto University, Kyoto, Japan

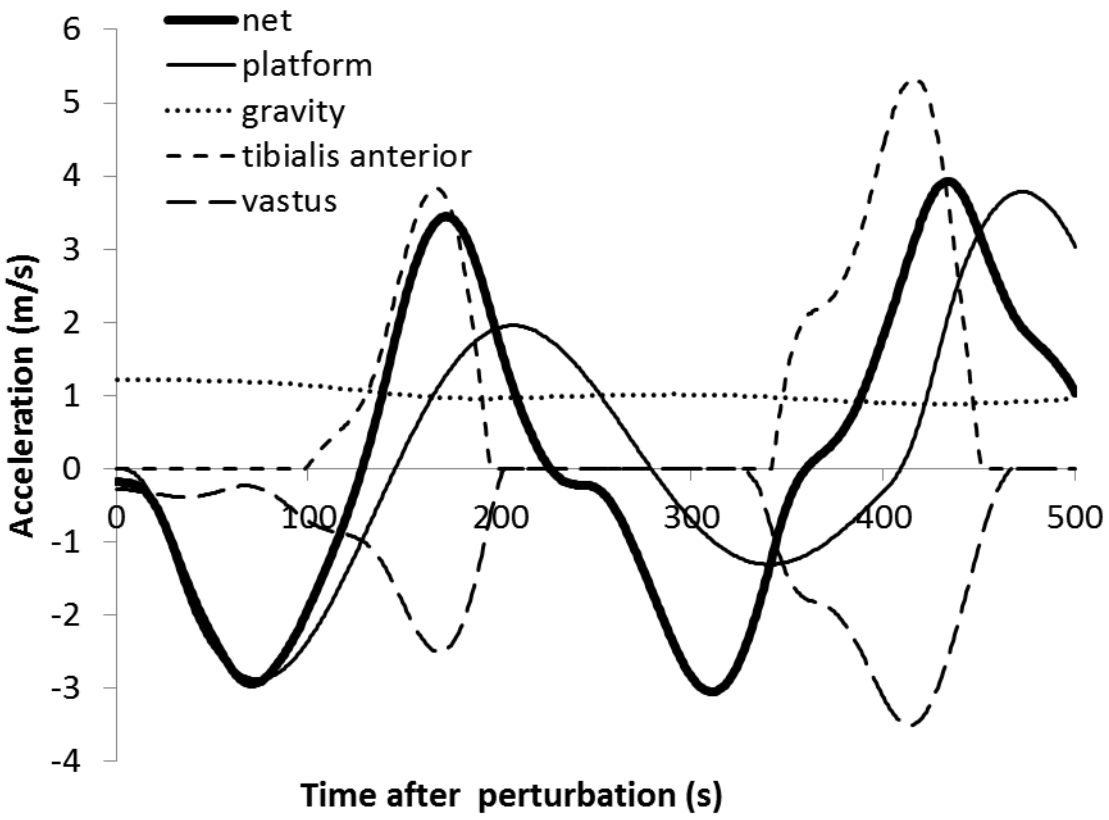
Introduction and Objectives: Loss of standing balance leads to a fall, which results in fractures in older people. Muscle activations have a crucial role to control the center of mass (COM) against perturbation and to recover balance. However, the muscle that mainly contributes to prevent perturbation is unknown. In previous reports forward musculoskeletal simulation analysis revealed contributions of the muscle on joint accelerations during gait. We used this method to analyze recovering balance after a platform translation and investigated muscle contributions to the COM acceleration.

Methods: This study has two steps, namely 1) motion capture and 2) analysis using forward simulation. For the motion capture, 1 older female subject aged 70 years old who had no serious dysfunction participated. Six reflective markers were attached to the subject's bony landmarks (acromion, greater trochanter, lateral knee, lateral malleolus, heel, and fifth metatarsal). The participant was instructed to stand on a computer-controlled moving platform and maintain balance with foot fixed to the platform. Ankle, knee, and hip sagittal angles were measured using a video camera during anterior platform translations, with a velocity of 15 cm/s and amplitude of 6 cm. Before the measurements, 10 practices were performed to improve familiarity with the device. The motion data were low-pass filtered at 15 Hz. Next, a standing model, which included 4 segments (foot, shank, thigh, and trunk), 3 joints (ankle, knee, and hip), and 9 muscles in the lower limb (tibialis anterior, soleus, gastrocnemius, vastus, rectus femoris, short hamstrings, long hamstrings, gluteus maximus, and iliopsoas), was constructed for the forward simulation analysis. The model was scaled to the subject's height and weight. The parameters of the segments (segment weight, inertia, and position of segment COM) and musculo-tendon units (force-length and force-velocity relation, maximum force, optimal fiber length, pennation angle, and tendon slack length) were referred to previous studies. Sinusoidal-shaped acceleration induced by the platform translation was applied to the model in the same experimental manner. Time series muscle forces were determined using the Lagrange formation with an optimization process to minimize the sum of square muscle activations to track measured angles. The linear translational spring damper was applied to the foot-floor pressure. The spring-damper parameters were determined by the fifth metatarsal marker acceleration. To evaluate muscle contributions to the COM acceleration, decomposition of the horizontal COM acceleration into contributions by muscles, platform translation, gravity, and centrifugal components was accomplished. At each instance of the simulated motion, an induced acceleration method was applied for the angular acceleration in each joint to decompose net angular acceleration into the individual components. Next, the horizontal acceleration of the COM was calculated from the joint accelerations by taking the segment mass and length. The muscle component was also divided into individual muscles.

Results: The individual contributions of the major components to the COM acceleration are shown in Figure. The strongest component to induce the COM acceleration was the platform translation, especially posterior COM acceleration

during the first 100 ms after perturbation. However, the contribution of the muscle component gradually increased after 100 ms. Acceleration induced by gravity did not show a remarkable change in the time series. The centrifugal component had little effect on the COM acceleration. For individual muscles, the tibialis anterior and vastus muscles mainly activated within 100–200 ms during the early recovery phase to resist the platform translation. The tibialis anterior greatly contributed to induce the anterior COM acceleration against the posterior acceleration perturbed by the platform translation. In contrast, the vastus muscle induced posterior COM acceleration. The other muscles had little contribution or activated during the later stage after 200 ms.

Figure:



Caption: Contributions to center of mass acceleration

Conclusion: Against the backward loss of standing balance perturbed by a platform translation, COM acceleration is strongly affected by the magnitude of the platform translation during the early phase. After the muscle reaction time, the muscle can gradually increase its contribution to the control of COM acceleration. The tibialis anterior has an early response and resists backward COM acceleration. These results indicate that the tibialis anterior may play an important role in recovering COM against backward balance loss.

PO-0019

QUANTIFYING PERFORMANCE AND EFFECTS OF LOAD CARRIAGE DURING A CHALLENGING BALANCING TASK USING AN ARRAY OF WIRELESS INERTIAL MEASUREMENT UNITS

Stephen M. Cain [1 2,*] Ryan S. McGinnis [3] Steven P. Davidson [1] Rachel V. Vitali [2] Noel C. Perkins [2] Scott G. McLean [1]

[1]School of Kinesiology, [2]Department of Mechanical Engineering, University of Michigan, Ann Arbor, MI, [3]MC10, Inc., Cambridge, MA, United States

Introduction and Objectives: Understanding how human movement is affected by load is critical for designing the equipment that warfighters and emergency responders must carry during missions or rescues. Advancements in inertial measurement unit (IMU) technology have made it possible for researchers to easily and unobtrusively measure body segment kinematics in real-world environments. In this study, we utilize an array of wireless IMUs to measure the movements of subjects traversing an outdoor zigzag-sloping balance beam as quickly as possible, both with and without load. Our objectives are: 1) to use data recorded by the IMU array to calculate metrics that quantify performance (e.g. speed and stability) and 2) to investigate the effects of load on performance. We hypothesize that added load significantly decreases subject speed yet increases the stability of subject movements.

Methods: We tested 30 subjects (11 females, 19 males; age = 20.8±2.6 years; body mass = 75.4±11.1 kg; height = 1.75±0.08 m; mean ± standard deviation). The University of Michigan IRB approved the study, and all subjects gave informed consent. Subjects completed an outdoor obstacle course both with and without a 20.5 kg load (body armor and tactical assault panel); the order of trials was random. In this study, we focus on a balance beam obstacle composed of five elevated aluminum planks (0.15 m wide, 3.05 m long). The first plank is level, whereas the other planks alternately slope up or down at 9 degrees. The junction between the first and second planks is straight, whereas the other junctions are alternating right and left 90 degree turns.

We secured eight APDM Opal wireless IMUs (APDM, Inc.) to each subject's feet, shanks, thighs, sacrum, and torso. Each IMU contains a 3-axis accelerometer, angular rate gyro, and magnetometer; a proprietary Kalman filter estimates the directions of gravity and magnetic north relative to sensor-fixed axes. Subjects performed calibration movements prior to testing, allowing us to deduce body segment-to-sensor alignments in post-processing. Foot-strikes and push-offs are identified via a wavelet analysis applied to foot segment angular velocities, allowing calculation of the duration of double support for each stride. Sacrum accelerations are resolved in an inertial frame and integrated to obtain vertical velocity of the sacrum; peaks in the vertical velocity signal reveal the jumps onto and off of the beam, which define the time required to traverse the beam. The ratio of the RMS acceleration in the medial-lateral (M-L) to the RMS acceleration in the anterior-posterior (A-P) direction for the sacrum measures the magnitude of lateral balance corrections (M-L) relative to propulsive/braking accelerations (A-P). Orientation of the torso-mounted IMU relative to gravity is used to calculate M-L tilt (left-right lateral flexion) of the torso.

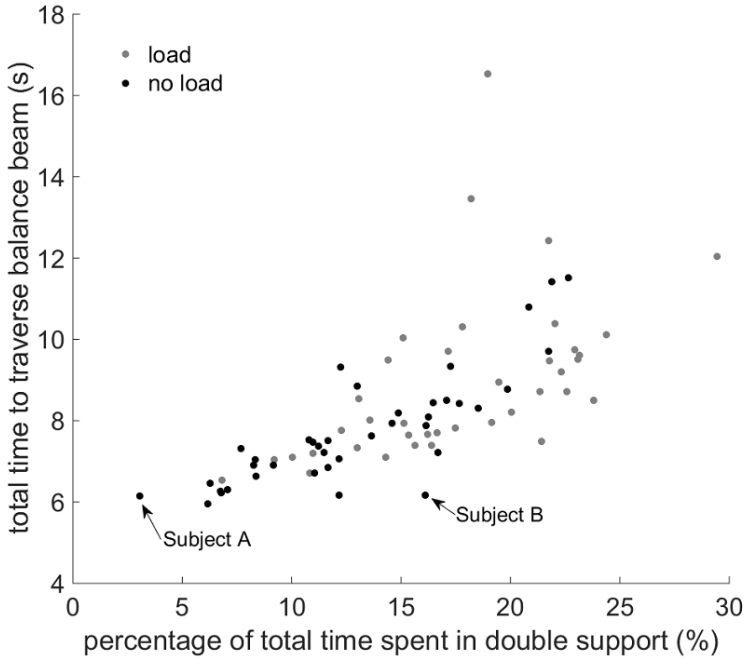
We focus our analysis on four metrics: 1) time to cross beam (less time = more speed), 2) percentage of total time spent in double support (more double support = more stable), 3) ratio of sacrum M-L to A-P RMS acceleration (lower ratio = less lateral balance corrections = more stable), and 4) M-L torso range of motion (smaller range of motion = less balance

corrections = more stable). We used paired t-tests with a Bonferroni correction (α = 0.05/4 = 0.0125) to test for significant differences between loaded and unloaded conditions.

Results:

As hypothesized, speed decreased significantly with load, as quantified by an increase in the total time needed to cross the beam (mean diff=1.28s, t=4.85, p<0.001). Stability metrics also changed significantly with load, suggesting increased stability; double support time increased (mean diff=4.64%, t=6.04, p<0.001), the ratio of sacrum acceleration RMS decreased (mean diff=-0.19, t=-5.56, p<0.001), and the M-L torso range of motion decreased (mean diff=-5.41 degrees, t=-2.82, p=0.009). Figure 1 illustrates the trade-off between speed (time to traverse beam) and stability (percentage of total time spent in double support). The two subject data points highlighted in Figure 1 demonstrate that some subjects are able to maximize speed while simultaneously maintaining high stability.

Figure:



Caption: Figure 1. Time to traverse beam versus double support time. Subjects A and B traverse the beam in a similar amount of time (6.14 versus 6.16 seconds). However, Subject B spends much more time in double support (16.1%) than Subject A (3.1%), allowing Subject B to maximize both speed and stability.

Conclusion:

Using data from an array of IMUs, we developed metrics for quantifying the performance of subjects during a challenging balance task. Load carriage had a significant effect on the performance of the subjects, decreasing their speed while increasing their stability (increasing caution). Future work will explore additional performance metrics (e.g. foot trajectories) and quantify differences in technique between high and low performing subjects.

PO-0020

MUSCLE RATE OF TORQUE DEVELOPMENT IN FEMALE FUTSAL PLAYERS

Ana Carolina de Mello Alves Rodrigues [1,*] Nathália Arnosti Vieira [2] Sergio Augusto Cunha [2] Sérgio Rocha Piedade [1]

[1]School of Medical Science, [2]University of Campinas, Campinas, Brazil

Introduction and Objectives: Futsal players are known by developing maximum strength in a short periodof time, providing greater efficiency in tasks such as sprints and change of direction. In the early stages of muscle contraction (1), the strength development ratio (SDR) is a useful parameter to evaluate the dynamic of muscle contraction in sports activities (2), as well the joint stability in order to promote actions to prevent injuries (3).In clinical practice, the SDR is the ratio of Δstrength / Δtime calculate between 0 ms and 500 ms (1,2,4-7), resulting in an average value. However, in athletes the maximum SDR occur in the beginning of movement, due to its important for performance of the tasks in game. Thus, it is necessary to know the maximum of the acceleration of dominant and non-dominant member of these athletes, instead of the average value, to assist in the training of prescription. Therefore, the aim of this study was to analyze the maximum torque developmentratio (maximum TDR) of knee extensors in dominant and non-dominant member.

Methods: We analysed the performance of the best trial of 18 amateur female futsal players aged 21.0±2.8years (mean±SD), body mass of 56.4±6.1kg and height 160±0.1m. A Biodex system-3 was used for the isokinetic testing of knee extension torque. Each subject performed 1 set of 5 knee extension and flexion repetitions at 180°·s^{-1} with dominant (DM) and non-dominant (NDM) member.After find the peak torque for extensors it was possible calculate the maximum TDR by the derived, torque as a function of time derivation in the corresponding time interval. This variation interval goes from the beginning of the movement till the instant at which the maximum torque is reached. So, the maximum TDR (N·m·s^{-1}) was calculated for knee extensors of DM and NDM of athletes. As the data had normal distribution, ANOVA was performed to compare maximum TDR between DM and NDM adopting, $p<0.05$.

Results: Table 1 showed no difference ($p=0.97$) between the maximum TDR of extensor muscle group and the DM (646,96 N·m·s^{-1} ± 155,14) and NDM (648,82 N·m·s^{-1} ± 144,45). This may be due to the training that athletes are subjected, which consisted in improving muscle performance and promotion of joint stability in order to prevent injuries. Thereby, the athletes showed symmetry between the lower limbs, results consistent with those found in the literature (8,9).

Conclusion: The symmetry between the lower limbs corroborates to the achievement of greater efficiency of the tasks performed in futsal.

Table:

Subjects	Maximum TDR of Extensors (N•m•s^{-1})	
	DM	NDM
S1	441,77	624,33
S2	586,51	464,77
S3	494,33	501,73
S4	593,18	710,68
S5	770,94	801,10
S6	801,52	765,18
S7	499,76	597,18
S8	727,92	801,26

PO-0021

LEVEL OF SYNERGIES IN SIMPLE, REPETITIVE TOOL USE

Chris Baber [1] Sandra Starke [1,*]

[1]Electronic, Electrical and Systems Engineering, University of Birmingham, Birmingham, United Kingdom

Introduction and Objectives: From a systems perspective, the coupling of human-tool-material, in a specific environment for a specific task, sets constraints for performance. However, variability might arise as a result of the degrees of freedom problem, or as a result of noise in movement control, or as a result of noise in the 'system'. Here, we focus on the manner in which variability in simple, repetitive tasks is managed using the example of sawing. Our objective was to quantify sawing frequency and cycle duration across a range of conditions and participants. Specifically, we wondered whether individuals would operate a saw in a random manner, in a task-specific manner or as the result of some form of internal timing (as predicted by Bernstein's level of synergies).

Methods: Data were recorded for two sawing tasks. For task #1, five participants were asked to use a wood saw (blade length 10 cm) and cut into a piece of wood, holding the saw horizontally or vertically. Each participant repeated the activity five times. A Qualisys motion capture system was used to track markers attached to the saw tip in 3D space at 200 Hz. For task #2, 18 participants recruited from a School of Jewellery were asked to use a piercing saw (blade length 14 cm) and, holding the saw vertically, cut lines into a piece of copper. The saw was instrumented with sensors, including an accelerometer aligned with the primary movement direction of the saw's handle. Each participant repeated the task five times.

For task #1, displacement components for a single axis in global space (horizontal/vertical component for horizontal/vertical sawing) were extracted. For task #2, calibrated accelerometer signals corresponding to movement in the direction of the long-axis of the saw were extracted. Individual sawing cycles were detected by identifying minima in the data stream for each trial. For each participant and trial, median and interquartile ranges (iqr) were calculated across cycle durations corresponding to one trial. After initial inspection, k-means clustering was performed for a group size of 3 (task #1, vertical and task #2) and 2 (task #1, horizontal) to report central tendencies while reflecting banding of data. A Friedman test was performed to examine whether median sawing duration changed as a function of trial number. For task #1, within-trial iqr was compared between horizontal and vertical sawing using the Wilcoxon signed-rank matched-pairs test.

Results: For task #1, mean (SD) cycle duration were 379 (69) ms for horizontal and 442 (272) ms for vertical sawing. The identified cluster centers across all trials and participants were 318 ms (11 cases) and 428 ms (14 cases) for horizontal sawing and 238 ms (11 cases), 506 ms (12 cases) and 1179 ms (2 cases) for vertical sawing. There was increased variation between participants for vertical sawing resulting from sawing at distinct, widely spaced bands. There was an effect of trial number on sawing cycle duration for horizontal sawing ($P = 0.028$) but not for vertical sawing ($P = 0.246$). Variation within participants' sawing frequency during a trial was significantly greater for vertical compared to horizontal sawing ($P < 0.0005$), with a mean (SD) participant-specific iqr of 58 (54) ms for horizontal sawing and 314 (369) ms for vertical sawing. For task #2, the mean (SD) cycle duration was 439 (71) ms while the identified cluster centers across all

trials and participants were 319 ms (10 cases), 434 ms (52 cases) and 550 ms (13 cases). There was a significant effect of trial number on median sawing cycle duration (P = 0.046).

Conclusion: In this study we found that use of a saw resulted in highly constrained operation across tasks and participants: the sawing motion was executed within specific cycle duration bands that were near-multiples, the most common cycle duration corresponding to a frequency of around 2.5 Hz. This suggests that saws were not operated in a random or task-specific manner, but rather under global constraints. A possible explanation for the observation stems from the notion of level of synergies, in which the response patterns arise from the internal coherence of movement dynamics. The observation is that participants attempt to produce consistent sawing actions, irrespective of material or posture, suggests that this activity might be independent of system components and more a matter of endogenous timing of this activity.

PO-0022

EFFECT OF MECHANICAL PARAMETERS HAIR CAUCASIAN PREGNANCY WOMEN

Marie Skřontová [1,*]Lucie Šimková [1]Josef Zeman [2]Karel Jelen [1]Bohumil Chalupa [2]

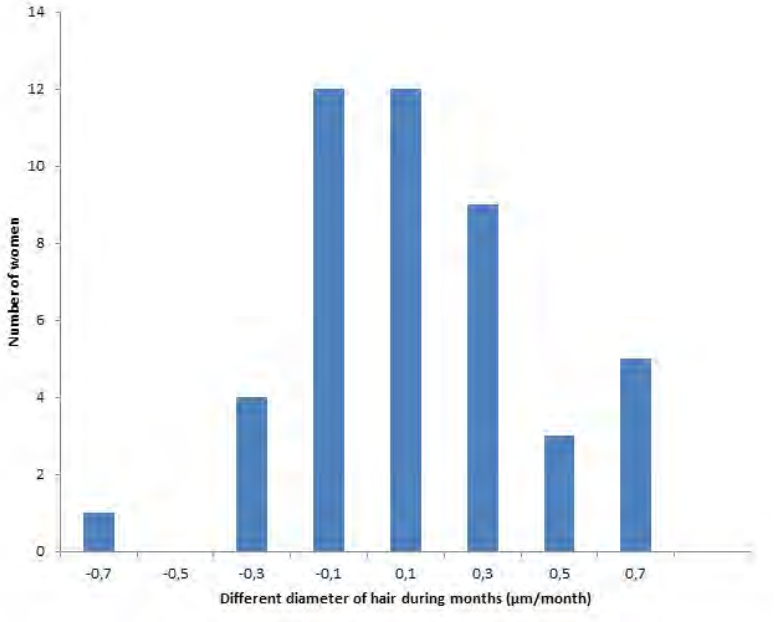
[1]Department of Anatomy and Biomechanics, Faculty of Physical Education and Sport, Charles University Prague, Czech Republic, [2]Department of Physics, Faculty of Engineering, Czech University of Life Sciences Prague, Czech Republic, Prague, Czech Republic

Introduction and Objectives: The objective of this report is to show the changes of mechanical parameters of hairs found that come up during gravidity. The hair shaft consists of three concentric layers: the cuticle, the cortex and the medulla. Each of these components has different structure and function. The cuticle protects the inner parts from the outer environment and from derogation caused by daily treatment. The cortex (90 % of the hair) determines mechanical properties of the hair, and the medulla can sometimes be completely absent [1].

Methods: Samples of hairs have been taken from 50 Caucasian women's scruff each month of their pregnancy. The age of the women ranged from 23 to 43 years. Other samples have been taken after confinement end. Four hairs have been analysed from each taking; 3 samples have been subjected to tensile test and the last one to a relaxation test. Following mechanical parameters have been determined from the measured data: Diameter, modulus of elasticity, elastic limit, yield limit, relaxation times τ_1 and τ_2 and the total percentage of relaxation in the elastic region.

Results: Detectable trend that the gravid women have embodied in mean value has been found for some of these parameters. Although by far not all women display the trend that is valid for mean population, the trend is significant in the whole set e.g. for the hair diameter. It turns out that the hair diameter increases during gravidity, with a rate of 0.4 μm per month, the mean diameter being 84 ± 16 μm.

Figure:



Conclusion: The distribution of the hair diameter change during gravidity can be seen in fig. 1. No dependence between the diameter, standard deviation and the women's age has been found in the age range given.

PO-0023

MODULATION OF H REFLEX AMPLITUDE DURING MENTAL TASKS IN ABLE BODIED VOLUNTEERS

Mohammed S. Jarjees [1 2,*] Aleksandra Vuckovic [1]

[1]Biomedical Department, University of Glasgow, Glasgow, United Kingdom, [2]Technical College of Mosul, Foundation of Technical Education, Mosul, Iraq

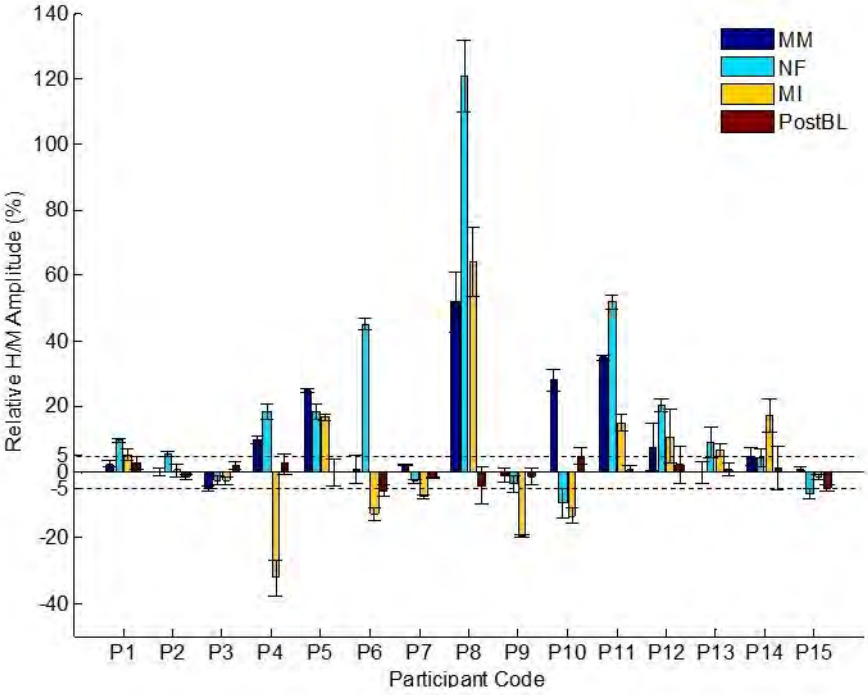
Introduction and Objectives: The H reflex is the monosynaptic reflex evoked by percutaneous electrical stimulation of the Ia sensory fibers [1]. It is considered as a measure of integrity of spinal pathways [2]. Research showed that it is possible to modulate H reflex from the higher centres, e.g. during imagination of movement [3] or even during mental math. By providing a biofeedback based on electromyogram (EMG) it is possible to increase or decrease the amplitude of H reflex [4]. Although it is believed that H reflex can be voluntarily modulated, cortical activity during H reflex modulation task has never been measured. The objective of this study was to explore whether the amplitude of the H reflex can be modulated by voluntary increasing or decreasing the amplitude of the sensory-motor rhythm (SMR, 8-12 Hz), which is a brain rhythm closely related to voluntary control of movements. Voluntary modulation of H reflex amplitude by modulating SMR might be beneficial for creating novel neurorehabilitation strategies for motor control.

Methods: Fifteen able bodied volunteers (9 M, 6 F; 27.9 ± 4.2 years) with no known neurological deficit or injury to their legs performed three different tasks: Motor Imagery (MI), Mental Math (MM) and Neurofeedback (NF). During MI, participants were asked to imagine dorsiflexing their feet for 60% of the maximum voluntary contraction and they were allowed 5s to perform MI before evoking H reflex. During MM, participants were asked to subtract numbers in steps of 7 starting from 100. While both MI and MM resulted in decreasing of SMR, it is believed that only MI directly modulates the activity of cortico-spinal pathways. NF was used to enable participants to voluntarily increase their SMR. In order to learn NF strategy, participants had 3 training pre-experimental session. Participants' EEG was recorded from electrode location Cz located over the primary motor cortex of legs. H reflex was evoked from right leg's tibial nerve and recorded over the soleus muscle. H reflex was evoked 5 times with at least 15 s interstimulus interval in each task (MI, MM and NF) and in the resting state before (PreBL) and after (PostBL) neuromodulation tasks. H reflex was evoked when the Power Spectral Density (PSD) of SMR was for at least 0.5s: 60% above the baseline for NF, 80% under the baseline for MM and MI. The stability of background EMG was confirmed by calculating Root Mean Square Value (RMS) of the EMG for 1s before the stimulation. Modulation of H reflex was considered significant if it was larger than 5%.

Results: The ratio of peak-to-peak H reflex amplitude to peak-to-peak muscle wave amplitude (H/M) with respect to the baseline during MI, MM, NF and PostBL are presented in Figure1. No differences were noticed in M wave amplitudes with respect to the baseline. Fourteen out of 15 participants achieved modulation of H reflex larger than 5% in at least one task. On the contrary, the modulation of H reflex in 14 volunteers varied less than 5% in PostBL. Statistically significant change in H/M ratio in all subject and overall tasks was noticed ($P<0.0001$) and NF showed the larger change than MM and MI. H reflex amplitude was modulated in 11 participants during NF (9 increase and 2 decrease), in 11 participants during MI (6 increase, 5 decrease) and in 7 participants during MM (6 increase). The average absolute value

of H reflex modulation was 20(±3.7) for NF, 16(±2.1) for MI and 12(±1.8) for MM. No increases in RMS values of the background EMG were observed (RMS under 7.5 μV).

Figure:



Caption: Figure 1: Relative H/M ratio with respect to the baseline (PreBL) values. The two horizontal dashed lines mark the 5 % change of the H reflex amplitude compared to the PreBL; any change larger than 5% was considered significant.

Conclusion: Modulation of SMR results in modulation of the H reflex, but its effect is mostly excitatory independent on the direction of modulation of the SMR rhythm. While NF and MM dominantly increased the H reflex, results on the influence of MI on H reflex are inconclusive. Previous studies showed that MI increased H reflex in general population [3] and decreased H reflex in elite athletes [5]. In this study the level of fitness was not measured but participants were mostly healthy young adults corresponding to volunteers in [3]. The decrease of H reflex is believed to be related to the decrease of spasticity in people with spinal cord injury [6], but in healthy people it does no influence locomotion [6]. Further analysis of cortico-muscular coherence and analysis modulation of EEG signal in different frequency band would be needed to better understand the relation between modulation of H reflex and related brain rhythms.

PO-0024

FOREFOOT MORPHOLOGICAL PARAMETERS FOR ASSESSING INTRINSIC RISK FACTORS OF HALLUX VALGUS

Chien-Chung Kuo [1 2,*] Hsuan-Lun Lu [2] Horng-Chaung Hsu [1] Tung-Wu Lu [2 3]

[1]Department of Orthopedics, China Medical University Hospital, Taichung, [2]Institute of Biomedical Engineering, [3]Department of Orthopedic Surgery, School of Medicine, National Taiwan University, Taipei, Taiwan, Republic of China

Introduction and Objectives: Hallux valgus (HV) is a common foot pathology in the modern society. The deformities diminish the function of the hallux and first metatarsophalangeal (MTP) joint in transmitting forces during locomotion, resulting in the progression of lesions beneath the 2nd/3rd metatarsal heads [1]. Footwear has been considered to be the main extrinsic factor of the development of HV. However, HV was also reported in the unshod population in South Africa [2]. This suggests that apart from the extrinsic factors HV is also affected by intrinsic factors such as heredity, ligamentous laxity and Achilles contracture, etc. However, previous studies have focused mostly on the 1st MTP without considering effects of the forefoot morphology [3] that may predispose the foot to HV when subject to improper external loads. The purpose was thus to identify forefoot morphological parameters that may be the intrinsic risk factors of HV.

Methods: Forty patients with HV and forty normal subjects participated in the current study. Both groups were evaluated by the standard weight-bearing anteroposterior radiography of the foot. Selected bony landmarks of the forefoot, namely heel, 5th metatarsal head, and 1st & 2nd proximal phalanx bases and metatarsal heads, were identified by an experienced surgeon on each radiograph image in a house-developed program in MATLAB. The lengths of the foot (L), 1st toe (L_1) and 2nd toe (L_2), forefoot width (W) and 1st web space (W_{12}) were then calculated using the relevant landmarks. Five morphological parameters were defined, namely normalized toe lengths (L_1/L and L_2/L), length-to-width ratios (L/W, L_1/W and L_2/W) and length-to-web ratios (L/W_{12}, L_1/W_{12} and L_2/W_{12}). Mean values and standard deviations of these parameters were calculated and their differences between HV and normal groups were compared using an independent t-test. The statistical analysis was performed using SPSS with a significant level set at $\alpha = 0.05$.

Results: Normalized toe lengths for the 1st and 2nd toes did not have significant differences between groups. In contrast, patients with HV showed significantly reduced ratios between toe lengths and the forefoot width, as a result of wider 1st web space, increased forefoot width and thus larger space between 1st and 2nd toes. The normal subjects had greater values of all the ratios (Table 1).

Conclusion: Morphological parameters based on toe lengths did not appear to be risk factors for HV because no significant differences of the normalized toe lengths were found when compared with the normal group. People with greater length-to-width and length-to-web ratios may be at a higher risk of developing HV if subject to improper medially applied external forces such as shoes with a narrow toe box for a long period of time. Therefore, proper and careful fitting of shoes is suggested for those with this specific forefoot morphological feature.

Table:

	L_1/L	L_2/L		L/W	L_1/W	L_2/W		L_1/W_{12}	L_2/W_{12}
Normal	0.22 (0.02)	0.22 (0.02)		3.19 (0.20)	0.71 (0.06)	0.69 (0.07)		2.05 (0.22)	2.00 (0.23)
HV	0.22 (0.01)	0.22 (0.02)		2.94 (0.22)	0.66 (0.05)	0.64 (0.08)		1.78 (0.20)	1.74 (0.26)
p-value	0.49	0.64		<0.001	<0.001	0.01		<0.001	<0.001

PO-0025

THE ASSESSMENT OF TOXICITY OF HYDROXYAPATITE (HAP) AND BORON NITRIDE (BN) NANOPARTICLE USING ATOMIC FORCED MICROSCOPY

Mohammad Alim I. Rasel [1,*] Trung Dung Nguyen [1] YuanTong Gu [1]

[1]Chemistry, Physics, Mechanical Engineering, Queensland University of Technology, Brisbane, Australia

Introduction and Objectives: Nanoparticles have considerably found practical applications in the field of biotechnology in recently. The large surface to volume ratio and the flexibility to deliver in desired positions makes them more attractive than any other nanomaterials. Because of their unique physical and chemical properties researchers have proposed sophisticated applications of nanoparticle ranging from biosensing, molecular imaging to drug delivery, optical storage and so on. Despite all these exciting applications and prospects, one thing has always bothered researcher about nanomaterial, their toxic nature. No matter how appealing the nanoparticle is, it can't be used for clinical treatment unless it's safety is properly assessed. This study focuses on two nanoparticles, Hydroxyapatite (HAP) and Boron Nitride (BN), which gained much popularity for their exceptional properties. A number of researchers have already proposed a wide variety of application of HAP and BN. However, as always their toxicity is a great concern. Several researchers have adopted traditional methods to quantify their toxicity. In this study, we tried to adopt a completely different approach. The idea is to quantify the mechanical property of cells and compare the properties between normal cells and cells with nanoparticles. The aim is to investigate whether there is any change in mechanical property due to the cellular uptake of nanoparticles and assess the cellular response in terms of mechanical property.

Methods: Confocal microscopy imaging is utilized to ensure cells are successfully uptaking the nanoparticles. The osteocytes, osteoblasts cells are cultured with both HAP and BN nanoparticles for 24 hours. After that, the attached cells are fixed with 4% Paraformaldehyde (Sigma-Aldrich). The cells are then stained with DAPI, and Alexa Fluor 568 Phalloidin (GIBCO, Invitrogen Corporation, Melbourne, Australia) for 15 minutes to observe the cells' nuclei and actin filament network, respectively. The samples were then properly washed and imaged on a confocal microscope (Nikon A1R confocal, Japan) using a 40X Nikon oil immersion objective lens.

Once the cellular uptake of nanoparticle is ensured, Atomic Forced Microscopy (AFM) is used to quantify the mechanical property of cells. AFM is a state of the art facility to study the mechanical and topological property of nanoscale materials. The AFM used in the current study is a Nanosurf FlexAFM (Nanosurf AG, Switzerland), which is mounted on a Leica DM IRB (Leica Microsystems). Nanosurf C3000 software is used to conduct AFM experiments. A colloidal probe SHOCONG-SiO2-A-5 (AppNano) cantilever is used. The diameter of the colloidal probe is around 5 μm and its spring constant is around 0.224 – 0.3114 N/m.

Results: From the confocal images, it can be confirmed that both HAP and BN can successfully go into the cells, therefore they can be used as a drug delivery vehicle or any other advanced biomedical application. This is the first to report that Boron Nitride nanoparticles successfully going into the cells.

From the preliminary AFM results it is observed that, for both BN and HAP, there is no significant difference between cells with and without nanoparticles. The nanoparticle does not seem to alter the mechanical property of cell much.

Conclusion: As confocal report confirms that both HAP and BN can go into the cell successfully, therefore they both can be used for a wide range of advanced biomedical applications. Although there are several reports about HAP going in the cell, this is the first report revealing that BN can also successfully going into the cell. This opens a new door in the field of biotechnology with huge potential.

The AFM experiment results demonstrate that both HAP and BN fails to alter the mechanical property of cells. This signifies that, it does not matter whether the particles are in or outside of the cells; mechanically they are still functioning at the same level. Therefore, it is perfectly safe to use them in the recommended amount.

PO-0026

STUDY ON THE LOADING RATE BEHAVIORS OF ARTICULAR CARTILAGE UNDER COMPRESSIVE LOAD

Yan Bao [1,*] Chunqiu Zhang [2] Zhidong Liu [2] Wei Yao [1]

[1]University of Strathclyde, Glasgow, United Kingdom, [2]Tianjin University of Technology, Tianjin, China

Introduction and Objectives: Articular cartilage is a connective tissue that locates between the articular and bone, bearing and transmitting load while allowing low-friction and low-wear joint articulation depending on its special structure. It is difficult to repair the damaged cartilage by itself when cartilage has experienced trauma or degeneration, which may affect people's activity and will be inconvenient to human life. Therefore, it is vitally important to study the mechanical properties of articular cartilage, in particular its structure and different composition. Articular cartilage is divided into three layers from above to below, and the biomechanical property of different layers show diversity. So it is difficult to completely reveal the biomechanical property while regarding articular cartilage as a whole for researching. The study is focused on the rate behaviors of different layers for fresh pig articular cartilage under compressive load.

Methods: An optimized digital image correlation (DIC) technique was applied to investigate the rate behaviors and the micro mechanical properties of cartilage were obtained. Iron-oxide nanoparticles were embedded in the cartilage samples as tracer elements and the change of the relative position of nanoparticles under loading shows the sample deformation.

Results: Compressive stress-strain curves under different loading rates (0.1N/s, 0.3N/S, 0.5N/S, 1N/S, 3N/S) show the mechanical property of cartilage changes along its depth from surface to deep layer and this property is related to the loading rate. Under constant loading rate, the strain amplification in the surficial layer is the largest and the deep layer is the smallest, which is related to the microscopic structure of different layers. Under the same compressive load, the Possion's rate is smaller in the surficial layer than that in the deep layer of articular cartilage.

Conclusion: Persistent low stresses also can cause large deformation in cartilage, which will damage its inner structure. Therefore, persistent loading should be avoided in order to prevent injury caused by chronic stress.

PO-0027

THE IMPORTANCE OF THRESHOLDING IN MICRO-CT FOR THE HISTOMORPHOMETRIC ANALYSIS OF MAMMALIAN BONE TISSUE

George Adams [1]Richard Cook [2]John Hutchinson [3]Peter Zioupos [1,*]

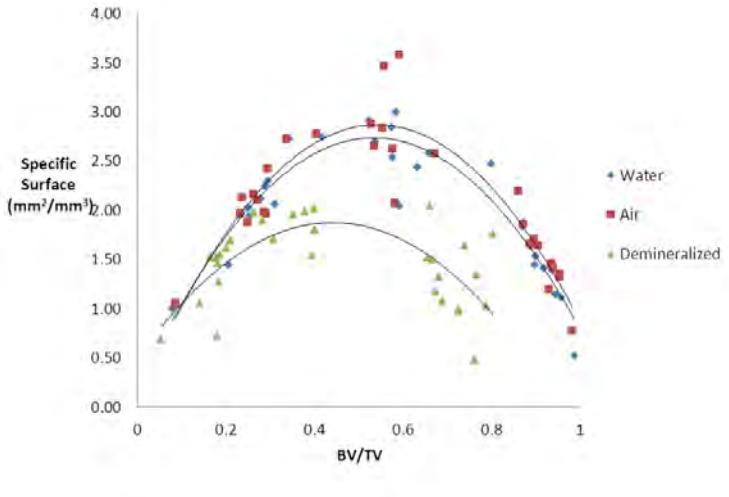
[1]Cranfield forensic institute, Cranfield Univeristy, Swindon, [2]National Centre for Advanced Tribology at Southampton, Univeristy of Southampton, Southampton, [3]Department of Veterinary Basic Sciences, University of London, Hatfield, United Kingdom

Introduction and Objectives: In recent years the use of micro-computed tomography (μCT) has become popular in the assessment of bone microstructure. There are 2 main considerations that need to be addressed when assessing samples by μCT; the material surrounding the samples during the scan and where the threshold is drawn when evaluating the scan data. Determining which method of scanning and thresholding provides the truest and most accurate value is important to validate the use of μCT in the assessment of bone morphology.

Methods: 31 Samples of bone from an elephant femur of varying porosities were scanned with the ambient medium being water and air. Before scanning each sample had a slice of bone tissue removed and demineralized using EDTA leaving behind only the organic phase of the bone. Each sample was then scanned in both conditions and with the presence of the demineralized slice.

Results: The results showed that scanning the samples in water gave an average difference of 6.3% from results obtained by conventional densitometry, but when the samples were scanned in air the difference was reduced to 5.7%. In determining where the threshold should be drawn to determine morphology 3 different “backgrounds” were used; air, water, and collagen (from the demineralized slice). The results showed that there was little difference between the samples with air and water taken as the background, however when collagen was considered to be the background the morphology varied significantly.

Figure:



Caption: Specific surface distribution for all three thresholds

Conclusion: Contrary to popular protocol our results suggest that scanning samples in air rather than water produce results more similar to other conventional histomorphometry methods such as the Archimedes principle. One argument for scanning in water over in air scanning could be that the results are likely to be more similar to clinical scanners. However this is flawed as the type of scanner (cone beam or spiral), voxel size, volume of soft tissue between source and target as well as many other factors vary to such an extent that they make this a redundant point. In the interest of obtaining the most accurate morphological data it is suggested to scan the samples in air rather than water.

ENERGY COST AND PHYSIOLOGICAL RESPONSES IN UPPER LIMBS EXERCISES PERFORMED WITH DIFFERENT POSTURES

Yomara L. Mota [1,*] Renato Silva [1] Guilherme Molina [1] Ciro Brito [1] Flávio Pires [1]

[1] Department of Physical Education, Universidade Católica de Brasília, Taguatinga, Brazil

Introduction and Objectives: It is not well described in the literature the influence of the variation in position on the physiological responses and the energy cost of exercises performed with the upper limbs. Therefore, the aim of this study was to characterize the physiological responses during upper limbs exercises performed with different postures.

Methods: Eight men physically active for at least 1 year, with no experience in upper limbs exercises, with 28.2 (± 5.7) years old, 173.7 (± 7.4) cm of height, 74.1 (± 11.4) kg of body weight, 30.2 (± 2.09) ml · kg · min-1 VO2peak and 24.4 (± 2.5) kg / m2 of BMI were recruited to participate in this study. All subjects were instructed for an initial cardiopulmonary exercise testing, two familiarization sessions andtwo upper limbs exercises sessions lasting for 30 minutes have been applied on different days. Themetabolic and hemodynamic responses obtained in sitting postures (SP) and vertical positions (VP) werecompared.

Results: The results demonstrated that the upper limbs exercises session performed in a VP generated energy expenditure 14.3% higher than during the SP ($p = 0.014$) and significantly increased the lipid catabolism ($p = 0.004$) compared to the SP session. In vertical exercise the pressure rate product was higher ($p = 0.037$).

Conclusion: The upper limbs exercises performed in VP modify the VO2 responses and increase ventilation. This way, the cost energy and cardiovascular load associated with orthostatic position.

IDENTIFICATION OF ORTHOTROPIC MATERIAL PARAMETERS FOR HEALING MYOCARDIAL INFARCTS IN THE RAT

Mazin Sirry [1,*] Laura Dubuis [1] Neil Davies [1] Jun Liao [2] Thomas Franz [3]

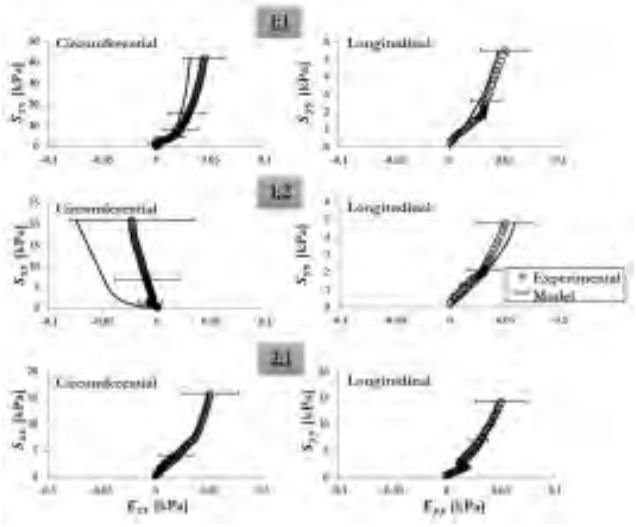
[1]Cardiovascular Research Unit, Chris Barnard Division of Cardiothoracic Surgery, University of Cape Town, Observatory, South Africa, [2]Tissue Bioengineering Laboratory, Department of Agricultural and Biological Engineering, Mississippi State University, Mississippi , United States, [3]Division of Biomedical Engineering, Department of Human Biology, University of Cape Town, Observatory, South Africa

Introduction and Objectives: Myocardial infarction (MI) is one of the major causes of mortality globally. Research has been devoted to study the biomechanical aspects of MI and its emerging intramyocardial injection treatment [1]. Finite element (FE) models have been effectively utilized in such research. Although the rat is a widely used animal model for MI, there is a lack of data on material models for rat infarcts in the literature. This study aimed at identifying the parameters of Fung orthotropic constitutive model for different healing stages of rat infarcts through inverse FE analysis utilizing biaxial (cardiac circumferential and longitudinal axes) tensile mechanical data obtained in a related study. The temporal stages of healing infarcts included immediate (0 day), 7, 14 and 28 days.

Methods: Four 3D models of the infarct sample (square sample dissected from the infarcted left ventricle wall) were developed in Abaqus CAE 6.12-2 (Dassault Systèmes, Providence, RI, USA) utilizing the average physical dimensions of samples in each stage and mimicking the setup of the biaxial tensile experiment. Models were meshed using C3D8RH elements. Through a user-defined subroutine, 14 transmural layers of fibre angles ranging linearly from -50° (epicardium) to 80° (endocardium) were incorporated. The orthotropic case of the generalized Fung constitutive model was utilized to model the material properties of the infarct. The parameters of Fung model were optimized so that the FE solution best fitted the biaxial experimental stress-strain data. Three simulations were run for each infarct stage to fit the experimental data which were obtained with three different biaxial loading ratios; namely 1:1, 2:1 and 1:2. The computed stress data were compared to the experimental data at predefined strain values. The objective function (OBJ) utilized in the optimization was developed so that it returns the mean absolute percentage error. A genetic algorithm (GA) was used to minimize the objective function (SCILAB 5.4, Scilab Enterprises S.A.S, Versailles, France).

Results: The identified Fung orthotropic material parameters for different infarct stages are shown in the table. The FE model predictions best approximated the experimental data of the 28 days infarct stage with 3.0% error. The worst approximation was for the 7 days stage with 3.6% error. The figure illustrates the best fit of FE model predictions to the experimental data for the 28 days infarct stage in circumferential and longitudinal directions from three loading conditions.

Figure:



Conclusion: The experimental stress-strain data of healing rat infarcts could be successfully approximated using inverse FE methods and genetic algorithms. The material parameters identified in this study will provide a new platform for FE investigations of biomechanical aspects of MI and the development of therapies.

Table:

Material parameter	0d	7d	14d	28d
b_{1111}	64.31	176.09	16.38	159.65
b_{1122}	14.08	-70.92	-16.16	-25.52

PO-0030

THE EVALUATION AND CHARACTERISATION OF THROMBIN-INDUCED MAMMALIAN THROMBI MODELS FOR THE INVESTIGATION OF VASCULAR OCCLUSION IN ACUTE ISCHEMIC STROKE.

Fiona Malone [1,*] Patrick Delassus [1] Eugene McCarthy [2] John Thornton [3] Paul Fahy [1] Liam Morris [1]

[1]GMedTech, [2]Marine and Freshwater Research, GMIT, Galway, [3]Neuroradiology Dept., Beaumont Hospital, Dublin, Ireland

Introduction and Objectives: A lack of blood supply to any part of the brain for an unknown period of time may lead to brain tissue necrosis, commonly known as stroke. Stroke remains the third most common cause of death worldwide and kills more than 2,000 people a year in Ireland. Stroke is also the leading cause of acquired long-term disability and is almost twice as prevalent among women as men. Over 80% of all strokes are ischaemic that can result from a thrombus occlusion of a major cerebral artery.

Thrombosis is an important repair mechanism within the human body but also occurs if blood flow becomes stagnant. In vivo, erythrocyte rich thrombi are generally formed in relatively static, low flow-regions, as with arterial fibrillation. On the other hand, fibrin rich thrombi arise in areas of rapid moving blood flow and often originate from damaged endothelia. Animal thrombi models[1] have played a unique role in understanding the pathophysiology, morphology and mechanical characteristics of thrombi underlying the vascular occlusion in acute ischemic stroke. This project concerns the histological and mechanical examination and characterisation of thrombin induced, erythrocyte rich mammalian thrombi. Such thrombi models will be used to experimentally model and simulate ischemic stroke.

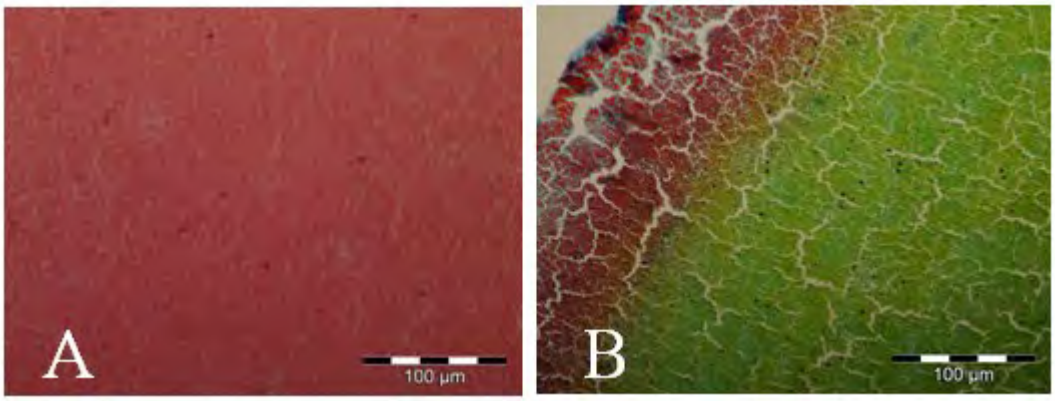
Methods: Mammalian blood (ovine and bovine origin) was harvested from a local abattoir. Samples were induced immediately using bovine thrombin. Haemotoxylin and Eosin (H&E) and Martius, Scarlet and Blue (MSB) stains were completed on ovine and bovine thrombi specimens at day 1 and day 33 (n=35). The presence of nuclei and erythrocytes correlated significantly with stained human thrombi samples reported from literature. Compositional differences were noticed in the thrombi after 33 days.

9 patient specific scans of the aortic arch in DICOM format were imported into Mimics Version 16.0 to generate 3D models using segmentation techniques. Models were geometrically characterised and differentiated for flexible model production. These models will be incorporated into a cerebral test facility for releasing the animal thrombi and tracking the trajectory within the cerebral vasculature. This test will further characterise the thrombi behaviour and lodgement morphologies within the cerebral vasculature.

Results: Figure 1(A) displays H&E stain of thrombin induced ovine thrombus (6NIH Units/ml blood). Figure 1(B) displays MSB stain of thrombin induced bovine thrombus (9 NIH Units/ml blood). The presence of fibrin and collagen was determined in high concentrations of thrombin induced mammalian thrombi.

Tensile and compression tests were conducted at day 1 at varying strain rates. Initial results indicate a possible increase in elasticity with increase in thrombin concentration (NIH units/ml blood).

Figure:



Caption: Figure 1: H&E stain ovine thrombus at day 1 (A), MSB stain bovine thrombus at day 33 (B)

Conclusion: The successful development of such thrombus models and future clot flow studies may provide a basis for the characterisation of post-operative thrombi removed from humans. Knowledge about the histological characteristics and lodgement morphologies of thrombi may provide a means for improving current endovascular therapies and the development of new treatment strategies for revascularisation in patients with acute ischemic stroke. These findings could indicate that the composition of thrombi is a potential key variable regarding the selection of the appropriate treatment options for ischemic stroke patients and in predicting the performance of mechanical thrombectomy devices and thrombolytics

AN IN VITRO STUDY OF CONFIGURATION DEFORMATION OF TRANSCATHETER HEART VALVE

Wentao Feng [1 2 3,*] Xianda Yang [1 2 3] Yang Liu [1 2 3] Yubo Fan [1 2 3 4]

[1]School of Biological Science and Medical Engineering, Beihang University, [2]International Research Center for Implantable and Interventional Medical Devices, [3]Key Laboratory for Biomechanics and Mechanobiology of Ministry of Education, [4]National Research Center for Rehabilitation Technical Aids, Beijing, China

Introduction and Objectives: Currently, percutaneous transcatheter aortic valve implantation (TAVI) has evolved into a safe, effective therapy for aortic valve replacement (AVR). However, TAV devices have had serious leakage and durability problems. Some of these problems are associated with geometric configuration deformation of TAV stent implantation in the calcified aortic annulus that has a non-concentric geometry. This study evaluated the hydrodynamics of different geometric configurations with different leaflet tissue thickness.

Methods: Three 22mm sized TAV devices with the same self-expanding nitinol stents with different leaflet tissue thickness's (0.25mm, 0.4mm, 0.55mm) were tested on pulse duplicator system. Six vary configurations were simulated as nominal, undersized (20mm), elliptical with commissure along minor axis, elliptical with commissure along major axis, triangle with commissures in edge and triangle with commissures in vertex. Hydrodynamics patterns such as traxnsvalvule pressure, regurgitant fraction and effective orifice area (EOA) were tested to analyze.

Results: The nominal shape had the smallest transvalvule pressure (15.4mmHg) and regurgitant fraction (6.83%) with the largest EOA (1.569cm^2) while the triangle shape had opposite results. The elliptical configuration with commissure along the major axis had a larger EOA (1.496cm^2) and lower regurgitant fraction (8.35%) than the same shape. There is no statistically significant differences between the undersized type and the elliptical tape with commissure along the minor axis. The triangle with commissures in side had a largest regurgitant fraction (15.02%) and smallest EOA (1.218cm^2). The regurgitant fraction and EOA of 0.55mm thickness valve were the smallest in all configurations.

Conclusion: The results showed significant hydrodynamics performances are impact by valve stent deformation and leaflet thickness. The triangle deformation should be neglected in TAVI procedures.

12-WEEK SUPERVISED EXERCISE REHABILITATION IMPROVES SKELETAL MUSCLE CONTRACTILE FUNCTION AND STRENGTH IN PATIENTS WITH CARDIAC DISEASE.

Yumna Albertus [1,*] Angus Hunter [2] Wayne Derman [1]

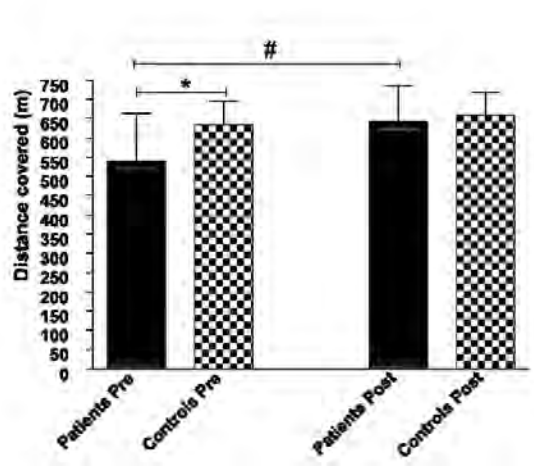
[1]Human Biology, University of Cape Town, Cape Town, South Africa, [2]Sports Studies, University of Stirling, Stirling, United Arab Emirates

Introduction and Objectives: Patients with cardiac disease are shown to have secondary structural and functional changes that occur in the skeletal muscle, which can result in decreased functional capacity and exercise intolerance. Previous studies have shown that supervised exercise rehabilitation programs result in improvements in functional capacity [(1; 2)] but the exact effect of exercise training on skeletal muscle activity in these patients is unknown. Therefore the aim of the study was to determine the effect of a supervised 12-week exercise rehabilitation program on skeletal muscle activity and muscle fiber conduction velocity (MFCV) during static, dynamic muscle contractions and during the 6 min walk test.

Methods: 9 patients with cardiac disease and 9 age matched healthy controls undertook testing before and after a 12-week period. During the 12 weeks the patients underwent exercise rehabilitation whereas the controls continued with normal daily activities. An electrode array (4 electrodes, 4 mm inter-electrode distance) was placed on the Vastus lateralis of the right leg to measure MFCV. Both groups performed two 5 s isometric maximal voluntary contraction on the Biodex dynamometer, followed by 5 s submaximal contractions at 20 %, 40%, 60 % and 80% MVC. Three maximal concentric isokinetic contractions were then performed at 60, 120 and 180 deg.s^{-1}. For the 6 min walk test, surface electrodes were placed on the vastus lateralis, vastus medialis, medial and lateral gastrocnemius muscles of the right leg. Resting heart rate (HR) and blood pressures (BP) were taken. They then walked around a 70 m track for 6 min, trying to cover as much distance as possible. HR and rating of perceived exertion (RPE) were measured every minute during the test. Post 1 min recovery HR and BP was recorded. After 12 wks the same protocol was repeated. The EMG was normalized to the participants walking at a normal pace over 10 m.

Results: Patients had significantly lower muscle strength (191 ± 27 Nm) compared to controls (230 ± 38.8 Nm) ($p=0.026$) and their strength significantly improved after 12 weeks of rehabilitation (218 ± 50 Nm) ($p=0.038$). MFCV has shown no difference between Controls (2.8 ± 0.7 – 3.3 ± 0.9 m.s^{-1}) and Patients (3.1 ± 0.7 – 3.6 ± 0.7 m.s^{-1}) in the Pre and Post Intervention trials during MVCs and dynamic contractions. Interestingly, the patients had significantly greater EMG activity during dynamic contractions ($p < 0.03$) before rehabilitation, whereas Post Rehab the EMG returned to levels of the controls, but with a significant increase in muscle strength. Similarly during the 6 min walk test, EMG activity was not significantly different between the Controls and Patients nor did EMG change, however patients showed a significant improvement in distance covered Post rehabilitation of 17.7 % (± 107 m) ($p=0.00$), whereas the Controls did not improve. Patients average HR increased significantly from 97 ± 5 bpm to 112 ± 7 bpm during the 6 min walk test Post rehabilitation ($p=0.007$). RPE remained similar Pre and Post rehabilitation in both the Patients and Controls.

Figure:



Caption: Distance walked in the 6-minute walk test by patient and control group Pre and Post intervention.

Conclusion: The findings of this study suggest that skeletal muscle contractile function was altered so as to produce greater force output but with unchanged relative EMG activity and conduction velocity. This suggests that patients become more efficient in performing the required exercise task following exercise rehabilitation training.

PO-0032

RELIABILITY OF A FASCIAL MODEL CONNECTIVITY IN VIVO BETWEEN THE PELVIS POSITION AND MEDIAL GASTROCNEMIUS

Carlos M. Cruz-Montecinos [1,*] Mauricio Cerda [2] Antonio Cuesta-Vargas [3]

[1]Kinesiology, [2]SCIAN-Lab. ICBM, University of Chile, Santiago, Chile, [3]Psychiatry and Physiotherapy, University of Malaga, Málaga, Spain

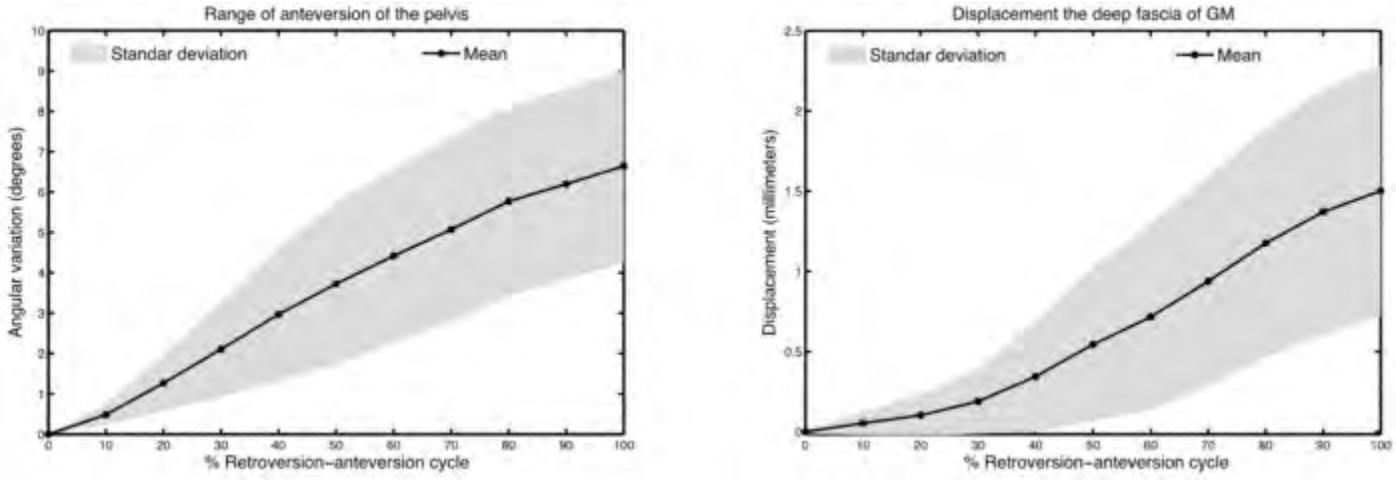
Introduction and Objectives: Different authors proposed the existence of myofascial tissue connectivity at a distance [1,2]. However, models that show the level of connectivity myofascial tissue in vivo are scarce. For example, the thoracolumbar fascia, responds to mechanical traction induced by muscular activity, in order to effectively transfer the load between spine, pelvis, legs and arms [1]. Other authors have questioned the existence of myofascial force transmission in response to physiological motion of joints [3,4]. In this context, an important step toward understanding distant myofascial tissue connectivity is to validate measurement methodology. The objective of this study was to evaluate the reliability of fascial model connectivity automatic measurement in vivo between the pelvis position and deep fascia displacement of medial gastrocnemius (DFMG) during anteversion of pelvis (AP) motion from retroversion position with the hip at 80 degrees, knees blocked in extension and ankles at 90 degrees.

Methods: With the approval of the local Ethical Service, 17 asymptomatic, sedentary young male were recruited. Each individual was asked to perform the motion AP three times. Measurement was performed by 3 stages automatic method: (i) DFMG tracking, (ii) AP Tracking, (iii) Variable synchronization, and a manual method to compare. (i) DFMG tracking was evaluated by Lucas-Kanade Tracker method with pyramid and iteration (LKPI), using real-time ultrasound. Within the range of interest (ROI), 9 pixels of greater representation were automatically detected. (ii) Angular variation of the AP was determined by 2D kinematic analysis; in order to tracking the markers Lucas-Kanade affine template method (LKAT) was used. (iii) Synchronization between the variables of interest, was performed offline with pressure sensors. All of the data had a normal distribution. In order to establish reliability of the proposed model in our study, intrasubject reliability for displacement DFMG and AP was determined by using Intraclass Correlation Index (ICC). To establish displacement reliability of DFMG and AP tracking, the maximum value obtained by automated tracking was compared to manual tracking in 20 videos using the Blant-Almant method (BAM) to verify their agreement.

Results: All of the participants were males, aged 22.76 ± 1.8 years old. Intrasubject reliabililty ICC of the DFMG model was of 0.903 (IC95%0.782 to 0.962) with a $p<0.001$.The intrasubject reliability ICC for AP of the pelvis was of 0.781 (IC95% 0.509 to 0.914) with a $p<0.001$. Reliability between manual tracking and tracking with the LKPI algorithm was of 0.973 (IC95% 0.993 to 0.989) with a $p<0.001$. Using BAM, an average difference of 0.034 mm could be observed between the two methods, with an according percentage <0.95%. LKAT tracking reliability for determining maximum AP motion during execution, was of 0.967 (IC95%0.917 to 0.987) with a $p<0.001$. An average difference of 0.879 degrees was observed with the BAM between both methods, with an according percentage <0.95%.

The result of a normalized simple linear regression at each 10% of the total cycle between AP motion and displacement of DFMG was $r= 0.791$ with a $p<0.001$.

Figure:



Conclusion: The present model of myofascial connectivity at a distance between the pelvis and leg, presents a good reliability. The results confirm and support the concepts of myofascial tissue connectivity. Future work will include to study other in vivo human movements.

PO-0033

VALIDATION OF FINITE ELEMENT MODEL OF DENTAL PROSTHESIS USING EXPERIMENTAL DATA

Bruno Agostinho A. Hernandez [1,*] João Paulo de Oliveira Freitas [1] Edson Antonio Capello Sousa [1] Cesar Renato Foschini [1] Max Laurent Albarracín [2] José Henrique Rubo [2]

[1]Mechanical Departament, Engineering College of Bauru - São Paulo State University (Unesp), [2]Dentistry, Prosthesis and Dental Materials Department, Dentistry College of Bauru – São Paulo University (USP), Bauru, Brazil

Introduction and Objectives: The bioengineering field consists in applying the engineering methods on the developing of devices that will support the life. One of areas that bioengineering acts is in the field applied on dental prostheses studies. The dental prostheses are typical biomechanical structures because they have an objective to restitute the mastication functions and they are responsible for replacement the original dental component that was damaged. In the last few years, many studies have been realized and big achievements have been noticed in this area. However, clinical studies, experimental procedures or analytical stress studies for these conditions are sometimes impractical, due to the biological nature of these components and their non-linear conditions. Consequently, many researchers have applied the Finite Element Method (FEM) in their researches. This method allows the evaluation of non-linear situations (e.g. biomechanical interactions), with complex geometries where experimental tests are usually difficult to be conduct. But in dental prostheses studies, the development of a model that simulates and predicts the real life condition of the mechanical behavior becomes very complicated, since the prosthesis structure is composed of many parts, with distinct geometries, materials and mechanical functions. Then, in order to improve the modeling techniques and the quality in Biomechanical studies, improved models have to be generated, studied and validated. As reliable the model is, more accurate the results will be. Therefore, this project aims to develop a tridimensional finite element model of dental prosthesis and validate this model using an experimental data.

Methods: A geometric model from a single dental prosthesis will be generated from Micro CT and Scanning data. Then, the geometry will be exported to finite element software where a finite element model will be created. After that, boundary conditions and loads will be applied in order to simulate an experimental procedure. Finally, the simulation results (strains) will be compared with experimental results (strains) so that the model can be validated.

Results: Comparing the results between the methodologies (numerical and experimental), it can see that the model is reliable because the strains results of numerical simulation were similar to the experimental results.

Conclusion: The results obtained in this study illustrate the accuracy of Finite Element Method has in simulate the biomechanical conditions, mainly in dental prosthesis. In this study, modeling techniques were improved and a reliable model was developed. In the next studies, this model will be used in the evaluation of fatigue problem in dental prostheses.

AGE EFFECTS ON INTER-JOINT LOAD-SHARING AND MUSCLE ACTIVITIES DURING CYCLING

Jia-Da Li [1,*] Hsing-Po Huang [1] Hsuan-Lun Lu [1] Tung-Wu Lu [1 2]

[1]Institute of biomedical engineering, [2]Department of Orthopaedic Surgery, School of Medicine, National Taiwan University, Taipei, Taiwan, Republic of China

Introduction and Objectives: Deterioration of the musculoskeletal system due to geriatric degeneration has been studied in recent decades. Reduced muscular strength [1], ability of dynamic balance control [2], joint coordination, and sensory feedback would increase the risk of injuries and decreased quality of life. Cycling has been widely applied in the rehabilitation of lower extremities and also played an important role in transportation, recreation, and sport in our daily lives. Previous studies on the lower limb mechanics during cycling have focused mainly on young subjects. However, it remains unclear how the elderly would adapt their lower extremities to meet the demands during cycling. Knowledge of such adaptation strategies will be helpful for preventing injuries, improving rehabilitation efficacy and designing bicycles for the elderly. Therefore, the current study aimed to identify the changes of inter-joint load-sharing and muscle activities in the elderly during cycling when compared with the young.

Methods: Fifteen healthy older adults (Age: 77.4 ± 7.7 years, height: 164.9 ± 9.6 cm, mass: 68.7 ± 9.9 kg) and fifteen young healthy controls (Age: 25.0 ± 4.4, height: 171.4 ± 5.5 cm, weight: 72.1 ± 16.5 kg) participated in the current study. Each subject wore 30 skin markers on the pelvis and bilateral lower extremities, and performed cycling movement on a self-developed ergometer at an average resistance of 20Nm mimicking rehabilitation conditions. A metronome was used to control the cycling speed at 35 rpm. The 3D marker trajectories were measured using an 8-camera motion capture system at a sampling rate of 120Hz (Vicon Motion System Ltd., UK) and the pedal reaction forces were measured by a 6-component load-cell installed on the left pedal. Electromyography (EMG) of the rectus abdominis, erector spinae, left iliacus, gluteus maximus, rectus femoris, biceps femoris, tibialis anterior and gastrocnemius were measured (ZeroWire, Aurion S.r.l.). Maximum voluntary contractions (MVC) were also acquired for each muscle. Joint moments were calculated using inverse dynamics analysis. Inter-joint load-sharing was indicated by joint contributions defined as the ratio of the extensor moment of a single joint to the summation of the extensor moments of the three lower limb joints when the maximum crank torque occurred. The maximum value of the MVC-normalized EMG envelope was used to indicate the muscle contribution. An independent t-test was used to compare the calculated variables between groups at a significant level of 0.05.

Results: Significant differences in joint contributions were found at the hip and knee, the older adults showing increased hip contribution (older: 37.0%, young: 24.5%) but decreased knee contribution (older: 45.4%, young: 56.7%) although the knee extensor moments were the biggest among all the joints (Table 1). Significantly increased muscle activities were also found in the older group for most of the muscles except for the rectus abdominis, maximum EMG values ranging from 7.0% to 29.4% in the older group and from 4.3% to 18.8% in the young group. Both groups showed the highest activity in the rectus femoris muscle.

Figure:

Caption: An older subject was performing cycling

Conclusion: Under the same resistance and pedaling speed during cycling, the older group was found to increase their muscular activation when compared to the young, which may be related to the age-related reduction in muscle strength [1] when trying to maintain the pedaling speed. With this strategy, the older subjects increased the hip contribution to reduce the knee contribution because the knee extensor moments were the highest among the lower limb joints. This was achieved by increasing activations in most of the muscles, avoiding high contraction levels in a single muscle. The current results show that proper bike fitting (e.g., via changing the seat positions) is critical in the elderly to reduce knee extensor loadings and prevent overuse injuries.

Table:

	Elderly	Young	*P*-value
Joint Contribution (%)			
Hip	37.01 (10.11)	24.48 (7.65)	0.003*
Knee	45.37 (11.49)	56.69 (9.93)	0.019*
Ankle	17.62 (8.64)	18.84 (6.62)	0.707
Muscle Activity (%MVC)			
Iliacus	19.47 (8.27)	12.46 (5.97)	0.027*
Gluteus maximus	16.38 (6.98)	6.00 (2.64)	<0.001*
Rectus femoris	29.35 (13.09)	18.78 (9.39)	0.034*
Biceps femoris	20.40 (7.07)	8.02 (4.90)	<0.001*
Tibialis anterior	24.41 (8.30)	13.98 (4.00)	0.001*
Gastrocnemius	16.27 (6.34)	7.15 (2.59)	<0.001*
Rectus abdominis	6.95 (5.64)	4.29 (4.48)	0.219
Erector spinae	9.86 (4.75)	4.81 (3.40)	0.008*

PO-0035

EXERCISE TRAINING IN OLDER PEOPLE CAUSES JOINT MOMENT REDISTRIBUTION DURING STAIR DESCENT

James P. Gavin [1,*]Neil Reeves [2]David Jones [2]Vasilios Baltzopoulos [3]Irene Di Giulio [4]Michael Roys [5]Costis Maganaris [1]

[1]Research Institute for Sports and Exercise Sciences, Liverpool John Moores University, Liverpool, [2]School of Healthcare Science, Manchester Metropolitan University, Manchester, [3]Centre for Sports Medicine and Human Performance, Brunel University, [4]Sobell Department of Motor Neuroscience and Movement Disorders, University College London, London, [5]Building Research Establishment, Watford, United Kingdom

Introduction and Objectives: Stair descent presents a physically demanding task, routine to everyday life, which is made more challenging by age-related deteriorations in lower-limb musculoskeletal capacities. Decline in functional mobility is particularly limiting in built environments, where stairs comprised of increased rise steps may be encountered. Stair descent involves mainly eccentric contractions, and with the old operating at higher maximum eccentric ankle capacities than the young [1], exercise training may allow older adults to meet the varying biomechanical demands of descent [2]. This study examined the effects of lower-limb exercise training on the biomechanics of older adults when descending standard, and increased rise stairs.

Methods: Fifteen older adults (age, 75±3 years) descended a four step stair adjusted to standard rise (170 mm), and 50% increased rise (255 mm) higher than those common to public and residential buildings [3]. Trials were on separate visits before, and after 16 weeks of either: resistance exercise and stretching training (n = 8), or no training (n = 7). Three, unaided trials were performed on each visit, at a self-selected pace. Kinematic and kinetic data were measured during a single gait cycle, referring to the left leg [4].

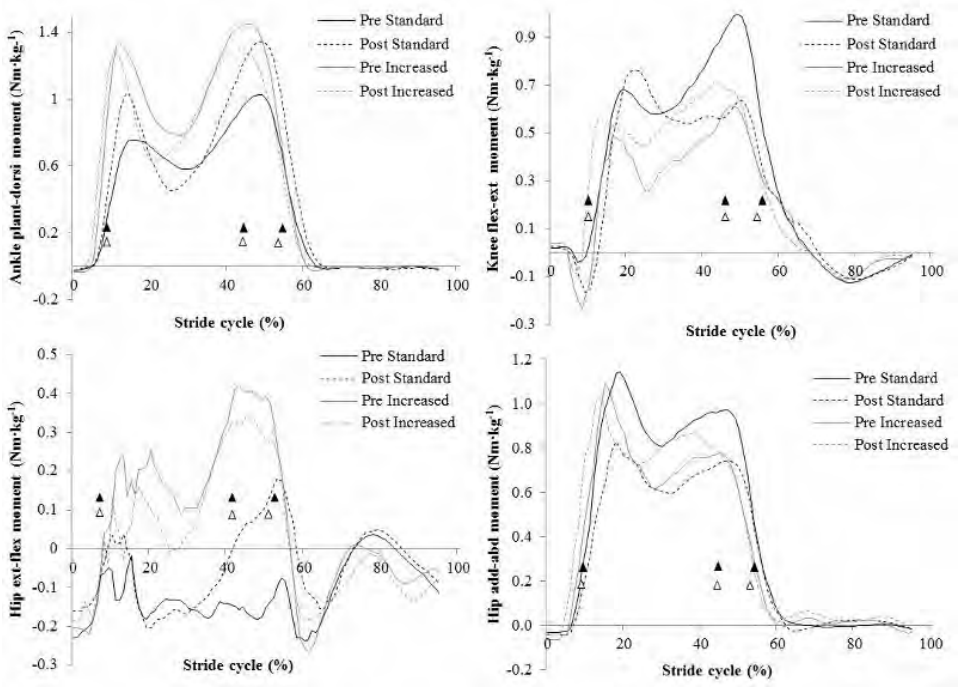
Kinetic data were measured from step-mounted force plates (Kistler type Z17068, Kistler Instruments, Winterthur, Switzerland), and kinematic data from motion-capture cameras at 120 Hz (VICON 612 system, VICON Motion Systems Ltd., Oxford, UK). Trials were calculated with a 'plug-in-gait' model, and processed by running a static and dynamic model using Workstation software (VICON Motion Systems Ltd., Oxford, UK).

Training involved two sessions per week of resistance exercises (three sets of ~8 repetitions for: leg-press, knee extension and calf-press, at ~80% three-repetition maximum), and static plantarflexor stretching (45 s holds, with three repetitions per leg). Eccentric, maximum voluntary contractions of the knee extensors (angular velocities of 60, 120, 180 and 240°·s^{-1}) and plantarflexors were assessed before, and after 16 weeks for training and control groups using an isokinetic dynamometer (Cybex NORM, New York, USA), as was maximum dorsiflexion angle. Repeated, two (time) x two (step rise) measures ANOVAs compared changes after 16 weeks for both groups on standard and increased rise stairs. Bonferroni Adjustments were used to identify step rise-specific training effects in each group. Data analysis was performed using IBM SPSS Statistics Version 21 (IBM Corp, Armonk, NY), with statistical significance as 0.05.

Results: Maximum eccentric torques increased at the knee (by 29.8% at 60°·s^{-1} and 43.2% at 180°·s^{-1}; P<0.001) and ankle (by 35.3% at 60°·s$^{-1;}$ P=0.001) after exercise training, as did maximum dorsiflexion angle. Training did not alter ankle angles when descending either stair. Training decreased knee flexion angle in single-leg stance (P=0.03) on standard

stairs, and increased flexion angle upon final foot contact on increased rise stairs (P=0.001). Training did not affect hip flexion angle for either stair, but hip abduction angle increased in double support for increased rise stairs (P=0.04). Descending increased rise stairs required higher ankle and hip joint moments, and lower knee joint moments, when compared to standard stairs (P<0.001). Training reduced ankle joint moment (P<0.001), but increased knee joint moment (P=0.01), on increased rise stairs; training increased ankle joint moment (P<0.001), but reduced knee joint moment (P<0.01), on standard stairs. Training did not alter hip joint moments on increased rise stairs; upon standard stairs, hip flexion moment increased (from foot contact to double support, P<0.001) and hip abduction moment decreased (from single-leg stance to double support, P<0.05; Figure 1).

Figure:



Caption: Figure 1. Lower-limb joint moments of older adults descending standard and increased rise stairs, pre and post-exercise training. Gait cycle events (· standard, · increased) refer to initial foot contact (0%), single-leg stance, double support, foot off and final foot contact with the above step (100%). Positive = abduction, negative = adduction.

Conclusion: Older adults after training descended i) standard rise stairs, by increasing ankle and hip joint moments, and reducing knee joint moments; and ii) increased rise stairs, by increasing knee joint moments and reducing ankle joint moments. These findings suggest older adults adopt neuromuscular strategies to meet the demands of stair descent, and strength improvements from exercise training can reorganise these strategies.

PO-0036

ASSOCIATION OF THE LENGTH OF INSTITUTIONALIZATION WITH OLDER ADULTS' BALANCE AND RISK OF FALLS

Gabriel Espinosa [1,*] Flávia Porto [2] Wagner Batista [1] Edmundo Drummond [1] Waldyr Castro [1] Jonas Gurgel [1]

[1]Fluminense Federal University, Niterói, [2]Rio de Janeiro State University, Rio de Janeiro, Brazil

Introduction and Objectives: The increase in longevity has raised various questions for the management of public policies, among which there is the increase in demand for Homes for the Aged (HAs). Living in these institutions, however, can promote social isolation, reduction in mental and physical activities, and a worsening in the older adults' quality of life. Moving to HAs is strongly associated with a decline in the abilities to undertake activities of daily living (ADLs) and a progressive reduction in opportunities for mobility. Consequently, this contributes to the failure to perform ADLs, inducing a hypokinetic routine for them, which becomes an intervening factor for falls. This study was realized in order to ascertain the association of the length of institutionalization with older adults' balance and risk of falls.

Methods: All subjects of this study live in a home for aged in a municipality of Três Rios, RJ, Brazil. From a total of 96 aged institutionalized, 40 subjects were eligible to take part in this study. Nevertheless, 4 of them were lost during the study (1 death; 2 bead resting and 1 returned for the family). The final sample size was composed by 36 elderlies. They were 75.44 years old, and havd Body Mass Index 22.67 kg/m². Subject's Length of Institutionalization varied between 07 and 231 months. The balance was assessed by three different methods. For the Berg Balance Scale, it was used the Brazilian-Portuguese validated version of the protocol. The test consists in a set of 14 different balance-related daily tasks. Each one classified between 0 and 4 (0 for the worst and 4 for the best performance). The maximal score is 56 that indicate the minor risk of fall. It was adopted the 41 value as a cutoff. The Get up and Go test was applied as proposed on the original protocol. Volunteers had to get up from a chair, walk 3 meters and then return fast as they could to the starting position, sited on the chair. The time was registered, and 20 seconds was considered as cutoff value. For the stabilometric tests, it was used a force plate. For the opened eyes test, subjects were requested to stand during 45 seconds at the center of the plate on orthostatic position, barefoot (30° between feet). There was a reference marked point 2.5 meters from de center of the plate on the wall to keep viewing fixed. The signal was processed and analyzed in a computer through the software LabVIEW (National instrumetns, 2012, for windows) and MATLAB (MathWorks, R2012a, for windows) respectively. After processing of the signal, the statokinesigram was analyzed considering the Elliptical Area as 95% (1.96 standard deviation of x and y axis) and mean velocities on the x and y axes of center of pressure displacement. The normality of data was tested by Shapiro-Wilk test, thus parametric (Pearson) and nonparametric (Spearman) correlations were used. The significance level was set at $\alpha \leq 0.05$.

Results: There was no significant correlation between the length of institutionalization and the tests for evaluation of risk of falling. The stabilometric parameters, on the other hand, demonstrated significance in the negative correlations between the elliptical area and the speed of the COP in the x axis (Table).

Conclusion: In the evaluation of the risk of falls proposed by the BBS and TUG clinical tests, a leveling effect was observed which was below the minimum established for their respective cutoff points. In the stabilometric behavior, a

reduction was noticed of the parameters of the COP whenever there is an increase in the LI of the older adults in the HAs, suggesting different strategies for postural control. These discoveries suggest the existence of an association of the LI with postural balance and the risk of falls; difficulty in undertaking motor tasks which require postural control is also indicated. These findings suggest that the length of residence in HAs negatively influences postural balance and, consequently, the risk of falls. This points out to the need to rethink health policy for institutionalized older adults, as well as to restructure the methods and strategies used in the care for the health of these individuals.

Table: Correlation of the lenth of institutionalization with balance and the risk of falls in older adults resident in Homes for the Aged. Três Rios, RJ, Brazil, 2012 (N=36)

PO-0037

CHANGING OF MUSCLE FIBER CONDUCTION VELOCITY ON VASTUS MEDIAL MUSCLE WITH AGING

Kazuyuki Mito [1,*] Noriyasu Ota [2] Satoko Soga [2]

[1]Graduate School of Informatics and Engineering, The University of Electro-Communications, Tokyo, [2]Kao Corporation, Tochigi, Japan

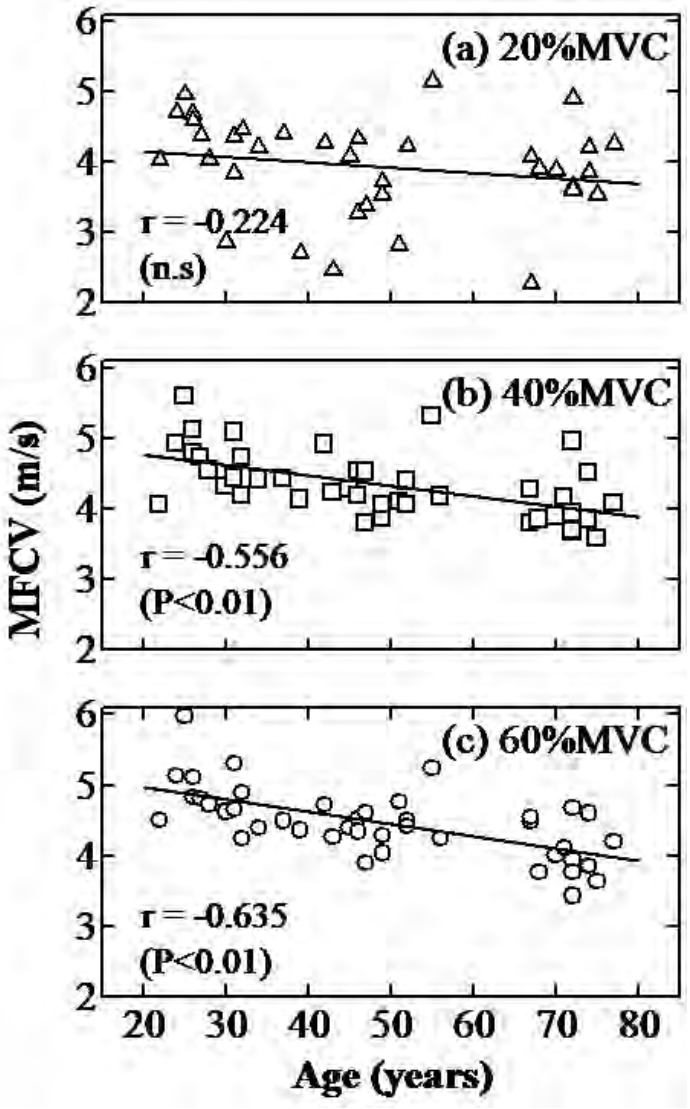
Introduction and Objectives: A decrease of muscle due to aging is associated with the atrophy of fast twitch (Type II) muscle fibers [1]. The aim of this study is to elucidate the difference of muscular activity by aging with the use of muscle fiber conduction velocity (MFCV).

Methods: The subjects were 42 healthy male volunteers 22-77 years of age, and they provided a written informed consent to participate in this study after a detailed explanation including the purpose and procedures of the experiment. The subject was seated in a chair and knee joint angle of dominant foot was fixed at 90-degrees, and maintained an isometric contraction force of 20%, 40% and 60% of the maximum voluntary contraction (MVC) for 5 seconds.

The surface myoelectric signals were measured by an electrode arrays which were installed on on vastus medial muscle. The electrode arrays were composed 5 silver-silver chloride poles each with a diameter 2 mm and a height of 3 mm attached on a silicon rubber plate (Unique-medical Co., Japan). The inter-electrode distance was 5 mm. The myoelectric signals detected between adjacent silver-silver chloride bars was amplified with use of differential bioelectric amplifiers. The frequency range and the gain of amplifier were set from 5 Hz to 1000 Hz and 60 dB, respectively. The amplified myoelectric signals of 4 channels were stored on a personal computer through an A/D converter with a 16-bit resolution and with a sampling frequency of 10 kHz. The muscle fiber conduction velocity (MFCV) was calculated by cross-correlation methods [2]. The cross correlation coefficient was evaluated from the two myoelectric signals in the neighboring channels. In each contraction force, Peason's correlation coefficient (r) was used to study the relationship between MFCV data and age.

Results: A significant statistical negative correlation was observed in 40% and 60% MVC between MFCV and age as shown in Figre 1. Peason's correlation coefficient (r) and corresponding P values for those correlation in 20, 40, 60%MVC were r = -0.224, -0.556, and -0.635, and P=0.153, 0.001, 0.001, respectively. As the muscle force is large, the MFCVs were significantly reduced depending on the age.

Figure:



Caption: Relationship between MFCV and age in (a) 20%, (b) 40%, and (c) 60%MVC.

Conclusion: In high contraction force, the values of MFCV were decreased in according to age. The fast twitch muscle fiber which MFCV is faster than slow twitch muscle fiber are mainly active in strong muscle contraction. Therefore, the reduction of MFCV at 40% and 60% MVC due to aging might reflect the atrophy of fast twitch muscle fiber.

ELDERLY WOMEN'S QUADRICEPS ACTIVATION IN RESPONSE TO A POWER KNEE EXTENSION TASK: A CONTINUOUS WAVELET ANALYSIS APPROACH

João P. Pinho [1,*]Bruno Mezêncio [1]Desidério Porras [2]João Claudino [1]Rafael Soncin [1]Ana Azevedo [1]Juliana Pennone [1]Julio Serrão [1]Alberto Amadio [1]

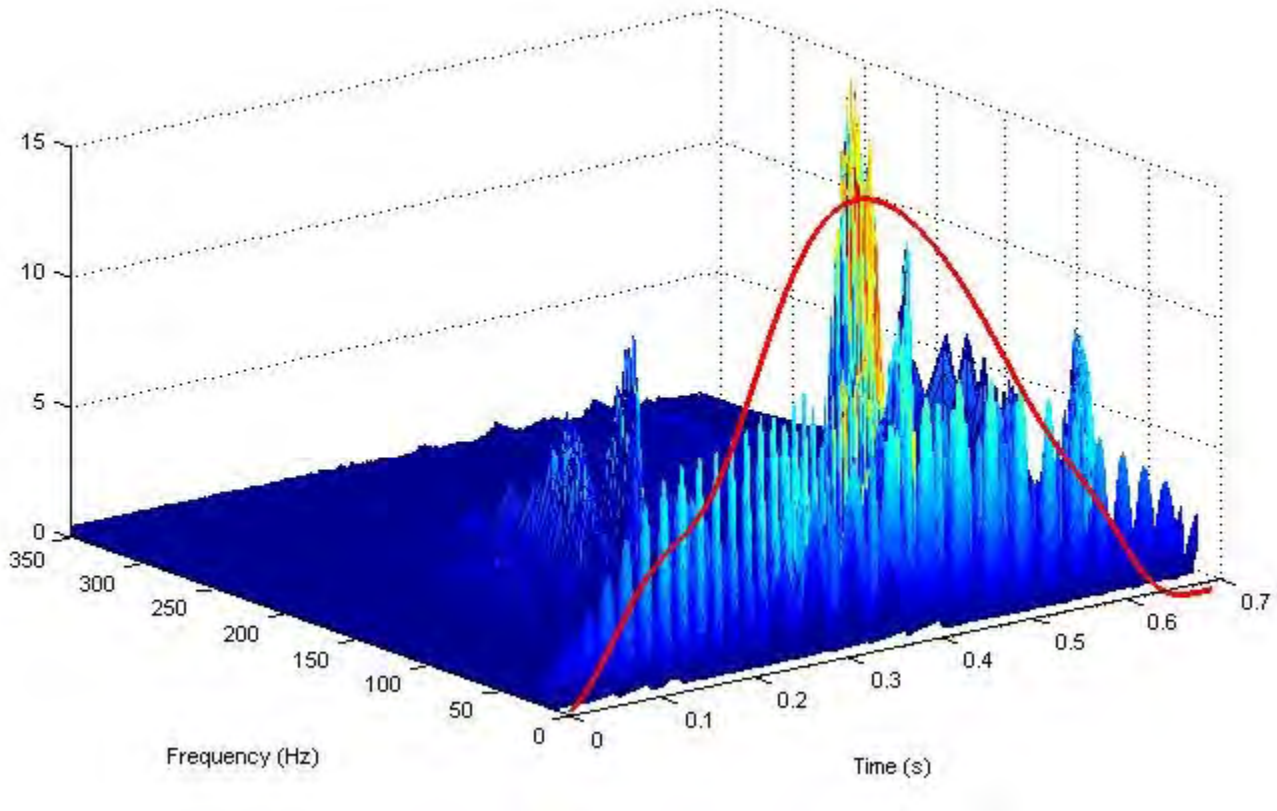
[1]Laboratory of Biomechanics, University of São Paulo, [2]Department of Physical Therapy, School of Medicine, São Paulo, Brazil

Introduction and Objectives: Among the main qualitative muscle changes in aging muscle power loss is the one that early occurs suggesting it as the most striking muscle alteration in the senescent locomotor system. Corroborating this statement, TSCHOPP et al. [1] pinpoint muscle power as the main independence determinant in the elderly. The authors showed that when compared with maximum muscle strength this parameter presents an earlier and abrupt reduction. Moreover, GREENLUND & NAIR [2] showed that between the third and the eighth decades the knee extensors ability to generate peak torque suffers a significant decline. The functional capacity diminution multifactorial origin makes the ideal exercise protocol to increase this ability to perform everyday tasks unclear. Notwithstanding, TSCHOPP et al. [1] suggest power training as the best nonpharmacologic strategy to attenuate, or even reverse, that functional capacity declining over one's life. A problem that arises alongside with this new protocol is the one related with the optimum training load. In fact, although for athletes the ideal training load to produce maximum power is known, for the elderly this is still to be found. Therefore, this study's aim was to investigate the training load that permits sedentary elderly women to produce the maximum peak power as well as examine their knee extensors electromyographic activation by a continuous wavelet analysis.

Methods: Thirteen sedentary elderly women aged between 65 and 70 years old (69,3 ± 4,06 years) took part in the study. The participants were previously informed of all of the operational procedures and gave their Written Consent informing that their involvement in the study was voluntary. The study was approved by the local Ethics Committee. The experiments were conducted in a conventional knee extensors machine (Gervasport Fitness Equipment) ensuring that the participants' trunk and thigh remained immovable. To avoid any risks to the participants' physical integrity a sub-maximum test was conducted. After estimating the maximum load effort by Brzycki [4] equation 3 load regimes were calculated: 30%, 50% and 70%. In a randomized order the participants executed 6 repetitions of each load condition with the concentric phase of the knee extension movement as quickly as possible. Reflexive markers were attached to the participants' ankle and knee axis being the knee aligned with the leg extensor machine axis. A digital video camera (Casio EX-ZR10) with an acquisition rate of 240Hz and a shutter speed of 1/2000s recorded the trials. The markers were digitized by the *Ariel Performance Analysis System* (*Ariel Dynamics, INC*). An external trigger was used to synchronize the video capture with an electromyography system (Lynx technology). Using the SENIAM procedures vastus lateralis and rectus femoris were monitored. A continuous wavelet analysis was used as a time-frequency transformation strategy of our EMG data. Daubechies 44 was selected to perform the transformation since it was found to be the most similar mother wavelet function to EMG signal [5]. All mathematical procedures were performed in MatLab (Mathworks, Inc).

Results: The repeated measures ANOVA showed an increased peak power in the 70% (221±84 W) and 50% load conditions (217±94 W) when compared with the 30% regime (185±78 W). Although no differences were seen between the conditions in the total median frequency (MF) of the studied muscles, the MF 200 milliseconds before the peak power in the 70% (69±23 Hz) condition was found to be different (p=0.009) that the 30% condition (58±17 Hz).

Figure:



Caption: Example data of the continuous wavelet transform db44 (3D graph) and knee extensors power (2D red line).

Conclusion: The results of the present study showed that in order to obtain higher peak power older adults need to exercise with higher loads. The wavelet analysis approach that allowed to obtain time as well as frequency resolution suggests that the load increment activates muscle fibers with higher frequency rates which could mean a better fast twitch fibers recruitment, which in turn have a close relationship with elderly's functional capacities. To the authors' best knowledge this is the first study to explain how the elderly's knee extensors are able to generate greater knee extension power with higher load regimes.

PO-0039

INFLUENCE OF THE LENGTH OF INSTITUTIONALIZATION ON OLDER ADULTS' POSTURAL CONTROL

Wagner Batista [1,*] Flávia Porto [2] Gabriel Espinosa [1] Edmundo Alves Junior [1] Waldyr Castro [1] Jonas Gurgel [1]

[1]Fluminense Federal University, Niterói, [2]Rio de Janeiro State University, Rio de Janeiro, Brazil

Introduction and Objectives: In human aging, postural control changes are perceived. These changes are related to a reduction of sensorial capabilities of the locomotor system and the interactions of different systems to realize adequate actions and reactions to maintain balance. The longevity increase have brought a number of relevant questions to the public health policies, among others, an increase of demand for Homes for the Aged (HAs). Otherwise, to reside in an HAs may contribute to social isolation, a reduction of mental and physical activities and a decrease of quality of life among elderly. The institutionalization of elderly in an HAs may be accelerating the physiological decline what shows restrictions to the maintenance of cognitive and motor abilities, essential to postural control. The aim of this study was to verify the effects of the length of institutionalization in HAs on postural control and stability limits of elderly subjects.

Methods: To evaluate the center of pressure (COP) behavior during the quasi-static stabilometry was utilized a force plate. The analyzed variables were COP velocities (cm/s) (in both, x axis and y axis) and 95% of COP elliptical area (cm2). The groups were stratified using the variables: residential time on HAs, age, fallers and non-fallers. Data were analyzed using independent Student´s t-test (parametric data) or Mann-Whitney test (non-parametric data). Each test was used to compare the different groups, stratified by length of institutionalization in HAs (7-63 months LI1 e 65-231 months LI2) and fallers and non-fallers. One way ANOVA with Tukey post-hoc test (parametric data) or Kruskal-Wallis with Dunn post-hoc test (non-parametric data) were used to compare the subgroups stratified by age and length of institutionalization in HAs (LI1AG1, LI1AG2, LI2AG1 and LI2AG2). For all tests, the significance level adopted was $\alpha \leq 0.05$.

Results: The data shows (Table) a reduction on the COP variables analyzed when the length of institutionalization in HAs increases. Mainly, this reduction can be perceived on the COP velocity in both axes and in the 95% of elliptical Area, comparing the LI1 e LI2 groups. Fallers and non-fallers presented significant differences on all COP variables, showing smaller valor on fallers group. The results did not show significant differences between the age groups with the same length of institutionalization in HAs, showing only significant differences between the groups with different length of institutionalization in HAs.

Conclusion: The presented results of the variables analyzed suggest a not usual COP behavior, what is in the opposite direction of classical scientific evidence. Otherwise, the same behavior was found by some researchers investigating debilitated population. What can be explained by a change on postural control strategies of the more debilitated elderly subjects, decreasing the limits of stability and the possible area for COP oscillation. The age does not appear to be an issue to change the COP behavior, but the length of institutionalization in HAs appears to be.

Table:

Variable	LI1 (7-63 months)	LI2 (65-231 months)	p	Faller (n=19) 52.77%	Non-faller (n=17) 47.23%	P

PO-0040

THE EFFECTS OF TAI-CHI EXERCISE ON COUNTERMOVEMENT JUMP IN OLDER ADULTS

Bo-Jen Ko [1,*] Chen-Fu Huang [1] Po-Chieh Chen [1] Tai-Yen Hsu [2]

[1]Physical Education, National Taiwan Normal University, New Taipei City, [2]National Taichung University of Education, Taichung, Taiwan, Republic of China

Introduction and Objectives: Lower limb muscle strength has great impact on functional performance of daily activities. Weakness lower limb muscle strength may cause fall risk. Previous research has been reported that muscle power decline 1.2%~2% per year after 65 years old [1]. Regular exercise is essential for older adults in order to maintain muscle function.

Many studies has been confirmed that Tai Chi exercise has advantages on people such as pain reduction, fall prevention and improvement on balance, strength and flexibility[2][3], but the advantage of lower limb biomechanics on elderly is still unclear. The counter movement jump (CMJ) is an efficient physical performance test which is common used for young adults and can be used to estimate lower limb biomechanics in older adults.

The purpose of this study was to investigate the biomechanical effects of Tai-Chi exercise in older adults by using CMJ test.

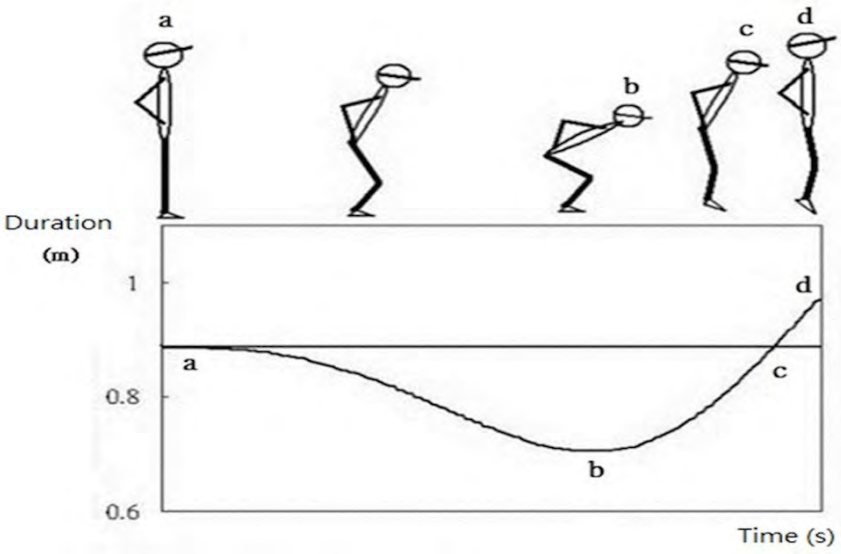
Methods: Nine older adults with regular Tai Chi exercise experience (age: 60.56 ± 2.4 yrs; height: 158.22 ± 6.53 cm; weight: 60.28 ± 6.07 kg) and nine older adults without regular and systematic physical training (healthy elderly: age: 62.22 ± 1.71 yrs; height: 155.89 ± 9.03 cm; weight: 58.78 ± 8.12 kg) participated in this study.

Ten cameras (Vicon MX13+, Oxford, UK, 250Hz) were used to record CMJ data. Two Kistler force plates (Kistler Instrumente AG, Winterhur, Switzerland, 1000Hz) were used to record the ground reaction forces (GRF) while the subjects performed 3 maximal effort CMJs. Vicon Nexus 1.81 and Visual3D V5 software were used to analyze kinematics and kinetics data. All data were analyzed by using an independent sample *t*-test ($\alpha = .05$).

Results: The results in table 1 showed that Tai Chi group had greater jump height. ($p<.05$). Tai Chi group also had greater peak vertical force as well as peak hip, and ankle moments in jump phase ($p<.05$).

These results showed Tai Chi group had greater lower limb muscle strength in hip and ankle and thus muscle strength could be enhanced by training Tai Chi exercise. Tai chi exercise usually used lower center of gravity pose to move their body and it could be the possible reasons for these results. It was concluded that older adults participated in Tai Chi exercise training had better performance in a maximal effort CMJ.

Figure:



Caption: CMJ Phase (a~ b: Countermovement phase; b~ c: Jump phase; c~ d: Air phase)

Conclusion: The Tai Chi group exhibited a better ability to generated energy to increase the CMJ jump height which indicated that Tai Chi exercise might be able to enhance muscle strength of lower extremity in older adults. These performance enhancements might also influence the functional performance of elder daily life and reduce fall risk.

PO-0041

ESTIMATING THE EFFECT OF ERGOMETRIC PEDALING EXERCISE IN ELDERLY PERSONS BY USE OF EMG

Kenichi Kaneko [1,*] Masako Shisido [1] Kazuyuki Mito [2] Hitoshi Makabe [3] Kazuyoshi Sakamoto [4]

[1]Industrial Engineering and Management, Fuji University, Hanamaki, [2]Informatics and Engineering, The University of Electro-Communications, Chofu, [3]Physical Therapy, Yamagata Prefectural University of Health Science, Yamagata, [4]Activation Research, The University of Electro-Communications, Chofu, Japan

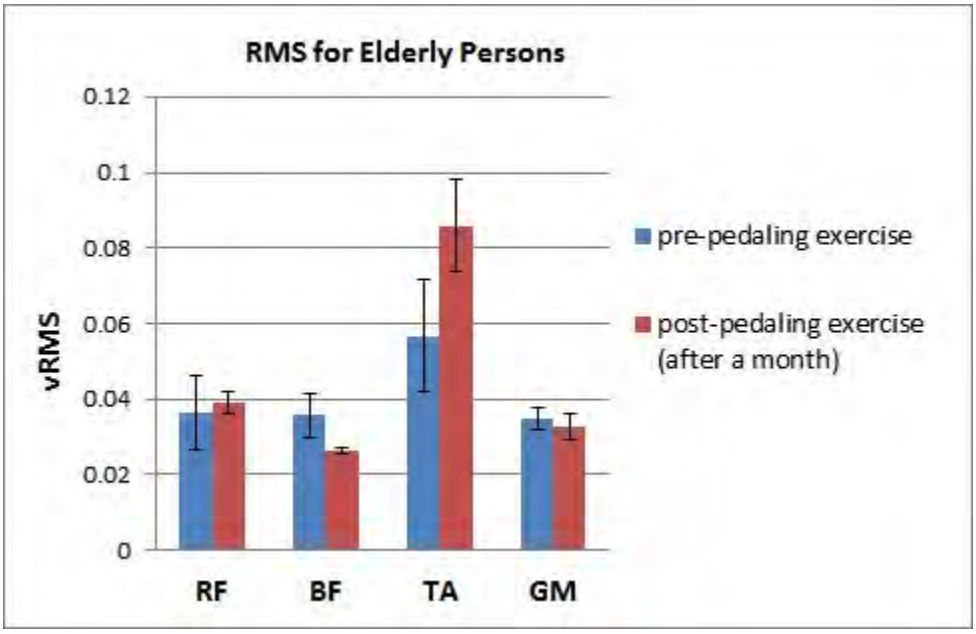
Introduction and Objectives: Japan has the highest proportion of older adults in the world. It is called “Super-Aging Society”. The population of person requiring care has been over four millions since 2005 in Japan. A fall and born fracture is one of the main causes of requiring care. Resistance trainings of muscles on the lower limbs are required to prevent the fall and born fracture. We studied on an effect of ergometric pedaling exercise as the resistance training of lower limb muscles in elderly persons. To estimate the effect of ergometric pedaling exercise, electromyographic activities of lower limb muscles in elderly persons were compared with the pre-ergometric pedaling exercise and the post-ergometric pedaling exercise (after a month). Furthermore, the ergometric pedaling exercise was carried out on young competitive road cyclists and young non-cyclists. The EMGs for the lower limb muscular activations were evaluated by using of values of RMS and Wavelet Transform. The comparisons of these values were useful to understanding the effect of ergometric pedaling exercise from the view point of kinesiological motor skills.

Methods: The subjects were three elderly females (ages 60-90 yr), five young competitive road cyclists (ages 18-22 yr) and five young non-cyclists (ages 21-22 yr). All subjects had an ergometric pedaling exercise (for 15min with 50% MVC) twice a week for a month. The electromyographic activity during ergometric pedaling was measured in the Rectus femoris (RF), the Biceps femoris (BF), the Tibialis anterior (TA), and the Gastrocnemius medialis (GM) by using of the wireless EMG sensors (Trigno Wireless System, DELSYS, U.S.A.). The EMG signals were stored on a personal computer through an A/D converter with a sampling frequency of 1 kHz. The EMG activities were evaluated by RMS, %RMS, and dimension of frequency. Firstly, the RMSs were calculated for the generating EMG relation to the ergometric pedaling on four muscles (RF, BF, TA, and GM). The starting time and the ending time for the generation of the EMG waveform were defined here as the amplitude reached and stabilized at 10% of the peak to peak. Secondly, the %RMSs were calculated as follows. The pedaling dynamics divided into two phases were the “down phase” and the “up phase” from the view point of the crank angle (down phase; 0 to 180 degree, up phase; 180 to 360 degree, respectively). The %RMS values for the EMG during the pedaling were calculated at a ratio of the RMS for the down phase to the RMS for the up phase. Finally, the Time-frequency analysis of the EMG signals were conducted using continuous wavelet transform (CWT). In addition to the CWT, the EMG data segments were also processed with a Daubechies 4 wavelet algorithm. The EMG data were decomposed into six separate scales (j=-1; 125-250 Hz, j=-2; 62.5-125 Hz, j=-3; 31.25-62.5 Hz, j=-4; 15.625-31.25 Hz, j=-5; 7.8125-31.25 Hz, and j=-6; 3.906-7.8125 Hz).

Results: Figure 1 showed that the values of RMS of the RF and the TA were increased by the ergometric pedaling exercise for a month in elderly persons. On the other hand, the young competitive road cyclists have decreased the muscle activities of the RF, the BF, and the TA in the post-ergometric pedaling exercise (after a month). The only muscle

activity of the GM was increased by the ergometiric pedaling exercise in young competitive road cyclists. The means of %RMSs for the BF and the GM were higher than 100% in the pre-ergometric pedaling exercise. In contrast, the mean of the %RMSs for the RF and the TA were lower than 100%. The individual differences of the %RMSs for the BF and the GM were larger than that for the RF and the TA in the young competitive road cyclists. There was no difference between the elderly persons, young competitive road cyclists, and the young non-cyclists about all %RMS values, though, the %RMS values at the TA and the GM were significantly difference between the three subject groups. The mean power of wavelet decomposition (Ej) are compared. The values of Ej for the young competitive road cyclists were significantly larger than that of the elderly persons and the young non-cyclists at j=-1, -2, -3, -4, -5 (from 7.81 Hz to 250 Hz).

Figure:



Caption: Figure 1. Root mean square (RMS) for EMG activities of four lower limb muscles relation to pedaling load in elderly persons.

Conclusion: These results suggested that the value of RMS, %RMS, and Ej at the TA and the GM were useful indices to evaluate the effect of the ergometric pedaling exercise in elderly persons.

PO-0042

CHARACTERISTICS OF THE GAIT IN ELDERLY PEOPLE WITH EXERCISE HABITS

Kentaro Takahashi [1,*] Minato Kawaguchi [1]

[1]College of Science and Technology, Kanto Gakuin University, Yokohama, Japan

Introduction and Objectives: While many studies on elderly people have analyzed the reduction in walking ability with increasing age, most of them were performed in the elderly population as a whole; few studies have assessed the gait of elderly people with exercise habits. This study aimed to analyze gait in elderly people with exercise habits and thereby elucidate its characteristics. This study aimed to analyze gait in elderly people with exercise habits and thereby elucidate its characteristics.

Methods: This study was performed in healthy young people and healthy elderly people who exercised once in a week. The subjects were instructed to walk on a path with a normal gait over 5 trials such that one foot passes each of the 2 force plates at least once during an analysis; these analyses were performed using a VICON system. A gait cycle, which was recorded in the middle of the measurement period, was obtained from the measurement data that were normalized to 100%. The muscle activities at 6 sites during walking were simultaneously recorded by performing electromyography for the right leg of each subject.

Results: In elderly people with exercise habits, the hip-flexion moment in the pre-swing phase was high and the hip-flexion angle from the initial swing phase to the terminal swing phase after the pre-swing phase was also high. Therefore, in comparison with younger people, these individuals show greater utilization of their hip and hamstring to elevate the lower extremity during outward motion of the extremity of the swing side. In the elderly people with exercise habits, the knee-extension moment and knee-flexion moment were high in the terminal-stance and terminal-swing phases and in the pre-swing phase, respectively, during elevation/forward movement of the lower extremity of the swing side; these findings indicate that in comparison with younger people, elderly people with exercise habits show greater utilization of knee-extension muscles in the terminal stance and terminal-swing phases and of the knee-flexion muscles in the pre-swing phase during the abovementioned movement. And, the RMS values for several muscles during a gait cycle were significantly higher than the corresponding values in young people.

Conclusion: Our results suggest that due to the habituation associated with training, the gait in elderly people with exercise habits is consciously modified to achieve motional effects as high as that achieved during walking training. Therefore, in such elderly people, the hip/knee/ankle have a wider range of motion during elevation/forward motion of the lower extremity of the swing side in comparison with the range of motion in general elderly or young people, and the hip flexion or knee extension/flexion muscle activation in these elderly people are more than those in young people or in elderly people with no exercise habits, thereby permitting a gait in which the said hip flexion and knee extension/flexion was achieved with a high motional effect. Furthermore, the results also suggested that biarticular muscles successfully compensate for the age-associated strength reduction of monoarticular muscles.

AGE-RELATED REDUCTIONS IN THE LENGTH AND NUMBER OF SERIAL SARCOMERES CONTRIBUTE TO SHORTENED FASCICLE LENGTHS: A SOURCE OF ELEVATED PASSIVE TENSION IN THE ELDERLY?

Geoffrey A. Power [1,*] Sean Crooks [1] Jared R. Fletcher [1] Brian R. MacIntosh [1] Walter Herzog [1]

[1] Human Performance Lab, University of Calgary, Calgary, Canada

Introduction and Objectives: With natural adult aging, there is a loss of muscle mass and alterations to the structural components of the human muscular system that results in impaired contractile function and performance [1, 2]. Muscle weakness associated with old age contributes to declines in neuromuscular function and is associated with impairments in activities of daily living [3]. On the other hand, older adults maintain force production during lengthening contractions (i.e. eccentric contraction) relative to other contraction modes [1]. The age-related maintenance of eccentric strength is evident in whole muscle and skinned single fibre preparations [1]. In addition to many of the mechanisms proposed for the preservation of eccentric strength, alterations to the structural properties of the muscle fascicle leading to elevated passive force have not been investigated [4]. A potential unexplored mechanism for increased passive force in old age could be decreased muscle fascicle lengths owing to either a decrease in the number of sarcomeres in series and/or shorter sarcomere length [5]. Thus for a given joint angular rotation, decreased fascicle length will result in greater sarcomere length change of muscles from old as compared to young rats, resulting in increased stiffness in the aged muscles, contributing to elevated passive tension and higher relative forces during lengthening. The purpose of this study was to compare the medial gastrocnemius (MG) of young and old rats to determine fascicle length, serial sarcomere numbers and the sarcomere length at which peak force is obtained (i.e. plateau of the force-length relationship; L_o). It was hypothesized that fascicle length in old rats would be shorter compared with young owing to fewer sarcomeres in series, however, the sarcomere length at L_o in old rats will remain unaltered as compared with young.

Methods: Two groups of Fisher344x Brown Norway hybrid rats ($n = 17$) were used in this experiment, a young cohort (7-8 months ≈20 human years) ($n = 9$) an old cohort (30-35 months; ≈75-80 human years) ($n = 8$). The MG from the right leg was surgically isolated, attached to a custom made muscle puller and force transducer. For whole muscle activation, the tibial nerve was isolated and electrically stimulated via a nerve cuff. The L_o was determined by performing a standard force-length relationship. Contractions were evoked at 200 Hz of 250 ms duration separated by 2 min rest across muscle lengths corresponding to the: ascending, plateau, and descending limb of the force-length relationship. The animals were then sacrificed and the hind limb was immediately placed in a VWR 10% Formalin (fixative) solution at the muscle length corresponding to L_o. After a 1 h period of fixation, the MG muscle was firmly secured to a wooden applicator stick at L_o and allowed to fix for a 2 week period in a VWR 10% Formalin solution. The muscles were then dissected into 4 lengthwise sections medial and lateral of the center of each MG muscle belly. After a 4 hour, 30% nitric acid digestion process, 5 individual fascicles from each muscle section were isolated and placed on slides for sarcomere length measurement at 5 locations along the fascicle by laser diffraction. In this method, the laser beam (1mm wide, λ=630 nm) penetrated through the thin actin filaments, but not the thick myosin filaments, creating a superposition of gratings of

aligned myofibrils [7]. The first order diffraction distance was used to mathematically determine the average sarcomere length in the measured area (Figure 1A).

Results: A reduction in muscle fascicle length of ~14% was observed in the old rats (average = 11.3 ± 1.0 mm) when compared to young rats (average = 13.1 ± 1.1 mm), $P < 0.05$. There was a reduction in average sarcomere length of ~4 % observed in the old rats (average = 2.22 ± 0.11 μm) versus the young rats (average = 2.31 ± 0.05 μm), $P < 0.05$. The MG of old rats showed ~10% fewer sarcomeres in series (average = 5087 ± 465 sarcomeres) when compared to young rats (average = 5684 ± 440 sarcomeres), $P < 0.05$ (Figure 1B.).

Figure:

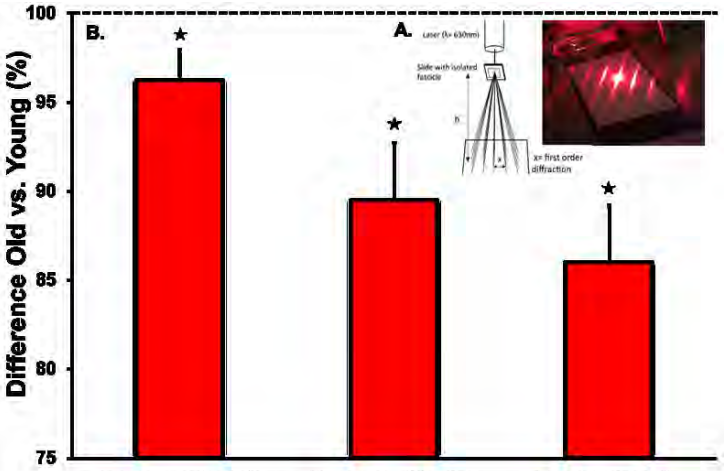

Figure 1. A. Laser diffraction set up and diffraction pattern. **B.** Percent difference in sarcomere length, sarcomere number and fascicle length from the MG of young rats (100%-dashed line) vs. old rats (red bars) measured at L_o. Bars indicate standard error. Significance indicated by ★ ($P<0.05$).

Conclusion:

The results of this study were in accordance with the hypotheses that as individuals age, not only are sarcomeres lost in parallel but are also lost in series, resulting in shorter fascicles. But quite unexpectedly average sarcomere length was shorter at L_o in the old compared with young muscle. The functional consequences of these age related changes could be a reduced range of motion for older adults and less force production capacity throughout that range of motion to perform activities of daily living. These results may also help to explain the increased passive tension observed for muscles of older individuals.

PO-0044

DOES A PROLONGED WALKING SESSION IMPAIR STAIR NEGOTIATION IN THE ELDERLY?

Marcos R. Kunzler [1,*] Emmanuel Rocha [1] Maarten Bobbert [2] Felipe Carpes [1]

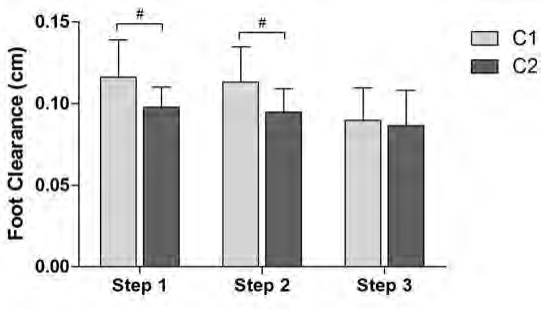
[1]Applied Neuromechanics Research Group, Federal University of Pampa, Uruguaiana, Brazil, [2]University Amsterdam, Amsterdam, Netherlands

Introduction and Objectives: Elderly self-report climbing up and down stair as being a difficult activity in daily life [1], and difficulty with stair locomotion serves to predict functional decline in the elderly [2]. A routine of chronic aerobic exercise can improve mobility and stability in the elderly [3, 4]. However, single sessions of exercise eliciting fatigue in the lower extremity were shown to impair performance in both unobstructed level ground walking and obstacle crossing in the elderly [5, 6]. Here we set out to determine whether prolonged walking also has an acute effect on foot clearance during stair ascent in elderly.

Methods: Thirty elderly (age 67 ± 5 years, height 1.55 ± 0.05 m, body mass 65.4 ± 11 kg) participated in this study. Participants wore casual street shoes in order to achieve natural gait patterns. After 3 min of familiarization with walking on a treadmill, they walked during 30-min on the treadmill at their preferred speed, which was on average 4.05 ± 0.9 km/h. Before and after the prolonged treadmill walking, the participants performed at least 10 trials of locomotion on a three-step stairs built according to the recommended standards in Brazil (rise height 17 cm for each step, tread depth 30 cm, without nosing, and width 90 cm). The ascent phase of stair locomotion was considered in this study. Kinematic data were recorded using a motion analysis system (Vicon Motion Systems, Oxford, UK) with fifteen cameras sampling at 120 Hz. Retroreflective markers were attached to the participants' body and to the stairs. Positional data were processed using the Nexus 1.5.2 software and foot clearance (FC), defined as the vertical distance between foot and stair when the foot was right over the edge of each step. Foot clearances were analyzed for steps with the preferred foot leading. Leg preference was determined using the revised Waterloo inventory. Normality of data distribution was checked using Shapiro-Wilk and with the data considered parametric, to compare foot clearance pre versus post walking in each step of the stairs we used t-test for paired samples (SPSS version 21.0) at a 0.05 level of significance.

Results: After exercise, foot clearance was lower for step 1 ($t_{(29)}$= 2.074, p= 0.047) and 2 ($t_{(29)}$= 2.082, p= 0.046). However, the differences were very small in amplitude (on average less than 5 mm).

Figure:



Caption: Figure 1. Foot clearance before (C1) and after prolonged walking (C2), considering the three steps of the stairs. # Indicates significant difference between before and after walking ($P<0.05$).

Conclusion: Walking at preferred speed during 30 minutes on a treadmill decreased foot clearance in the elderly during negotiation of stairs. From the three steps analyzed, decreased foot clearance was observed in the first and second steps. We were not able to measure force output before and after exercise. Most likely the prolonged exercise caused a reduction in force output, like it did in other studies [5, 6], causing a reduction in lower limb elevation during stair negotiation. The marker on the top of the shoe makes it difficult to assess the actual clearance, but does not interfere with the difference pre-post. Considering that foot contact with an obstacle or with the step of a stairs is one of the determinants of stumbling, participants in our study may have experienced an increased risk of stumbling after the walking exercise.

QUANTITATIVE EVALUATION OF FALL RISKS USING A DIMENSIONALITY REDUCTION METHOD

Yi-Horng Lai [1 2] Bo-Ching Yang [1] I-Ching Lin [3] Lan-Yuen Guo [1,*]

[1]Department of Sports Medicine, Kaohsiung Medical University, [2]Department of Mechanical and Electro-Mechanical Engineering, National Sun Yat-Sen University, Kaohsiung, [3]Changhua Christian Hospital, Changhua, Taiwan, Republic of China

Introduction and Objectives: Lately instrumented versions of the motor performance tests in which objective sensors were used as the measurement system are being considered. Similar to the biomechanical laboratory-based measurements, a very high number of the measurements can be computed from the modified tests [1]. Although the interdisciplinary collaboration of objective measurements has the strongest effects in fall risk assessment, high dimensionality gait and balance measurements often confound the interpretation [2].

We hypothesized that the high dimensionality objective parameters, followed by a feature selection and dimension reduction process, could promote the capability of discriminating fallers from non faller group among the elders.

The aims of this study are to select a reduced subset of informative features by using dimensionality reduction method and compare the ability of discrimination with other traditional functional measurement.

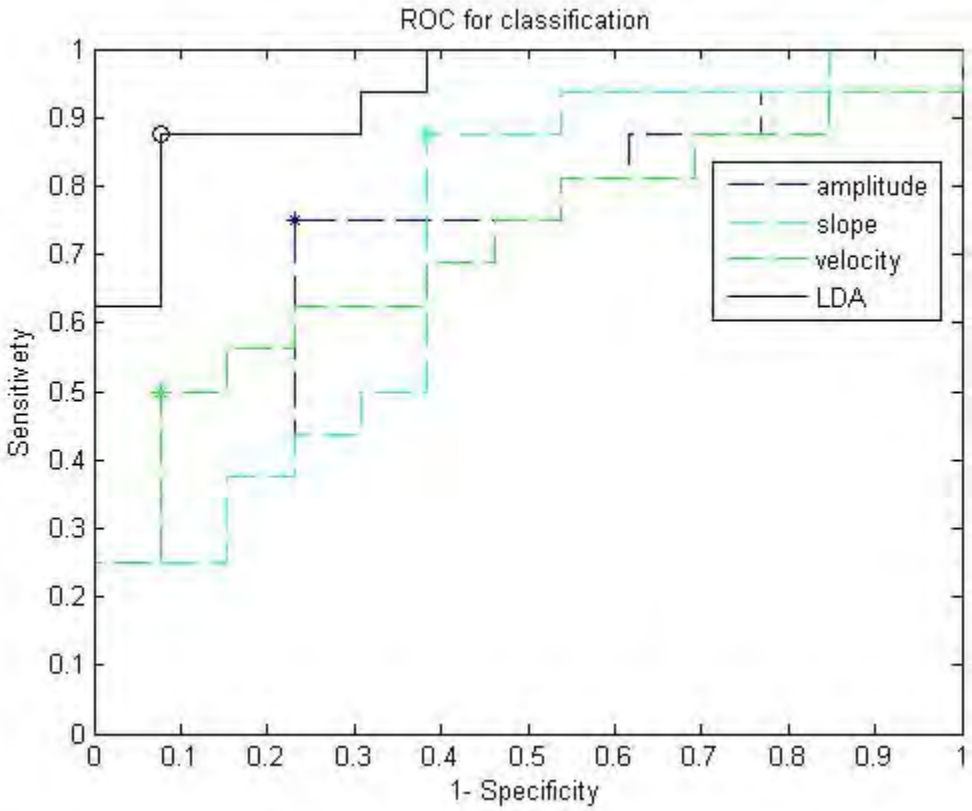
Methods: Twenty nine community-living elders (faller: n=13; non faller: n=16) were recruited. The fallers were included only if they reported one or more falls with no obvious reasons in the previous year. Subjects with a history of stroke, dementia, major depression, Parkinson's disease, or any diseases likely to have an impact on gait were excluded. The interdisciplinary measures include both gait and balance assessment. For instrument time up and go (iTUG) test: Subjects wore the custom made Arduino based 9-axis motion tracking device and performed two TUG trials with their own preferred comfortable pace. For center of pressure assessment (COP): Subjects stood barefoot 30 seconds on a force platform (Kistler 9286AA, USA) with eyes open and eyes close respectively. Based on our review, a total of 12 scalar measures were extracted from the both test. Mann–Whitney U-tests were used to investigate the effect of 12 scalar measures. Only the p-value less than or equal to 0.05 was considered as candidate feature.

Linear discriminant analysis (LDA) which is easy to interpret and visualize was selected. LDA cast multidimensional features into a single dimension for best classification. Receiver-Operator Characteristic (ROC) curves were constructed to compare the predictive quality of the candidate features and LDA feature. The sensitivity was defined as the percentage of correctly identified fallers. Area under ROC curve (AUC) was used as a filter feature quality metric.

Results: Candidate features extracted from iTUG and COP test are amplitude of sit-to-stand, slope of stand-to-sit and velocity of COP in eye close trail.

The ROC curves were shown in Fig 1. The AUC of all the features were LDA dimension reduction feature (0.937), amplitude (0.721), slope (0.716) and velocity (0.712). The LDA feature has the best predictive quality (sensitivity: 0.875; sepecificity: 0.923).

Figure:



Caption: The ROC curves of all features

Conclusion: For community-dwelling elder, Single functional measures usually lack the ability to capture all gaits and balance impairment at its early phase. Because of the complex nature of falls, effective approaches should include interdisciplinary assessment. However, high dimensional quantitative parameters assessments are challenging. The LDA dimension reduction method has the additional advantage in interdisciplinary collaboration measures.

WAVELET ANALYSIS OF MULTI-CHANNEL SURFACE EMG ACTIVITY OF THE LOWER BACK DURING THE BACK SQUAT

Richard Twycross-Lewis [1,*] Dylan Morrissey [1] Roger Woledge [2]

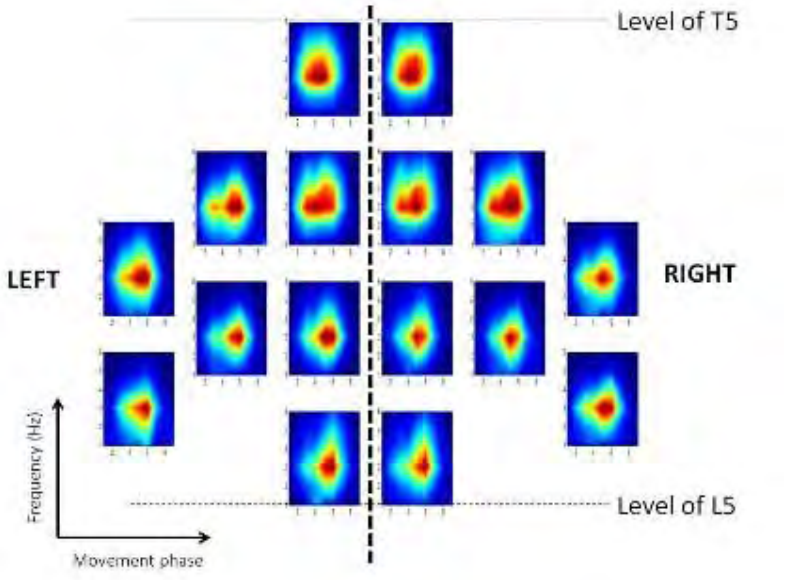
[1]Centre for Sports & Exercise Medicine, Queen Mary University of London, [2]Comparative Biomedical Science, The Royal Vetinary College, London, United Kingdom

Introduction and Objectives: Muscle fatigue in the lower back during the back squat results in decreased vertebral load tolerance and abnormal loading of the spine, which is, in turn, associated with acute muscle injury. We determined focal regions of EMG activity within the lumbar erector muscles which occur during the performance of the back squat.

Methods: Ten resistance trained men (age = 23.8 ± 1.9 years; height = 1.75 ± 0.1 m; weight = 82.8 ± 14.7 kg; years lifting = 2.7 ± 0.9 years) volunteered to take part in the study. High surface area, low density EMG data was collected using 16 differential EMG channels placed on the lower back (Figure 1). Lift phase was determined using marker height from active infra-red motion analysis markers placed above, below and around the EMG markers. Raw rectified EMG was subjected to a wavelet transform algorithm.

Results: Analysis of interactions between channel, phase of momvement and frequency by 3 factor ANOVA revealed significant interactions between lumbar region and movement phase ($F = 30.92$, $p < 0.01$) and with frequency band ($F = 58.81$, $p < 0.01$) . The greatest interaction was obsrved between movement phase and frequency band ($F = 212.07$, $p < 0.01$) (Figure 1).

Figure:



Caption: Figure 1: EMG placement during the squat and wavelet activity throughout the movement across the lower back either side of the spine from the level of T5 to L5.

Conclusion: : There is notable asymmetry in the patterns of activtion from the top to the bottom of the back. This seems to suggest the addition of faster motor units in the lower back as the squat progresses from eccentric mechanical movement to concentric activity in the lower back, whereas faster motor unit recruitment appears to occur throughout both the eccentric and concentric phases of the lift towards the upper region of the area of measurement. Finally, whilst there are characteristic patterns within different areas of the upper and lower back, there is notable left to right symmetry either side of the spine.

SPATIAL DISTRIBUTION OF THE GASTROCNEMIUS MEDIALIS ACTIVITY FROM EXTENDED TO FLEXED KNEE JOINT IS UNSENSITIVE TO MUSCLE ARCHITECTURE CHANGES

Liliam Oliveira [1 2,*] Carolina Avancini [1] Luciano Menegaldo [1] Taian Vieira [2]

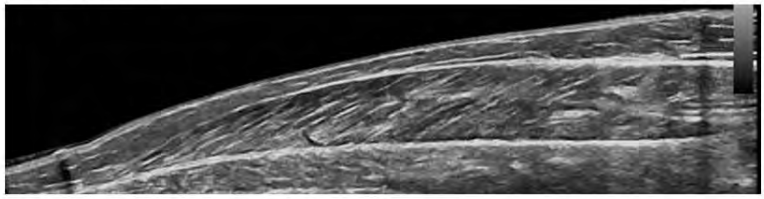
[1]Programa de Engenharia Biomédica, [2]Escola de Educação Física e Desportos, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Introduction and Objectives: The gastrocnemius muscles produce greater plantar flexion torque withthe knee inextended than flexed position. At flexed knee positions, the reduced plantar flexion torque is typically explained by the gastrocnemius tension-length relation [1]. Bipolar EMGs with low amplitude have also been documented for the gastrocnemius muscle during isometric plantar flexion contractions with knee flexed; this has been conceived as a strategy of the nervous system to more efficiently distribute the neural drive across plantar flexors [2]. Anatomical and electrophysiological evidence suggest however the changes in architecture and activation may distribute unevenly within the gastrocnemius muscle [3-5]. In this study we use ultrasound and a large array of surface electrodes to investigate how knee joint angle affects the distribution of activity and of fibres' length within the medial gastrocnemius (MG) muscle.
Methods: The muscle architecture was estimated for knee flexed and extended positions from ultrasound (US) panoramic images taken during rest and with the ankle joint held in neutral position (Figure 1). MG muscle was divided into proximal and distal portions and pinnation angle, fibre length and fat thickness were measured at each region. Surface EMGs were detected from the MG muscle of 16 healthy participants with a linear array of 16, silver bar electrodes (1 cm inter-electrode distance) positioned to cover as much as possible the muscle longitudinal axis. Subjects were asked to exert isometric plantar flexions at 60%MVC for 5 seconds, with the ankle joint at 90º. Submaximal efforts were performed with the knee fully extended (180º) and flexed at 90º. The channels detecting RMS amplitudes greater than 70% of the maximal amplitude were considered *active channels*. The barycentre coordinate of *active channels* was calculated, indicating where the RMS amplitude is mainly distributed along the muscle proximo-distal axis.
Results: Marked differences in MG architecture were observed when subjects moved their knee from extended to flexed position but the proximo-distal differences in MG architecture were not significantly associated with knee position. Regardless of the MG region considered, the proximal (32.0 ± 5.6 mm) and distal (34.0 ± 5.4 mm) values obtained for MG fibre length with knee flexed was significantly smaller than those observed for the proximal (42.0 ± 6.8 mm) and distal (43.2 ± 8.5 mm) MG regions with knee extended. No significant interaction or additive effect of knee position and/or muscle region was observed for the MG pinnation angle. The distribution of EMG amplitude along the skin surface changed markedly. When flexing the knee the amplitude of surface EMGs decreased and the barycentre coordinate shifted to the MG proximal region. For the knee flexed and extended conditions, the barycentre mean position was located at respectively 39-53% (interquartile interval) and 50-74% of the distance from the femoral condyle to the distal extremity of the MG superficial aponeurosis.

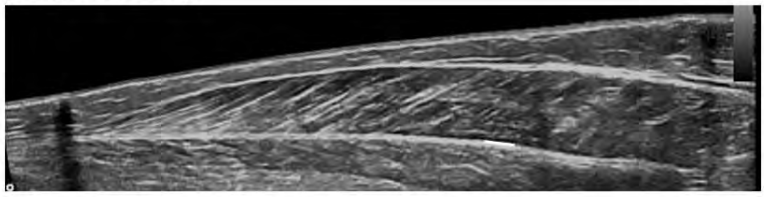
Figure:

Figure 5

Knee fully extended



Knee flexed at 90 deg



Caption: Figure 1. Panoramic ultrasound images of the gastrocnemius muscle. The images shown in the top and bottom panels were collected with knee fully extended and flexed at 90 deg, respectively.

Conclusion: These results indicate that RMS amplitude was mainly distributed distally when plantar flexion contractions were exerted with knee extended whereas, during knee flexed, EMG amplitude distributed at more proximal, skin regions. These results suggest knee position greatly affect the redistribution of activity within the MG muscle. Changes in MG proximo-distal activity were unlikely explained by regional changes in MG fibre length, pinnation angle and fat thickness. Finally, if detected locally, either proximally or distally, EMGs may provide different indication on the degree of MG activity for different knee positions.

EFFECT OF THE INSTRUCTION FOR CONSCIOUS ACTIVATION OF ABDOMINAL MUSCLES ON THE SCAPULAR MUSCLES ACTIVATION – PRELIMINARY DATA

Angie S. Vega [1] Anamaria Oliveira [1,*] Ann Cools [2]

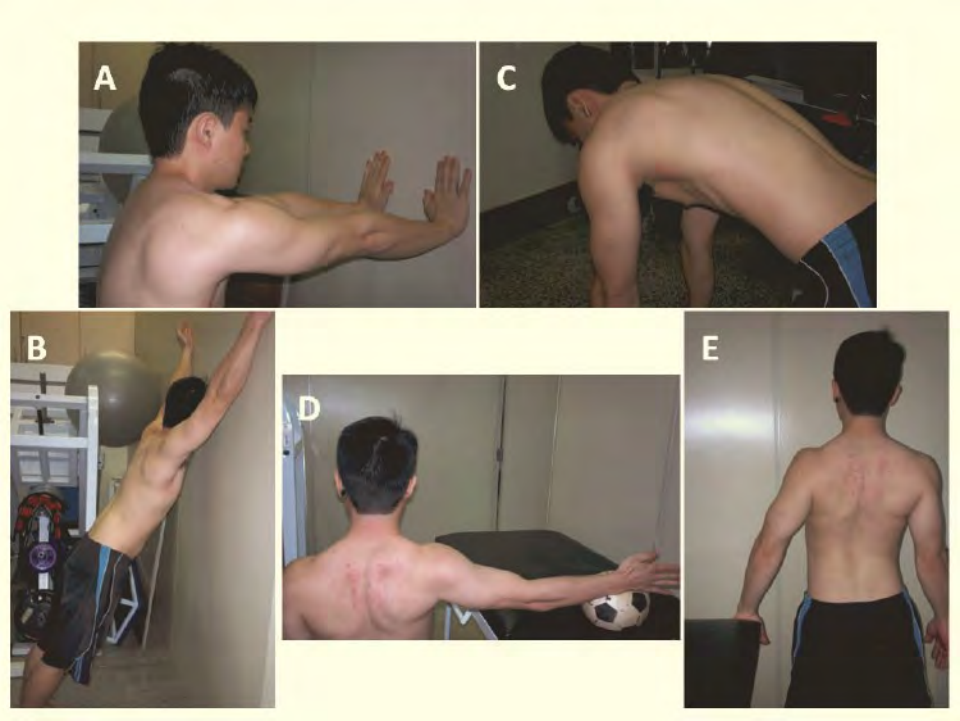
[1]Programa de Pós-Graduação em Reabilitação e Desempenho Funcional, Universidade de São Paulo, Ribeirão Preto (São Paulo), Brazil, [2]Department of Rehabilitation Sciences and Physiotherapy, Ghent University, Ghent, Belgium

Introduction and Objectives: Functional relationship between trunk and periscapular muscles can be explained from different approaches.One is the Anatomic Trains Theory(1) that considers serratus anterior and the external oblique muscles as forming a lateral myofascial meridian in the trunk chain.Other one is the interdependence between the control of the distal segments and the stability of proximal ones according to the concept of functional kinetic chains(2).Posture and movement are refined by feedback and feedforward mechanisms.Feedback(biofeedback) could be represented by verbal, visual, auditory or kinesthetic stimulus(3).Although biofeedback mechanisms applied to scapulothoracic muscles have been already studied, there are no studies that have investigated whether biofeedback applied to muscles of trunk muscle results in more activation in during exercises for motor control and strengthening focused on the serratus anterior muscle(4).The aim of this study is to investigate the effect of verbal instruction and manual tapping for consciously increasing activation of the abdominal muscles voluntary contraction on the surface myoelectric activity of the scapulothoracic muscles.

Methods: Twenty healthy asymptomatic individuals(10 female and 10 male) aging 24±3.9 years old were evaluated.Three repetitions of wall press,knee push,wall slide,inferior glide,and isometric low row exercises were performed during 5 sec,with 5 sec of rest interval between each repetition(FIGURE1).Surface electromyographic amplitude was obtained from serratus anterior and external oblique muscles during exercises without and with verbal commands consciously activation of the abdominal muscles and manually tapping on the abdominal muscle.The familiarization was performed with abdominal training exercises as abdominal bracing e abdominal hollowing using verbal commands based on *Pilates* and *Core* techniques (5).EMG amplitude values are represented by normalized root mean square(RMS) for isometric exercises and by integrated EMG(iEMG) for dynamic exercises.Raw data was normalized by EMG RMS amplitude of the maximal voluntary isometric contractions,for each muscle.Data analysis was performed to compare amplitude averages between with and without instruction conditions using Student's *t*-test, with significance level set at 5%.

Results: Verbal instruction for consciously activation of the abdominal muscles significantly increased activation of the serratus anterior and external oblique muscles during wall slide,wall press,knee push,inferior glide and isometric low row exercises($p>0,05$)(TABLE1).Preliminary results showed an increase of the periscapular muscles activation as resulting of the biofeedback applied to trunk muscles.Those results support neuroanatomical linkage and functional interdependence between trunk and shoulder girdle as as suggested before by the Anatomic Trains Theory and functional kinetic chain concept(2,6,7).Kibler(2010) also proposed that synergistic muscle activation between trunk and periscapular musculature contributes for a normal scapulohumeral rhythm.Our results require confirmation by increasing the sample sizes and checking prospectively effect size for analysis comparing with and without biofeeback EMG amplitude means.

Figure:



Caption: FIGURE1.Wall slide(A),wall press(B),knee push(C),inferior glide(D) and isometric low row(E)

Conclusion: Preliminary results demonstrated that verbal instruction for consciously activation of abdominal muscle and manual tapping increased the activation of the serratus anterior muscle during exercises for motor control and strengthening focused on the serratus anterior muscle.

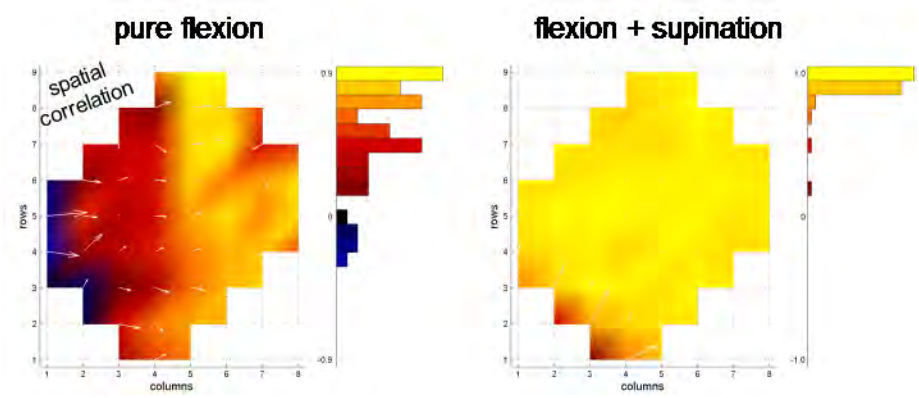
NONNEGATIVE MATRIX FACTORIZATION TO ASSESS SPATIOTEMPORAL MUSCLE ACTIVATION

Didier Staudenmann [1,*] Dick F. Stegeman [2] Jaap H. van Dieen [3]

[1]Movement and Sport Science, Department of Medicine, University of Fribourg, Fribourg, Switzerland, [2]Donders Institute, Radboud University Medical Centre, Nijmegen, Nijmegen, [3]MOVE Research Institute Amsterdam, Faculty of Human Movement Sciences, VU University, Amsterdam, Netherlands

Introduction and Objectives: Changes in the distribution of activity across a muscle has been observed. Spatial heterogeneity of muscle activity has been assessed by comparing EMG amplitudes between channels within a grid of electrodes [1]. This procedure, however, averages amplitudes over time and hence discards temporal information. As an alternative method a k-means clustering algorithm was applied considering both temporal and spatial information [2]. However, this approach requires predefining the amount of clusters and if this amount does not correspond with the true spatial distribution, this method will not provide an adequate representation. The aim of this study was to explore the utility of nonnegative matrix factorization (NMF) in the quantification of temporal and spatial variability of muscle activation.
Methods: In eight subjects we measured surface EMG (49±8 electrodes covering the entire biceps brachii) during two contraction types: 1) pure elbow flexion and 2) elbow flexion with a superimposed forearm supination. The monopolar EMGs were spatially filtered with principal component analysis [3], rectified, smoothed and normalized to maximum voluntary contraction. We used NMF [e.g. 4] to decompose spatiotemporal muscle activation and represent it by W (‘common mode’ signal) and H (spatial gain of W over the muscle) Furthermore, we propose a method to quantify: i) the contribution of the common mode to spatio-temporal pattern as the variance in the signals accounted for (VAF) by W and ii) the spatial distribution over the muscle of the common mode correlations to W (spatial correlation).In eight subjects we measured surface EMG (49±8 electrodes covering the entire biceps brachii) during two contraction types: 1) pure elbow flexion and 2) elbow flexion with a superimposed forearm supination. The monopolar EMGs were spatially filtered with principal component analysis (Staudenmann 2006), rectified, smoothed and normalized to maximum voluntary contraction. We used NMF [e.g. 3] to decompose spatiotemporal muscle activation and represent it by W (‘common mode’ signal) and H (spatial gain of W over the muscle) Furthermore, we propose a method to quantify: i) the contribution of the common mode to spatio-temporal pattern as the variance in the signals accounted for (VAF) by W and ii) the spatial distribution over the muscle of the common mode correlations to W (spatial correlation).
Results: VAF was significantly (43%) larger for flex+sup than for pure flex (89±3% vs. 51±9%, $p<0.01$), whereas the spatial gains showed a marginal and non-significant difference between contraction types ($p>0.882$). The standard deviation of the spatial correlation was significantly (-57%) lower for flex+sup than for pure flex (0.08±0.05 vs. 0.18±0.07, $p<0.01$). The correlations with W showed a clear topographical distribution for pure flexion (see Figure) indicating that the variation in the EMG amplitudes captured by W was representative for one head of the biceps only, whereas it represented coactivation of the whole biceps in the combined contraction.

Figure:



Caption: Spatial correlation shows how the time signal W correlates over the muscle surface of biceps brachii. Note that the flex+sup contraction showed higher correlations and lower variability compared to pure flex contraction.

Conclusion: This study shows that NMF is a powerful method to quantify spatiotemporal muscle activation. The advantages of NMF are that it is unbiased and directly provides temporal and spatial information. The VAF and spatial correlation were sensitive to the contraction type, while the spatial gain represented by H was not. It can be concluded that the outcomes proposed were sensitive to contraction types and can be interpreted in a physiologically meaningful way.

PO-0052

PATTERN CLASSIFICATION ACCURACY AND HIGH DENSITY EMG COLOUR MAPS FOR IMPROVED PROSTHESIS CONTROL

Usha Kuruganti [1,*] Victoria Chester [1] Yves Losier [2] Craig Prime [1]

[1]Faculty of Kinesiology, [2]Mechanical Engineering, University of New Brunswick, Fredericton, Canada

Introduction and Objectives: Myoelectric prosthetic limbs have evolved over several decades. While these systems have improved significantly over several decades, challenges remain. Traditionally, surface electromyography (EMG) has been used to investigate muscle activation patterns to determine which areas of a residual limb would be appropriate for electrode placement and control. Pattern recognition-based controllers have the potential to significantly improve myoelectric control systems for prosthesis control by increasing the number of controllable movements. These systems involve using pattern classifiers to analyze the neural signals produced by the muscle (EMG) and classify the movement produced based on predetermined settings. The effectiveness of the classifier is measured by its classification accuracy. Recently, high-density EMG (HDEMG) systems have allowed for non-invasive collection of myoelectric signals from many closely spaced electrodes. The data obtained can be examined through the use of 'colour maps,' which provide a visual indication of the distribution and intensity of muscle activation. The increased volume of data produced from HDEMG systems has not been extensively utilized in relation to classification accuracies. The relationship between pattern classification accuracy and HDEMG based colour maps is unknown, however understanding this relationship may help to better understand muscle activation patterns with applications in prosthesis development as well as imaging muscle activity in rehabilitation (e.g. in stroke or sport injury).

Methods: A HDEMG system (REFA, TMS International) was used to evaluate four different hand movements (hand open, hand closed, pronation, and supination) at a self-selected medium contraction level. Twenty able-bodied individuals (mean age = 31.6 ± 12.0 years, 9 females and 11 males) participated in this study. Sixty-four channels of EMG were collected and the electrodes were placed in an 8 by 8 grid formation over the forearm region to collect EMG data. The areas on the forearm that experienced muscle activity during given movements were illustrated in topographical (colour) maps for each trial. Pattern recognition was performed to determine how well each contraction could be distinguished using a Linear Discriminate Analysis (LDA) classifier. The colour maps were visually inspected to determine any changes in intensity (amplitude) and pattern repeatability between trials. Pattern classification accuracies were computed for all movements.

Results: The mean classification accuracies for each movement are shown in Table 1. Upon examination of each colour map it appears as both pattern and intensity changes differ in relation to classification accuracy with those with higher classification accuracy having (visually) more consistent colour maps (i.e. shape and intensity of the image). A mathematical relationship between classification accuracy and colour map changes is yet to be established, however the data collected in this work will help to investigate that relationship.

Conclusion: The results suggest that classification accuracy differ according to both pattern and intensity changes, however the exact relationship remains elusive. Understanding this connection may help to provide better understanding

of muscle activity for improved prosthetic control as well as develop new imaging techniques for those with reduced muscle activation due to injury or disability.

Table:

Mean Pattern Classification Accuracy	**HO**	**HC**	**PR**	**SP**
	87.9 ± 14.5	95.7 ± 11.1	86.4 ± 17.1	92.2 ± 13.6

SUBCUTANEOUS FAT THICKNESS IS NOT CORRELATED TO THE MAGNITUDE OF MEASURABLE TRUNK MUSCLE ACTIVITY IN SURFACE EMG OF NORMAL WEIGHT HEALTHY ADULTS

Stephanie Valentin [1,*] James Elliott [2] Theresia Licka [1]

[1]Movement Science Group, Equine Clinic, University of Veterinary Medicine Vienna, Vienna, Austria, [2]Feinberg School of Medicine, Northwestern University, Chicago IL, United States

Introduction and Objectives: Surface Electromyography (sEMG) is a non-invasive tool from which muscle activation parameters can be investigated during a variety of static and dynamic conditions. However, subcutaneous fat overlying a muscle of interest can reduce the amplitude of the signal obtained, as fat can act as a low pass filter [1,2]. The effect of subcutaneous tissue and skinfold thickness on measurements of muscle activity has been evaluated in previous studies using ultrasound and calipers [2,3]. However to our knowledge, magnetic resonance imaging (MRI) assessment, which is a more precise method of determining subcutaneous fat thickness, has not been compared to sEMG values of trunk muscle activity. Therefore, the aim of the study was to compare the sEMG output of two trunk muscles with skin/subcutaneous fat thickness determined from MRI.

Methods: From data obtained previously, EMG and MRI values of two separate measurement sessions from 12 healthy participants aged 18-25 years (female n=6) with a BMI of <25 were correlated. Muscle activity had been obtained through sEMG electrodes (Delsys Trigno, 1200Hz) attached over the left and right erector spinae (ES) 2cm laterally from the thoracolumbar junction, and rectus abdominis (RA) 2cm above the umbilicus and 1cm lateral to midline. Data had been collected during 3 trials of 10s at natural stance. For the present study, raw sEMG data were processed using two methods: (1) resampling, rectification, zero-mean offset, and a 4^{th} order low pass Butterworth filter applied, followed by the mean activity being calculated from the middle 6s of each 10s trial, and (2) EMG integration by cumulative summation of the rectified values. For the MRI aspect of the study, transverse images were obtained from the distal thoracic spine to the pelvis using a T1-weighted sequence (1.5T Philips Achieva; slice thickness 10mm, gap 1mm, repetition time 9.3ms, echo time 4.6ms, flip angle 15 degrees, field of view (FOV) 345mm, rectangular FOV 78%). Total skin and subcutaneous fat thickness (termed SC) of the abdomen was measured at L2-L3 disc level, equating to the RA sEMG site, and SC of the back was measured at T12-L1 disc level equating to the ES sEMG site (Sante DICOM viewer freeware, v4.0.5). For both locations, this was performed for the left and right side separately. Normal distribution of the data was confirmed using a Shapiro-Wilk test and Pearson's correlations were carried out between the total thickness of skin and subcutaneous fat and the respective sEMG value for each muscle, separately for each EMG processing method.

Results: Mean BMI of the participants was 21.7 ± 2.2. The means and standard deviations of the MRI and EMG data are shown in Table 1. Negative correlations were found between the SC values and EMG output in all muscles and from both EMG processing methods, although none of these findings were significant (all $p>0.05$).

Conclusion: The findings from the present study show that, although an inverse relationship i.e. negative correlation between SC and sEMG values was expected, this was not significant in either of the two muscles. Therefore, in healthy people who are not classed as being overweight, the effects of skin/subcutaneous fat thickness on resultant measurable

muscle activity with sEMG can be considered negligible in static, minimal effort conditions, based on the two different EMG processing methods described here. Identifying whether this also applies during dynamic and isometric contractions should be further investigated, however during dynamic activities the effect of the increased skin displacement with increased subcutaneous fat thickness should be considered.

Table:

DIFFERENTIATION CAPABILITY OF FREQUENCY AND TIME DOMAIN ELECTROMYOGRAPHY PARAMETERS IN WOMEN WITH PATELLOFEMORAL PAIN

Ronaldo Briani [1,*]Danilo Silva [1]Marcella Pazzinatto [1]Carlos Albuquerque [2]Deisi Ferrari [3]Fernando Aragão [2]Fabio Azevedo [1]

[1]Physical Therapy Department, University of São Paulo State, Presidente Prudente, [2]Physical Therapy Department, University of West of Parana, Cascavel, [3]bioengeneering department, University of Sao Paulo, Sao Carlos, Brazil

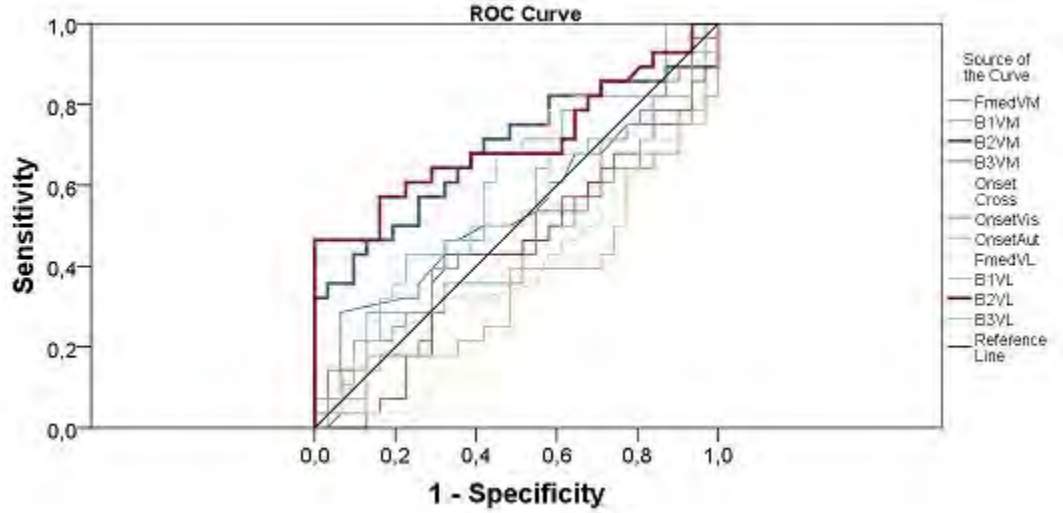
Introduction and Objectives: Patellofemoral pain (PFP) is one of the most common complaints in orthopedic practices and accounts for 25% to 40% of all knee problems in sports medicine centers. Despite its high incidence, PFP etiology remains unclear. A commonly accepted PFP etiology hypothesis is Vastus Medialis (VM) and Vastus Lateralis (VL) contraction dysfunction. Surface electromyography (sEMG) analysis, such as onset determination, of VM and VL has been widely reported in order to verify this hypothesis, however, onset has yielded controversial results[1]. sEMG frequency analysis, instead, has been recently proposed as a promising tool for PFP differentiation and, to the best of our knowledge, no prior study has compared sEMG frequency domain parameters and sEMG time domain variables. Therefore, the aim of this study was to determine the diagnostic accuracy of two different analyzes, sEMG in the frequency and time domain, on the VM and VL of individuals with PFP, compared to matched control.

Methods: 31 individuals with PFP and 28 control individuals (18–30 years) participated in this study. Data collection included a sEMG evaluation of each participant's symptomatic limb (those with unilateral symptoms) or most symptomatic limb (in those with bilateral symptoms) during stair descent. Data were collected using a conditioner module (Lynx®, Sao Paulo, SP, BRA; model EMG 1000-8-4I). The raw EMG signal was recorded at a sampling rate of 4000 Hz. A force plate (AMTI, OR6, Watertown, MA, USA) was positioned in the center of the fourth step and used to obtain ground reaction force data and, thus, to establish the moment when the subject was passing over the step. Each participant was asked to descend the stairs at their natural comfortable speed across the staircase and five successful trials were collected. The power spectrum density (PSD) of the frequency domain parameters were divided in bands: low (15-45Hz) (B1), medium (45-96Hz) (B2), and high (96-400Hz) (B3); and the onset analyzes were realized in 3 different manners: automatic algorithm, visual inspection and cross-correlation. Receiver operating characteristic (ROC) curves were done to assess the capability of differentiation (diagnostic accuracy) of each variable and the Younden index was used to identify the point when sensitivity (Sn) and specificity (Sp) were both maximized.

Results: ROC curves were performed (Figure 1), and the results of Sp and Sn for the optimal cut off and area under the curve values were obtained (Table 1). Regarding area under the curve, medium frequency bands were classified as moderately accurate for the VM (0.71) and VL (0.71), whereas other parameters were categorized as less accurate and non-informative. Similarly, the B2 presented the best Sn and Sp combination according to the Youden index, 72% and 69% for VM and 68% and 62% for VL, respectively. In spite of not presenting the best results compared to what has been shown in the literature when observed Sn and Sp separately[2], B2 demonstrated to be the most equally weighted variable presented for this goal. On the other hand, results from this study showed cross-correlation onset and visual onset AUC with non-informative values (.47) and (.49), respectively, and automatic onset with a fair AUC value (.60).

Concerning onset Sn and Sp, only automatic onset demonstrated an acceptable Sn (68%), yet, Sp as not suitable (55%). Other onset variables presented low values of sensitivity and specificity, as shown in table 1.

Figure:



Caption: Receiver operating characteristic curves for the sEMG frequency and time domain parameters.

Conclusion: This study provides some evidence on the behavior of sEMG parameters associated with PFP. Results from the present study provide an accurate new approach, able to differentiate individuals with this disorder.

MUSCLE ACTIVITY PATTERN COMPARISON BETWEEN TWO FILTERING METHODS DURING PRONE HIP EXTENSION IN CHRONIC LOW BACK PAIN INDIVIDUALS

Carlos V. Cruz-Montecinos [1,*] Rodrigo Nuñez [1] Giselle Horment [1] Pablo Letelier [1] Claudio Tapia [2]

[1]Kinesiology, [2]Electrical Engineering, University of Chile, Santiago, Chile

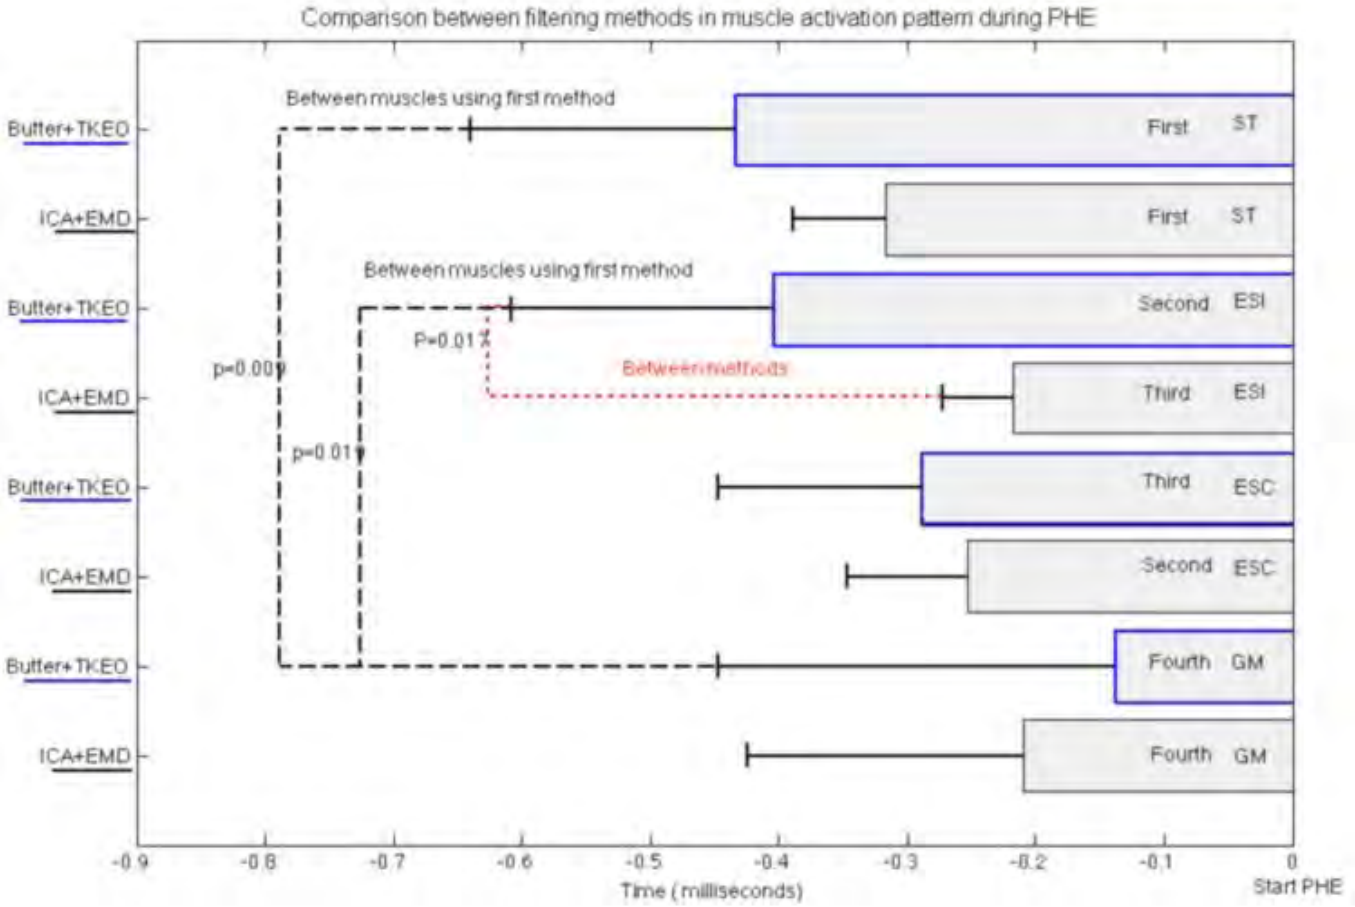
Introduction and Objectives: Analysis of muscle pattern during prone hip extension has been proposed as a clinical tool for assessment of musculoskeletal dysfunction [1]. However, some researchers have reported a consistent pattern [2], whilst others have concluded that no pattern exists [3]. Possible explanations for the differences include methodological issues. Different methods have been proposed for muscle onset determinations. Previous studies reported improvement of onset detection accuracy after using Teager Kaiser Energy Operator (TKEO), compared to other popular methods [4]. Recently, several advanced signal processing algorithms have been proposed for Independent Component Analysis (ICA) in order to remove noise from EMG recordings [5]. On the other hand, Emprirical Mode Descoposition (EMD), has been proposed for noise filter [6]. Both methods remove noise without removing frequency components of the muscle. The selection method for filter signal, can influence the determination of muscle patterns.

The objective of this study is to compare muscle pattern recruitment and onset muscle during prone hip extension (PHE) using Butterworth filter combined with TKEO versus (ICA) filter and combination with (EMD).

Methods: With the approval of the local Ethical Service, 9 chronic low back pain (CLBP) individuals were recruited. The surface electromyography (SEMG) electrodes were located in Semitendinosus (ST), Gluteus Maximus (GM), Erector Spinae ipsilateral (ESI) and contralateral (ESC) at L3 level. Each subject performed a PHE with knee in full extension, from neutral position to 20 degrees of hip extension. Movement speed was regulated with a metronome and all patients received training in order to adjust their motion speed to that rhythm. Each patient was asked to perform 6 repetitions. The starting movement was considered when velocity of execution reached 5% peak value during PHE. Muscle onset was calculated as the difference between the time lapse of the starting movement and the time lapse of muscle activation. Signal processing was compared between two methods. The first method consisted in high-pass Butterworth filter 10 Hz [7], which was later smoothed by a root mean square (RMS) with a window of 250 milliseconds, then TKEO was applied [4]. The onset of the EMGs burst was identified as the point in which the smoothed signal exceeded the threshold of the mean adding 3 standard deviations of the baseline signal. [1]. The second method consisted in filter processing using ICA and then using EMD, with a soft-threshold of the mean added by 2 standard deviations of the baseline signal. For the statistical analysis, Student *t*-tests and ANOVA were employed (when P value $p<0.05$ was considered statistically significant).

Results: 4 males and 5 females of the age 46 ± 12 were evaluated. All variables distributed normally. Comparing the onset between the two methods, significant differences were observed only in the onset of ESI ($p> 0.017$). On the other hand, the onset between the muscles, only presented differences in the first method. Differences between muscle onset could be observed in GM-ST ($p<0.009$) and ESI-GM ($p<0.019$).

Figure:



Caption: Figure.Comparison between filtering methods. Abbreviations: Butterworth filter (Butter); Teager Kaiser energy Operator (TKO); Independent Component Analysis (ICA) ; Empirical Mode Descomposition (EMD) .

Conclusion: Depending on the filtering methods used, our results proposed changes in the patterns during PHE. Therefore, for activity pattern detection, future studies using filter methods that do not remove frequency components of muscle are necessary.

PO-0057

SPATIAL DISTRIBUTION PATTERN OF SURFACE ELECTROMYOGRAPHY WITHIN HUMAN RECTUS FEMORIS MUSCLE ON OVERGROUND VS. TREADMILL WALKING

Kohei Watanabe [1,*] Motoki Kouzaki [2] Toshio Moritani [2]

[1]Chukyo University, Nagoya, [2]Kyoto University, Kyoto, Japan

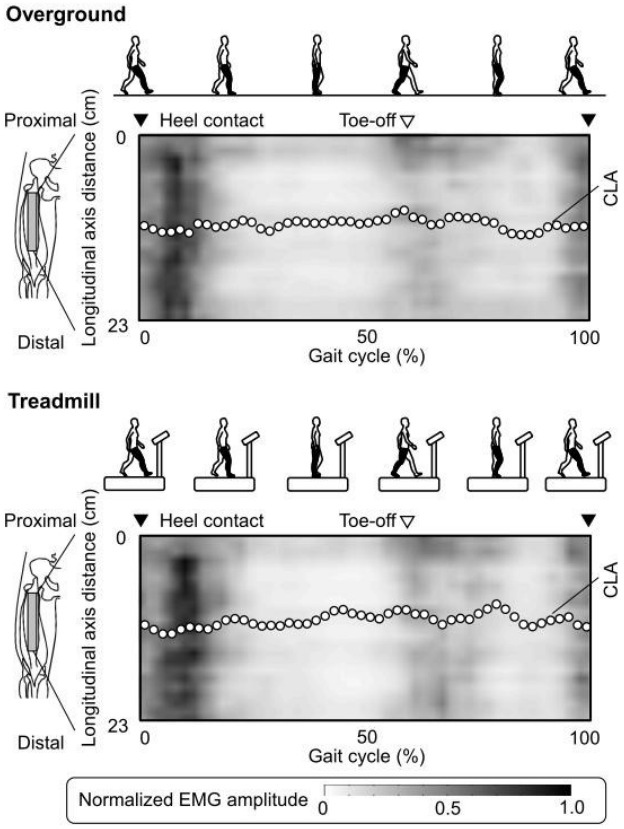
Introduction and Objectives: Based on its unique anatomy, it was previously thought that proximal and other regions of the human rectus femoris (RF) muscle act independently during human movements (1). Recently, we demonstrated differences in neuromuscular regulation between proximal and other regions of the RF muscle during walking on a treadmill (2). The objective of this study was to compare neuromuscular activation of the whole RF muscle during treadmill and overground (normal) walking.

Methods: Seven healthy young men performed overground and treadmill walking. The gait speed on the treadmill walking was to be the same as that on overground walking, being comfortable for each subject. During walking, surface electromyography (EMG) was recorded from the RF muscle with 24 electrodes, arranged along the longitudinal axis of the muscle. Central locus activation (CLA) of the surface EMG amplitude was calculated to quantify the spatial distribution pattern of surface EMG within the muscle. CLA in each phase and the surface EMG amplitude in each phase and at each electrode were compared between the two different walking conditions. Heel contact and toe-off timings were identified using a foot switch. The knee joint angle was also measured using an electrical goniometer.

Results: No significant differences were noted between the two walking conditions in the gait speed, toe-off timing, cadence, maximum knee joint angle, or timings of the minimum knee joint angle. Significant differences were demonstrated in the minimum knee joint angle and timing of the maximum knee joint angle between the two conditions ($p < 0.05$).

There were no significant differences in CLA between the overground and treadmill walking throughout a stride. Significant differences in the surface EMG amplitude were observed around the heel contact phase between the two walking conditions in middle to distal regions ($p < 0.05$). On the other hand, there were no significant differences in the surface EMG amplitude between two conditions in the proximal regions during a stride.

Figure:



Conclusion: Our previous study demonstrated activation of the whole muscle around heel contact and selective activation in the proximal regions around stance-to-swing transition (2). In the present study, differences in surface EMG between overground and treadmill walking were shown in middle and distal regions, but not in proximal regions. This suggests that neuromuscular activation of the RF muscle is regionally regulated based on changes in the walking condition. Also, the unique activation pattern of proximal regions is independent of the walking condition.

PO-0058

EFFECTS OF NIGH NEUTRAL WRIST SPLINTING THERAPY IN THE ELECTROMYOGRAPHIC ACTIVITY OF SHOULDER AND FOREARM MUSCLES, GRIP STRENGTH, AND PINCH STRENGTH: A CARPAL TUNNEL SYNDROME CASE STUDY

Helga T. Tucci [1,*] Mariana Fogaça Leme [1] Vanessa Diogo [1] Maria Santos [1]

[1]Department of Human Motion Science, Federal University of São Paulo, Santos, Brazil

Introduction and Objectives: Treatment of Carpal Tunnel Syndrome could be conservative or surgical, according to the level of disease. Between conservative rehabilitation methods for the treatment of carpal tunnel syndrome, the use of wrist splint is one of the most common indication. Orthosis could stabilize or restrict movements, helping to align the segment in a functional position in order to correct existing deformities

The purpose of this case study was to investigate whether the conservative treatment consisted of the use of night neutral custom-molded thermoplastic resin wrist splint, associated with neural gliding exercises could alter electromyographic activity of shoulder and forearm muscles, and to improve grip and pinch strength in a person with CTS after 45 days of treatment.

Methods: Participation in this case study a women diagnosed with moderate carpal tunnel syndrome in the right hand through electrodiagnosis exam. CTS was also confirmed based on physical findings, and clinical evaluation. Patient was instructed to wear a neutral custom-molded thermoplastic resin wrist splint only at night; and to perform gliding exercises every day during 45 days. A booklet was given to the patient, containing the gliding exercises instructions, and places to note if she had used splint at night, and if she had done the exercises. Experimental procedure consisted in an evaluation of grip and pinch strength, and an evaluation of electromyographic activity of selected muscles before and after the treatment. Electromyographic activity was sampled with the patient performing an upper extremity functional activity in the scapular plane holding a halter with 0,028% of total upper extremity weight. Patient was sit in a chair, with 30° of arm flexion in the scapular plane, forearm on the desk. The desk had 2 scapular plane aligned markers: point 1 (near) and 2 (far). Functional activity consisted in to hold the halter (“reach phase”) in the position 2, brings it to the position 1 (“flexion phase”), return it to the position 2 (“extension phase”). Once in the position 2 again, arm was elevated (“elevation phase) and lowered (“lowering phase”) with elbow full extended. Thus, movements of elbow, wrist and shoulder were done to activated the selected muscles. Three maximal voluntary isometric contractions of each muscle were done in the muscular function position to posterior signal normalization. Three channels of a 16-bit A/D converter board suit were used to record electromyographic signal, with simultaneous acquisition and sample frequency of 2 kHz per channel (Miotec©, Rio Grande do Sul, Brazil. Myoelectric signal were sampled by a disposable bipolar electrode (Ag/AgCl, 20 mm inter-electrode distance) made of polyethylene foam and medicine hypoallergenic adhesive gel, connected to a sensor. Sensors have input impedance of 10 GΩ, Common Mode Rejection Ratio of 130 dB and gain of 20 times (Miotec©, Rio Grande do Sul, Brazil). A circular disposable electrode was fixed in the sternum for reducing acquisition noise. Electrode placement on the upper trapezius was oriented according to SENIAM recommendations [1], and placement of flexor carpi ulnaris and extensor carpi ulnaris were defined according to Perroto et al. [2]. After data collection, SEMG signal was

filtered at a frequency bandwidth of 20-1000Hz. An additional channel was used as a trigger to mark phases of functional activity. Three maximum isometric handgrip and pinch measurement of dominant upper extremity were performed using Jamar© and Pinch Gauge© dynamometers, respectively. Descriptive analyzes of normalized electromyography, grip and pinch strength were done before and after treatment.

Results: Lower grip strength, and greater pulp-to-pulp, and lateral pinches strength were found after treatment. Normalized electromyogtraphic were lower after treatment. Extensor carpi ulnaris normalized electromyographic activity in the “reach phase” was [0,40(0,12)] before and [0,15(0,03)] after; “flexion phase” [0,84(0,28)] before and [0,62(0,02)] after; “extension phase” [1,03(0,53)] before and [0,48(0,02)] after. Extensor carpi ulnaris in the “reach phase” was [0,26(0,14)] before and [0,13(0,07)] after, “flexion phase” [0,47(0,11)] before and [0,33(0,09)] after, and “extension phase” [0,37(0,17)] before and [0,25(0,06)] after. Upper trapezius in “elevation” was [0,61(0,04)] before and [0,53(0,01)] after, and “lowering” [0,49(0,10)] before and [0,47(0,05)] after.

Conclusion: The treatment showed to be effective in reducing the electromyographic activity, and improved pulp-to-pulp, and lateral pinch strength.

PO-0059

DETERMINING THE ENERGY COST OF INDIVIDUAL LEG MUSCLES IN HUMAN WALKING

Neil Cronin [1,*] Patricio Pincheira [1] Lauri Stenroth [1] Janne Avela [1]

[1]Department of Biology of Physical Activity, University of Jyväskylä, Jyväskylä, Finland

Introduction and Objectives: Economy is a fundamental concept in human movement, and can be expressed as oxygen consumption normalised to body mass and speed (oxygen cost of transport, COT). The COT value reflects the net energetic cost of all active muscles, so changes in COT denote changes in the economy of some or all muscles. In walking, COT exhibits a U-shaped curve when plotted against walking speed; it is lowest at intermediate speeds of ~4.5 km/h and dramatically increases at speeds faster or slower than this optimum[1]. The aim of this study was to estimate the energy cost of individual leg muscles in young and older individuals in an attempt to determine which muscle(s) contribute to walking speed-dependent changes in COT.

Methods: 26 participants were recruited (13 young aged 18-30 and 13 old aged 70-80). Participants were equipped with an oxygen mask, and electromyography (EMG) electrodes were placed over 10 muscles of the right leg (vastus lateralis, vastus medialis, rectus femoris, semitendinosus, biceps femoris, tibialis anterior, lateral gastrocnemius, medial gastrocnemius, soleus, and flexor hallucis longus). Participants then walked on a motorized treadmill at seven different speeds for four minutes each in a random order: at the preferred speed (previously determined in overground walking) and 15, 30, and 45 % faster and slower than the preferred speed. A force-sensitive resistor placed under the right heel was used to synchronise data sources and detect gait events. Both groups wore a harness attached to the treadmill frame for safety purposes.

Mean oxygen consumption during the fourth minute of each walking speed was used to calculate COT. EMG data from the fourth minute of each walking speed were used for analysis on a stride-by-stride basis. The cumulative activity required to traverse a unit distance (CMAPD) was calculated for each muscle, speed and participant according to the method of Carrier et al[2], as this value has been suggested to be an indicator of muscle metabolism. To facilitate comparisons between muscles and subjects, CMAPD values were normalized to the value from the fastest walking speed for each subject and muscle.

Results: At the group level, speed-dependent changes in COT occurred in parallel with changes in mean CMAPD of all tested muscles for both young and old groups (Figure 1). In the young group, r^2 values for the correlation between CMAPD and COT ranged between 0.003 to 0.250 across all muscles. Proximal muscles such as vastus lateralis exhibited higher CMAPD at speeds faster and slower than the energetically optimal speed, whereas, for example, soleus CMAPD was relatively independent of speed. In the old group, COT was higher at all speeds, and preferred speed was slower. Regarding CMAPD, similar findings were observed as in the young group.

Figure:

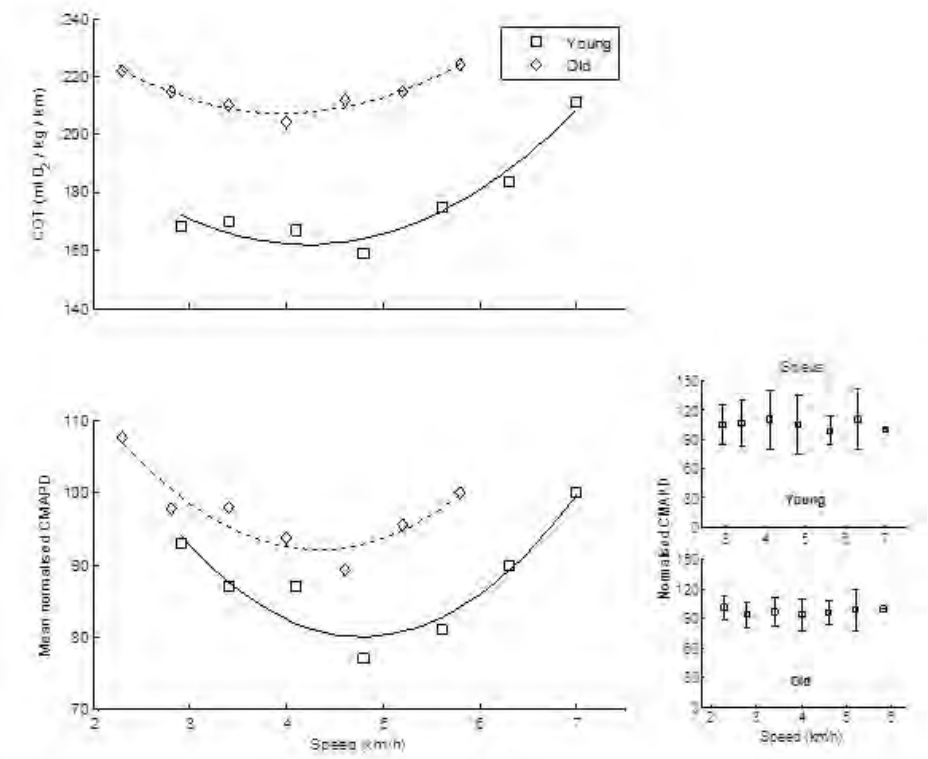

Figure 1. Walking speed versus group mean COT (upper panel) and group mean CMAPD from all muscles combined (lower panel). Inset: CMAPD values for soleus muscle only in both age groups. Note that due to the fact that values are normalised to the fastest walking speed within each group, absolute CMAPD values are not directly comparable between groups

Conclusion: In young individuals, speed-dependent changes in energetic cost of walking are reflected in the estimated metabolic cost of individual muscles. In general the quadriceps showed the largest changes in CMAPD with changes in speed, whereas soleus functioned at a constant CMAPD regardless of speed. Results were similar for older individuals. These results suggest that soleus may be an important target muscle in interventions aiming to maintain economy in old age. Moreover, in both age groups, the metabolic cost of contraction in proximal leg muscles such as the quadriceps seems to increase dramatically when walking at speeds faster or slower than the energetic optimum.

ACUTE EFFECTS OF LOW EMISSION PHOTOTHERAPY ON ELECTROMYOGRAPHIC FATIGUE OF BICEPS BRACHII IN YOUNG MEN

Kamila Verlene S. G. Vieira [1,*] Ana Cláudia Rennó [2] Paulo Henrique Azevedo [1] Carlos Eduardo Pinfildi [1] Emilson Colantonio [1] Helga Tatiana Tucci [1]

[1]Department of Human Movement Science, [2]Department of Biosciences, Federal University of São Paulo, Santos, Brazil

Introduction and Objectives: Low emission phototherapy (low level laser therapy and light-emitting diode therapy) has been studied as a resource for reducing fatigue onset during physical activity, and their positive effects could also be observed through electromyographic analysis done during physical exercise. However, to date there is not a consensus about the acute effects of low emission phototherapy in reducing electromyographic fatigue.

The purpose of this study was to analyze the acute effects of low emission phototherapy in the electromyographic fatigue of long head of biceps brachii muscle of young males.

Methods: Twenty males [mean (standard deviation) 22.5 (3.52) years; body mass 69.3 (0,04) kg; and height 1.74 (9.47) m] were randomized in Active and Placebo Group. Subjects were submitted to a fatigue protocol that consisted of 30-seconds of maximum voluntary isometric contraction biceps brachii performed in a Scott bench. Before experimental fatigue protocol, phototherapy was applied over biceps brachii of dominant upper extremity according to group randomization using a cluster with seven 850nm wavelength diodes (GaAlAs), 100 mW output power, and 4 J per diode. Due to cluster´s size, one application was necessary to cover the muscle, totalizing 28J for all diodes in 40 seconds of application (LEAL JUNIOR et al., 2009). Thus, subjects underwent a surface electromyographic sample of long head of biceps brachii muscle during the fatigue protocol. Before placing the electrode, the skin was shaved and cleaned with alcohol. Electrode placement on the biceps was oriented according to Surface ElectroMyoGraphy for the Non-Invasive Assessment of Muscles recommendations (HERMENS et al., 2000). Myoelectric signals from the biceps brachii were sampled by a disposable bipolar electrode (Ag/AgCl, 20 mm interelectrode distance) made of polyethylene foam with medicine hypoallergeni adhesive gel connected to a sensor that has input impedance of 10 GΩ, Common Mode Rejection Ratio of 130 dB and gain of 20 times (Miotec®, Rio Grande do Sul, Brazil). A circular disposable electrode was fixed on the sternum as a reference for reducing acquisition noise. SEMG signals were sampled by a 16-bit A/D converter board with 2 kHz frequency. After, 30-seconds raw signal was digitally filtered at frequency bandwidth of 20-1000Hz, and divided in 3 windows with 10-seconds each. Median frequency (MDF) of signal was used to data analysis. Electomyographic fatigue of biceps brachii (FB) was determined by dividing MDF obtained from the third 10-seconds window by MDF obtained from the first 10-seconds window. FB was compared intra-groups. Statistical analysis was done using a paired-samples t-test, with level of significance set at $P<0.05$.

Results: Results showed that there were not found statistical difference of FB obtained from Active Group [FB mean (standard deviation) 0.67 (0.08); $p=0.30$] when compared to the FB obtained from Placebo Group [0,72 (0,11); $p=0.30$]. The aim of this study was to analyze the acute effects of low emission phototherapy on electromyographic fatigue of the long head of the biceps muscle in young males. Researches has suggested that the low emission phototherapy acts on

muscle bioenergetics, helping to reduce muscle fatigue, blood lactate concentrations and inflammatory markers (LEAL JR et al., 2009; DE MARCHI et al., 2012). Thus, the effects of this resource could help to delaying the development of muscle fatigue, and allowing to improve the muscle performance during exercise. This result may be justified through the fact of the phototherapy parameters of this research could not be the more appropriate for this aim. However, there is not not an ideal parameters described to improve muscle performance, which suggest that new studies comparing different phototherapies could help to adjusted parameters.

Conclusion: In this experimental procedure, phototherapy did not show an acute effect in delaying electromyographic fatigue of biceps brachii muscle in young males.

EFFECTS OF LOW EMISSION PHOTOTHERAPY IN THE RATE OF FORCE DEVELOPMENT AND ELECTROMYOGRAPHIC FATIGUE OF QUADRICES FEMORIS IN ELDERLY WOMEN

Helga Tatiana Tucci [1,*] Patrícia Gabriele Vassão [2] Ana Carolina de Souza [2] Luis Henrique da Silva [2] Larissa Neves [1] Ana Claudia Rennó [2]

[1]Department of Human Movement Science, [2]Department of Biosciences, Federal University of São Paulo, Santos, Brazil

Introduction and Objectives: Aging is responsible for several biochemical and structural changes in the body that leading to a decline in the function of various tissues, with musculoskeletal system being the most affected. Low emission phototherapy (Low-level laser therapy and Ligth-emitting Diodes therapy), by its biomodulation effects, could be a resource to improve muscle performance [1, 2].

The objectives of this experimental procedure were to analyze the acute effects of low emission phototherapy in the rate of force development (Q_RFD) and Fatigue Index (FI) of quadriceps femoris in elderly women.

Methods: Eight females were randomized [mean (standard deviation) 65,60 (3,44) years; body mass 66,98 (6,93) kg; and height 156,60(3,78) m] in Active Group (n=4) and in Placebo Group (n=4). Quadriceps femoris fatigue protocol was performed in a leg extension chair, and consisted of 30-seconds quadriceps femoris maximum isometric voluntary contraction (MIVC) with subject sit in a leg extension chair with knee at 90° of flexion. From group randomization, phototherapy was applied over quadriceps femoris of dominant lower extremity immediately before experimental fatigue protocol using a cluster with seven 850nm wavelength (GaAlAs) diodes, 100 mW output power, and 4 J per diode. Due to cluster´s size, 4 applications were necessary to cover the muscle, totalizing 112J in 120 seconds. Before placing the electrodes, skin was shaved and cleaned with alcohol. Then, surface eletromyography (SEMG) was sampled from vastus medialis, rectus femoris, and vastus lateralis according to SENIAM recommendations[3]. Myoelectric signals from the vastus lateralis, rectus femoris, and vastus medialis of dominant lower extremity were sampled by a disposable bipolar electrode (Ag/AgCl, 20 mm inter-electrode distance) made of polyethylene foam and medicine hypoallergenic adhesive gel, connected to a sensor. Sensors have input impedance of 10 GΩ, Common Mode Rejection Ratio of 130 dB and gain of 20 times (Miotec®, Rio Grande do Sul, Brazil). A circular disposable electrode was fixed in the tibial plateau of dominant lower extremity for reducing acquisition noise. A load cell was used to sample force during fatigue experimental procedure (Miotec®, Rio Grande do Sul, Brazil). SEMG and load cell signals were sampled simultaneously by a 16-bit A/D converter board with 2 kHz frequency (Miotec®, Rio Grande do Sul, Brazil), and after filtered at a frequency bandwidth of 20-1000Hz. SEMG 30-seconds raw signal was windowed in 3 parts of 10-seconds each, and median frequency (MDF) was used to data analysis. Fatigue Indexes were determined by dividing MDF of third 10-seconds window by MDF of first 10-seconds window. Quadriceps femoris rate of force development (Q_RFD) was calculated through load cell signal, as a derivation of maximal force in its corresponding time interval, determined from the beginning of MCIV until the instant which maximum force was reached. Q_RFD, fatigue index of vastus lateralis (FI_VL), fatigue index of rectus femoris (FI_RF), and fatigue index of vastus medialis (FI_VM) were compared between groups. Student *t* test for not related sample was used as statistical analysis, with level of significance set at $p<0.05$.

Results: Results showed that there were not found statistical difference between Q_RFD of Active Group [mean (standard deviation) 25,69 (13,97); p=0.28] compared to Placebo Group [mean (standard deviation); 15,85 (8,29); p=0.28]. Also, there were not significant difference for FI_VM of Active Group [mean (standard deviation); 1,10 (0,39); p=0.37] compared to Placebo Group [0.90 (0.09); p=0.37]. The comparison of FI_RF between Active Group [0.87 (0,24) p=0.94], and Placebo group [0.88 (0.23); p=0.94] was not statistically different. Lastly, FI_VL [1,02 (0,15); p=0.76] of Active Group, when compared to Placebo Group [0.99 (0.90); p=0.76], was not statistically different. Small sample size, and photherapy parameters chosen could be possible explanations to absence of significant results between groups. Results could be justified to the small sample size, and through the fact that phototherapy parameters of this research are not the best choice to improve muscle performance in elderly women. However, there is not a consensus at the literature about the more appropriate photherapy parameters aiming to reduce or prevent muscle fatigue, and to improving RDF.

Conclusion: Low emission phototherapy has not effect on reducing FI_VM, FI_RF, FI_VL, and in improving Q_RFD in elderly women submitted to this experimental procedure. Results should be viewed with caution because sample is too small to have accurate conclusions.

PO-0062

MAXIMUM TRUNK MUSCLE ACTIVATION DURING DIFFERENT CONTRACTION MODES IN HEALTHY SUBJECTS

Stephan Kopinski [1,*] Tilman Engel [1] Jimmy B. Lawrence [1] Juliane Mueller [1] Steffen Mueller [1] Frank Mayer [1]

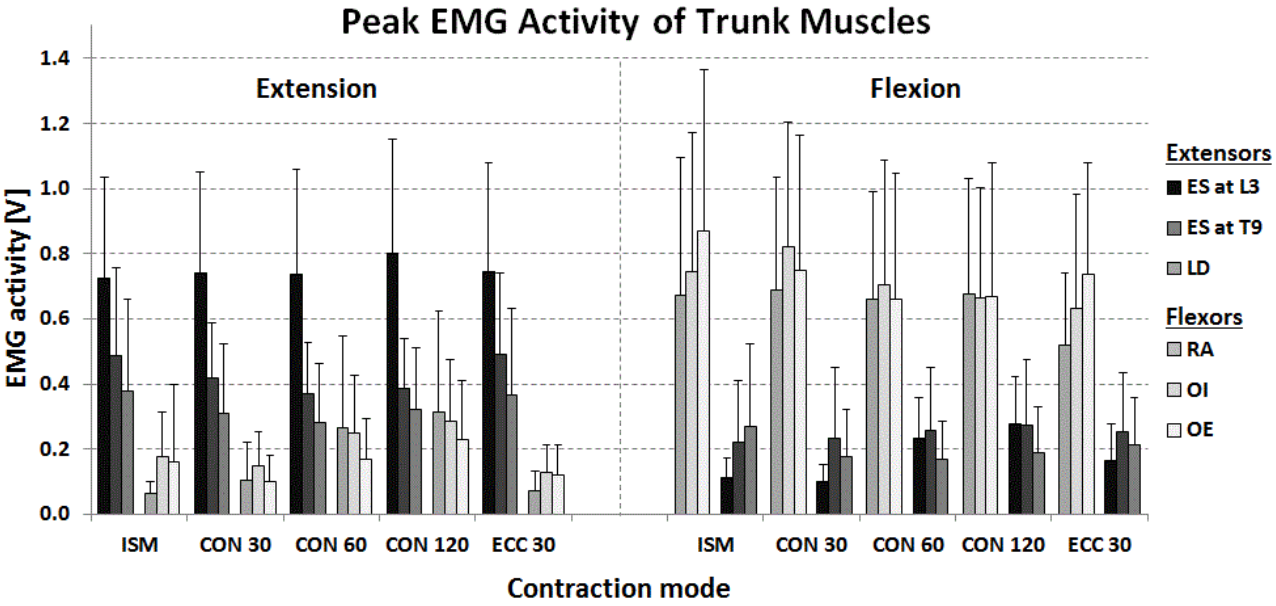
[1]Department Sports & Health Sciences, University Outpatient Clinic Potsdam, Potsdam, Germany

Introduction and Objectives: Isokinetic strength measurements and electromyographic activation measures of trunk muscles are widely used in research and clinical context. In general, normalization of EMG data is recommended to be done by maximum voluntary contractions (MVC) in isometric contraction mode. However, if the reference EMG should be taken preferably of the same contraction type as the task EMG, e.g. as in a dynamic trunk strength task, is of continual discussion. Therefore, the purpose of this study was to compare the activation of trunk muscles during isometric, and concentric and eccentric isokinetic strength tests in healthy adults.

Methods: Seventeen healthy participants (10 M, 7 F; 25±7yrs, 71±12kg, 1.78±0.11m; VAS back pain ≤ 0.1) performed a MVC trunk extension/flexion (ext/flex) test sequence. They were measured in a dynamometer (Con-Trex MJ, TP-module, Physiomed AG, Germany) in standing position, equipped with a 12-lead bilateral sEMG (myon RFTD-32, myon AG, Suisse) on Mm. erector spinae (ES, L3 and T9 level), latissimus dorsi (LD), rectus abdominis (RA), and obliquus internus (OI) and externus (OE). After an extensive warm-up the protocol consisted of two isometric trials (ISM; ext and flex, both in 17.5° flex for 5s) and four isokinetic trials (ROM: 45° flex to 10° ext) - three in concentric ($CON_{30/60/120}$; 30°/s, 60°/s and 120°/s, each 5 repetitions) and one in eccentric mode (ECC; 30°/s, 5 repetitions). All trials were separated by 60s rest. Peak torque in ext and flex ([Nm], for CON and ECC mean of 3 highest) was analysed (mean±SD). After the EMG signal was averaged for sides and moving average filtered (50 points), peak EMG activity [V] during agonist muscle work (ISM: time of peak torque ± 0.5s; CON/ECC: whole ROM) was evaluated (mean±SD). A one-way repeated measures ANOVA with Bonferroni correction was used to test for differences in agonistic muscle activity between the five contraction modes (α=0.05).

Results: Peak torque ranged from 281±87 Nm (ECC) to 200±71 Nm (CON_{120}) during ext, and from 144±52 Nm (CON_{30}) to 135±49 Nm (ISM) during flex, respectively. Maximum absolute muscle activity ranged from 0.80±0.31 V (ES at L3, during CON_{120}) to 0.28±0.18 V (LD, during CON_{60}) during ext, and from 0.87±0.49 V (OE, during ISM) to 0.66±0.33 V (OE, during CON_{60}) during flex (Figure 1). For trunk extensor muscles effect of contraction modes was found statistical significant only for ES at T9 ($p<0.05$, no statistical significant post-hoc result), with non-significant values for ES at L3 ($p=0.460$) and LD ($p=0.238$). During trunk flexion a statistical significant effect of contraction modes was present only for OI ($p<0.01$), but not for RA ($p=0.190$) and OE ($p=1.197$). Post-hoc pair-wise comparison for OI identified statistical significant differences between CON_{30} and each CON_{60}, CON_{120} and ECC modes (all $p<0.01$).

Figure:



Caption: EMG activity of trunk extensors Mm. erector spinae (ES, at L3 and T9 level) and latissimus dorsi (LD), and trunk flexors Mm. rectus abdominis (RA), and obliquus internus (OI) and externus (OE) during isometric trials (ISM), isokinetic concentric (CON, 30 to 120°/s) and eccentric (ECC, 30°/s) contractions. Bars represent peak muscle activity of 17 healthy subjects (mean±SD).

Conclusion: Trunk muscle activation during trunk flexion and extension in general was not affected systematically by contraction mode. The high variability of absolute EMG activity between participants contributed to this inconsistent outcome. Peak torque values were highest during ECC and non- to low velocity muscle contraction modes (ISM, CON_{30}). The usage of isometric MVC may be favourable concerning higher EMG signal stability, with low relative movement of electrodes over detected muscle fibres. On the other hand, isokinetic MVC may be more conclusive when normalizing results of dynamic strength testing. To conclude, the choice of contraction mode for MVC normalization of dynamometer supported muscle strength and activation tests is more a substantive question than a matter of method.

SURFACE ELECTROMYOGRAPHY AS A TOOL IN THE TREATMENT OF TEMPOROMANDIBULAR DISORDERS.

Fabiola Spolaor [1,*] Francesco Coccilovo [2] Claudio Cobelli [1] Antonio Gracco [2] Zimi Sawacha [1]

[1]Department of Information Engineering, [2]Department of Neuroscience, University of Padova, Padova, Italy

Introduction and Objectives: The clinical usefulness of the use of surface electromyography (SEMG) in diagnosing and treatment of temporomandibular disorders (TMDs) is still debated [1,2]. Temporomandibular disorders (TMD) is a complex disease affecting the Temporo-mandibular joint, the masticator muscles, or both, and its nature is not completely understood yet [3].

The aim of this work is to verify weather subjects with CrossBite display different Temporo-mandibular joints muscles activation patterns than controls during consecutive chewing task, maximum teeth clenching with and without cotton rolls.

Methods: 30 subjects participated in the study: 10 healthy (control group (CG), 20 with CrossBite (CB) who had not south any treatment. Subjects were asked to perform repeating chewing task (while eating a cookie), and surface electromyography (sEMG) activity was recorded. Afterword 2 maximum voluntary contractions (MVC) were performed through maximum teeth clenching either with or without cotton roll. Kinematics data (glabella, right and left Temporo-mandibular joints markers trajectories) were acquired together with sEMG signals of Right Temporalis (RT), Right Masseter (RM), Left Temporalis (LT) and Left Masseter (LM). A BTS motion capture system (6 cameras, 60-120 Hz) synchronized with a Free EMG system (8 channels SEMG system, BTS, Srl) were used. Ten consecutive chewing cycles and 10 consecutive seconds within the central part of each MVC trial were extracted and analysed. sEMG linear envelopes were estimated and the following parameters were determined: peak of envelope position (PoE) and Peak of Envelope (PE) [4]. Markers trajectories were used in order to define different chewing tasks. Welch's t test was performed (SPSS, version 19.0) in order to compare the data of the of the TMD and the CG groups.

Results: CB group showed a significant higher value of PE (Figure 1) and a delay in PoE when compared to CG (0.007

Figure:

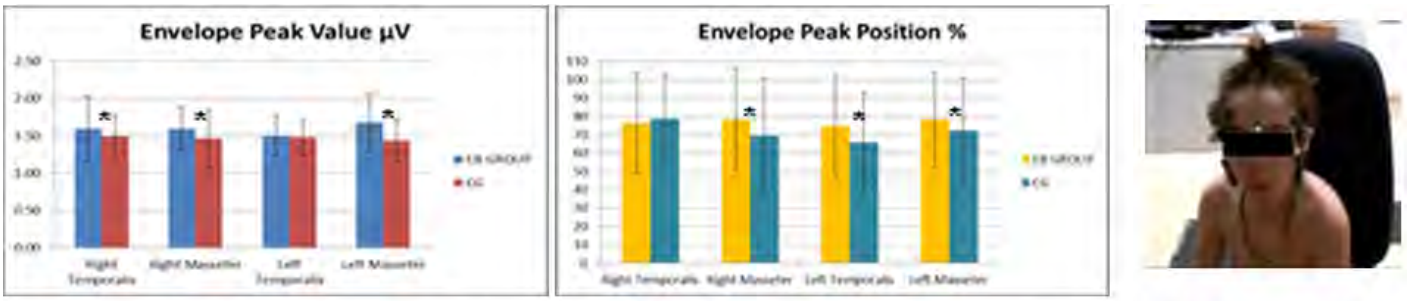

Figure 1. a,b: Each muscles PoE and PE (mean and standard deviation) estimated during the 10 consecutive chewing trials (Red=CG; Blue=CB). *= Significant p<0.05; c: a patient while executing the chewing task.

Conclusion: Delay in PoE and higher PE values can be justified by considering that CB subjects exhibit neuromuscular alterations that can lead to functional alterations. The latters may determine delayed muscle activation accompanied by larger amplitude of the muscle activity in order to cope with the underling deficit.

Preliminary results showed that sEMG allowed to highlight differences in timing of muscles activation between TMD and CG subjects. Future development will include increasing the number of subjects in order to differentiate between subjects affected by monolateral and bilateral crossbite.

EMG

PO-0064

THE NON-INVASIVE MEASUREMENT OF DEEP FOREARM MUSCLE ELECTROMYOGRAPHY USING SURFACE ELECTRODES

Jeremy D. Pitman [1,*] Lester R. John [1]

[1]MRC/UCT Medical Imaging Research Unit, Division of Biomedical Engineering, Dept. of Human Biology, University of Cape Town, Cape Town, South Africa

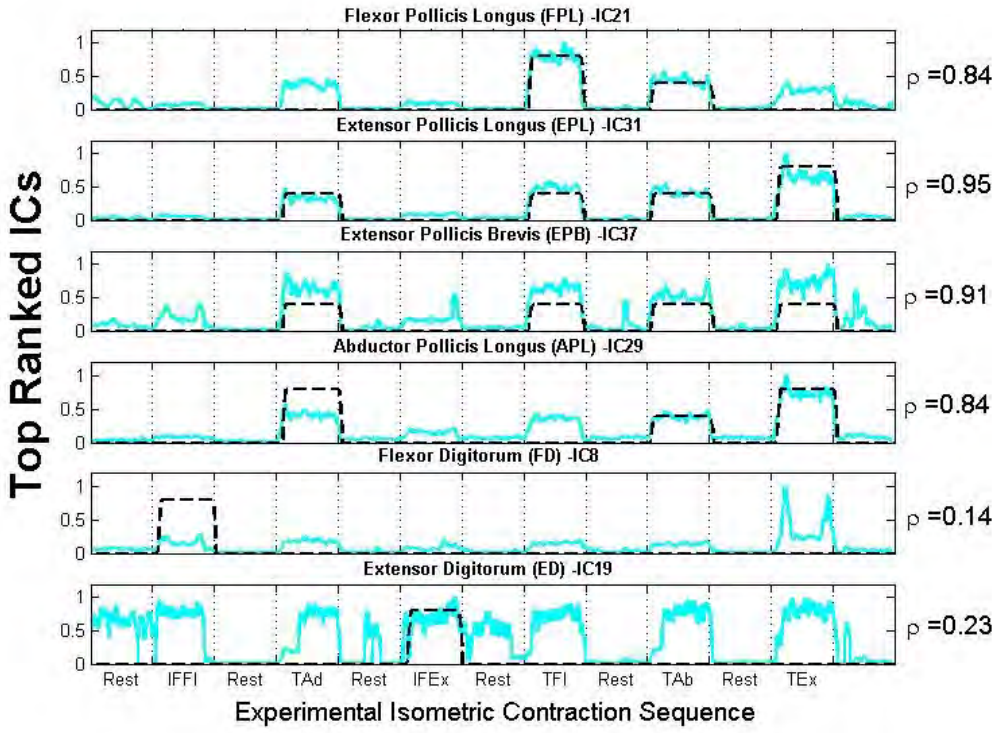
Introduction and Objectives: It is commonly accepted that surface EMG (sEMG) is limited to the measurement of superficial muscle activity. Deep muscle EMG detection is only considered possible through the insertion of intramuscular electrodes into the muscle, an invasive and inherently risky procedure. A method for non-invasive deep muscle EMG measurement combining monopolar EMG, an un-mixing method such as Independent Component Analysis (ICA) and an activation or movement protocol specific to the muscle being investigated[1] has been tested on Brachialis[2] and Tibialis Posterior[3], successfully detecting activity in both deep muscles. This technique was extended and applied to 4 deep forearm muscles (Flexor Pollicis Longus (FPL), Extensor Pollicis Longus (EPL), Extensor Pollicis Brevis (EPB) and Abductor Pollicis Longus (APL)) and two superficial forearm muscles (Flexor Digitorum (FD) and Extensor Digitorum (ED)) during isometric contractions of the thumb and index finger.

Methods: Monopolar EMG was recorded from two concentric rings, consisting of 20 electrodes each, placed at the distal and proximal thirds of the forearm from fifteen healthy male participants. The participants performed 10 repetitions of isometric thumb flexion (TFl), thumb extension (TEx), thumb abduction (TAb), thumb adduction (TAd), index finger flexion (IFFl) and index finger extension (IFEx). The isometric contractions (<30% of the Maximum Voluntary Contraction-verified by strain gauges) were performed in a randomized order and interspersed with rest periods for each experimental run. Contraction timing and sequence adherence information was derived from the strain gauges. The isometric contractions were selected to independently activate and thereby isolate the target muscles within the area encircled by the electrode bands. fastICA was used to un-mix the 40 monopolar EMG waveforms (containing EMG activity attributable to both superficial and deep muscles) and resolving the signals into 40 constituent components, known as the Independent Components (ICs). The ICs were root mean square (RMS) smoothed using a 250ms moving window and normalised to range from 0 to 1. A contraction sequence specific predicted EMG pattern was created for each muscle (based on corresponding intramuscular measurements[4,5]) and was correlated with the processed ICs using Pearson's Correlation Coefficient (ρ). The IC which best correlated with the predicted EMG waveform for each muscle was considered to represent the recovered EMG activity from that particular muscle (shown for a typical experimental run for one participant in Figure 1).

Results: Good correlation, of the predicted EMG with the processed ICs, was found for the deep FPL, EPL, EPB and APL (summarised for all experimental runs in Table 1). This indicated the ICs were highly likely to represent the activity of those muscles. Low correlation was found for the superficial FD and ED, due to either co-contraction that was un-accounted for in the predicted EMG waveforms or poor separation of the monopolar EMG by fastICA for these particular muscles. Occasionally, fastICA recovered activity when no EMG activity was predicted (ie during TAd for FPL; TFl for

APL). This phenomenon was seen across multiple experimental runs and was likely due to unintended co-contractions (due to poor contraction sequence adherence) or inaccurate estimation of the muscle activity by fastICA.

Figure:



Caption: The predicted EMG waveforms (dashed line) and processed ICs (solid line) with the highest correlation coefficient (ρ) values for one experimental run for one participant. The vertical dotted lines demarcate the waveforms into intervals according to the contraction performed and each rest period.

Conclusion: The ρ values in Table 1 for the 4 deep muscles indicate that the correlation of the predicted EMG with the ICs was consistent over all experimental runs, especially for EPL and EPB. The large variation of the ρ values for the 2 superficial muscles indicated the technique was largely inadequate in detecting activity from these muscles. The results indicate that EMG activity from FPL, EPL, EPB and APL is detectable using surface electrodes. Research verifying this technique is ongoing.

Table:

Muscles		Mean (Min - Max) ρ
Deep	FPL	0.80 (0.58 - 0.96)
	EPL	0.88 (0.72 - 0.96)
	EPB	0.92 (0.80 - 0.96)
	APL	0.83 (0.56 - 0.96)
Superficial	FD	0.40 (-0.07 - 0.88)
	ED	0.38 (-0.07 - 0.85)

Caption: Average (Fisher-transform corrected) ρ values between the predicted EMG and best-fit ICs for each muscle over all experimental runs (15 participants, 10 repetitions per participant)

UNGRADED MUSCLE CONTRACTION IS THE SOURCE OF TENDON PERTURBATIONS OBSERVED DURING IN VIVO TRICEPS SURAE LOADING

Saira Chaudhry [1,*] Hazel Screen [2] Dylan Morrissey [3] Dan Bader [3] Roger Woledge [3]

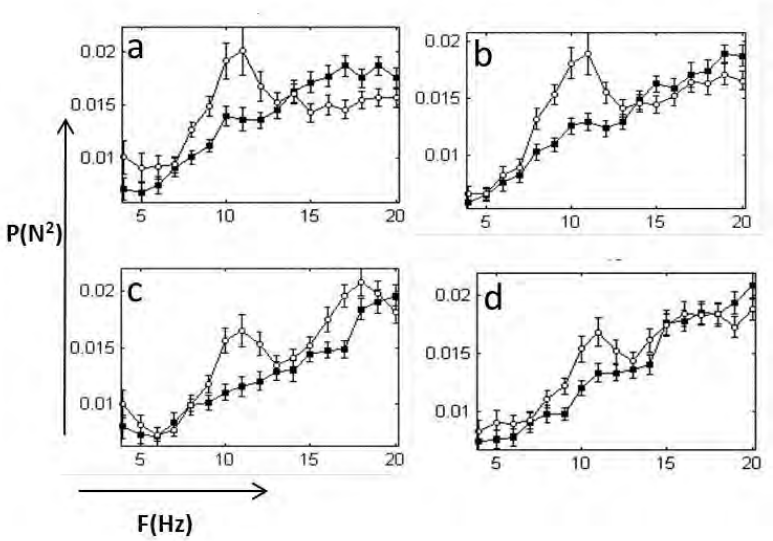
[1]Centre for Sports and Exercise Medicine, [2]School of Engineering and Material Science, [3]QMUL, London, United Kingdom

Introduction and Objectives: Achilles tendinopathy is a most common overuse injury in recreational and professional sports participants [1]. It is difficult to treat and prone to recurrence, with current treatments achieving only partial success. Eccentric loading (eccentric) has shown to promote significant healing in Achilles tendinopathy [2] as compared to concentric loading (concentric). However, the mechanisms underpinning its effects are unclear. Recent in vivo studies in healthy humans have reported no difference in the peak Achilles tendon force during applied eccentric and concentric [3], instead reporting that the primary difference between eccentric and concentric is 10 - 12 Hz tendon perturbations occurring during eccentric [4]. In order to establish the region specific origin of these perturbations, a study was carried out to characterise the pattern of muscle activity across the surface of the triceps surae during eccentric and concentric exercises. From this, it was aimed to investigate the anatomical origin of the 10 - 12 Hz perturbations observed during eccentric.

Methods: Nine healthy subjects participated in the study. Subjects performed eccentric or concentric on a step mounted on a force plate. EMG data was recorded in synchrony with motion analysis data. For mapping calf muscle EMG, 32 EMG electrodes were used on the leg, divided across the three compartments of the triceps surae muscle; the medial gastrocnemius, lateral gastrocnemius and soleus. Each muscle was further divided into proximal, middle and distal sub regions. EMG frequency components were calculated by taking the fast Fourier transform (FFT) of the raw EMG data from each electrode pair.

Results: Tendon perturbations were significantly higher during eccentric than concentric exercises ($P = 0.024$). Graded EMG magnitudes were found to be higher overall in concentric than eccentric EMG data (particularly at very high frequencies). For concentric, higher intensities of graded EMG were present from 10 Hz upwards, focused in the distal gastrocnemius. There was a less uniform spectrum of frequencies present across the triceps surae during eccentric. However, considering 10 - 12 Hz region, the highest graded EMG was observed during eccentric (Figure 1) mainly recorded from the distal, middle and proximal medial soleus, as well as the distal medial gastrocnemius and proximal lateral gastrocnemius. It is evident that certain triceps surae regions, clearly shows a 10 - 12 Hz peak in eccentric data only.

Figure:



Caption: Example data set for the Fourier transform of the calf EMG ± SE (filled circles concentric, empty circles eccentric). a) distal medial soleus. b) proximal medial soleus. c) mid medial gastrocnemius. d) proximal medial gastrocnemius

Conclusion: During eccentric, 10 - 12 Hz frequency peaks were observed in the soleus and the medial gastrocnemius regions of the triceps surae, indicating that these areas of the muscle are likely to be responsible for the specific 10-12Hz vibrations. These findings signify the importance of these regions in the triceps surae; It has been reported recently that tendon rupture mainly occur in the posterior-mid tendon [5], where the load bearing is maximal from the medial soleus and gastrocnemius; if 10 - 12 Hz stimulation is important in treating tendinopathy [6], these are the source. It is still unclear whether perturbations are a beneficial stimulus for tendon repair, or in fact indicate a muscle weakness or poorly synchronized muscle activity in the triceps surae, both of which may be risk factors for tendinopathy. It may be that eccentric treats tendinopathy by training the triceps surae to function more effectively and minimize perturbation, with a progressive load and speed challenge incorporated as the triceps surae adapts to the training stimuli.

The relevance of 10-12Hz perturbations remains unclear; however, finding the origin is an important step towards understanding if perturbations do have a beneficial effect on tendon healing.

PO-0066

ELECTROMYOGRAPHIC AND SUBJECTIVE RESPONSES DURING LOAD CARRIAGE IN GRADED UPHILL AND DOWNHILL WALKING

Sohini Paul [1,*] Tirthankar Chatterjee [1] Anilendu Pramanik [1] Deepti Majumdar [1] Madhusudan Pal [1] Dhurjati Majumdar [1]

[1] Ergonomics, Defence Institute of Physiology and Allied Sciences, Delhi, India

Introduction and Objectives: Thousands of Indian army soldiers are deployed in the mountainous border areas in the eastern and the western Himalayas. Execution of military objectives often demands patrolling and marches in this terrain with different intensities of load that include communication gear, weapons, ammunition, food, water and others. Load carriage in uphill and downhill gradient is always stressful, fatiguing and affects soldiers'combat performance. It is hypothesized that uphill and downhill walking continuously with load increases the muscular responses linearly while walking up the slope and almost in all cases decreases while walking down the slope. It is also hypothesized that this form of exercise affects the lower limb and back muscles differently. This study examined the effect of increasing load and incremental and decremental gradients during uphill and downhill treadmill walking on different muscle activities as electromyographic (EMG) responses and subjective responses using the Borg's scale of rating of perceived exertion (RPE).

Methods: Twelve physically fit Indian soldiers with mean (± SD) age- 26.8 (± 3.9) yrs, height- 170.6 (± 3.2) cm and weight 66.2 (± 6.8) kg volunteered for this study. All the experiments were conducted in controlled laboratory conditions with temperature ranging from 25-28^{0}C and 35-40% relative humidity. The subjects walked continuously for 1 hr in both uphill (30 mins) followed by downhill gradients (30 mins) at 3kmhr^{-1} speed carrying 0.0kg, 10.7kg and 21.4kg load. At first they walked uphill at 0%, 5%, 10%, 15% and 20% gradients followed by walking at downhill gradients of 20%, 15%, 10%, 5% and 0%. For each gradient the subjects walked for 6 mins. The EMG activity for all the load conditions at each of the gradient were normalised with the EMG data of the 0% gradient for the respective load conditions. All the experiments were conducted at random to avoid any biasness. During the experiment the electromyographic responses of Erector spinae(ES), Vastus medialis(VM), Gastrocnemius medialis(GM) and Soleus(SOL) of both sides were monitored continuously along with RPE.

Results: Significant effects of gradient on all the four pairs of muscles for all the conditions were observed. It was found that the activities of the right Erector spinae (RES) and the left Erector spinae (LES) increased as the load mass increased. Both the ES muscles showed an average increase of about 26% activity at 5% gradient while walking unloaded and about 250% increase in activity at 20% gradient in comparison to their respective load at 0% gradient. While walking downhill from 20% to 0% it was observed that the activities of RES and LES muscles decreased in comparison to their respective uphill gradients. There was an average increase in activity of the knee extensors [RVM (right Vastus medialis) and LVM (left Vastus medialis)] by 24% at 5% gradient while walking unloaded and about 272% increase at the highest uphill grade and load combination compared to their respective load at 0% gradient. On the other hand when the subjects started walking downhill an average 284% increase in muscle activity was observed at 20% downhill and carrying 21.4kg load. There was a significant effect of grade on these muscle pairs. A significant increase in

the RGM (right Gastrocnemius medialis) and the LGM (left Gastrocnemius medialis) activity in response to progressive increase of load and increasing and decreasing gradients were noticed. The GM muscles of both the sides increased linearly to about 9% while carrying no load at 5% gradient. At 20% gradient while carrying 21.4kg load at the same walking speed the muscle activity increased to about 72% as compared to the 0% gradient. At downhill gradients the muscle activity decreased compared to the uphill gradients. The SOL muscles showed an average increase of about 8% activity at 5% gradient while walking unloaded and that for carrying 21.4kg at 20% gradient there was 80% increase. It was observed that the activity of the RSOL (right Soleus) and the LSOL (left Soleus) was significantly affected by load and grade.

Conclusion: The present study indicated that while walking up the slope the ES and VM muscles were affected the most. On the other hand walking down the slope affected the knee extensors activity more in comparison to the other muscles. RPE was also significantly affected by the load and grade with the maximum rating of 16.5 out of 20 while walking with 21.4 kg load and 20% uphill grade. The Indian military personnel when subjected to similar exercises in routine military operations in higher altitude, the prevailing hypoxic condition there may further exaggerate and accelerate the risk of muscle injuries, soreness and fatigue to a larger extent affecting the combat fitness of the individual. Hence, adequate preventive measures are required by the individual while traversing at steep gradients with load.

PO-0067

THE USE OF INDEPENDENT COMPONENT ANALYSIS ON EMG DATA TO EXPLORE CROSSTALK

Róisín M Howard [1,*] Richard Conway [1] Andrew J Harrison [2]

[1]Electronic & Computer Engineering, [2]Physical Education & Sports Science, University of Limerick, Limerick, Ireland

Introduction and Objectives: Cross talk is a common problem associated with surface Electromyography (sEMG). Multiple muscles contribute to a movement which may cause multiple signals to be picked up by the sEMG sensor from neighbouring muscles. The combined signal is gathered and analysed, with the user being unaware if cross talk is contained and how much. ICA is a dimension reduction technique which can return data that was originally hidden from the larger data set. The data should be non-Gaussian and components should be statistically independent. EMG data fits the criteria for ICA and therefore has been used in studies to isolate EMG data. Willigenburg et al. makes use of ICA to remove ECG contamination from EMG recordings of the trunk muscles [1]. Similarly Azzerboni et al. uses a combination of techniques, ICA being one of them, in EKG artefact removal from EMG recordings [2]. The aim of this study is to explore the use of ICA on EMG signals to reduce cross talk from the gathered data, isolating individual muscle contributions.

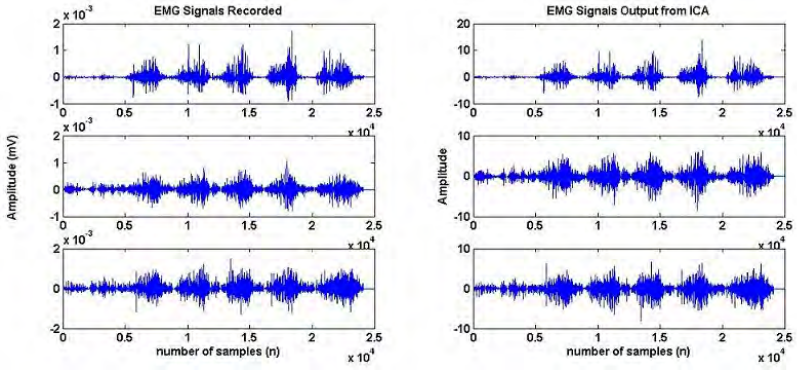
Methods: Seven volunteers, four males and three females, who were injury free at the time of testing, participated in this study. Ethical approval was granted by the local University Research Ethics Committee and all participants provided informed consent in writing before testing. The Delsys Trigno Wireless EMG system was used, EMG electrodes were attached according to SENIAM recommendations (with extra electrodes attached in unideal locations so as to gather cross talk data) [3]. Participants performed five reps of split squat which isolates the quadriceps muscle group.

EMG data was imported into Matlab. A mixed signal matrix was created with data from 3 of the combination of sensors for each movement, in multiple combinations. Each mixed matrix was analyzed using the ICA algorithm and subsequently compared to the signals gathered from the sensors in recommended locations. The integrated EMG (iEMG) of the analysed signals and the original ideal signals were compared using interclass correlation coefficients (ICC) with 95% Confidence Intervals (CI) [4].

Results: Table 1 shows the mean muscle activations (±SD) for the Rectus Femoris (RF), Vastus Lateralis (VL) and Vastus Medialis (VM) for the split squat exercise. The RF returned an ICC of 0.478 when compared with iEMG from the EMG signal gathered at the ideal sensor location and the iEMG of the average output from the ICA algorithm for the RF using sensors from other locations on the quadriceps. Similarly the VL returned an ICC of 0.359 and the VM returned an ICC of -0.006. In a comparison of iEMG on all the outputs from the ICA algorithm, the RF returned an ICC 0.941, the VL returned an ICC of 0.958 and the VM returned an ICC of 0.721. The systematic bias observed between the ideal EMG signals and the ICA output signals was significant; however the percentage difference was very small.

Figure 1 shows an image of the signals gathered in ideal sensor locations vs one set of output signals from the ICA algorithm. It can be seen that there are many similarities visually between both sets. Note must be made that ICA does not keep scaling properties but the signal profile remains the same.

Figure:



Caption: Figure 1. Comparison of ideal EMG signals to output from ICA algorithm

Conclusion: Results of this investigation identified that the ICA algorithm is a successful tool which can be used to distinguish between individual muscle activations. Results showed moderate agreement between the output from the ICA algorithm and the ideal EMG signals. However, these ideal EMG signals may still be picking up cross talk from neighbouring muscles groups. A moderate to high agreement was found between all the outputs from the ICA algorithm which leads to the conclusion that the results of the ICA algorithm may be returning the actual ideal EMG signals for the specific muscle groups. Further research into the use of this algorithm can be done to make results more accurate and reliable.

Table:

	Rectus Femoris	Vastus Lateralis	Vastus Medialis
iEMG ideal ± SD (mV)	1.17 ±0.56	1.89 ±1.14	2.09 ±1.04
iEMG of ICA output ± SD (mV)	1.50 ±0.22	1.59 ±0.79	1.60 ±1.01
% Difference	0.32	-0.30	-0.50
Systematic Bias	6	6	6
ICC (between ideal and ICA output)	0.478	0.359	-0.006
(95% CI)	(-0.782 - 0.898)	(-2.174 - 0.887)	(-3.195 - 0.815)
ICC (on all outputs of ICA)	0.941	0.958	0.721
(95% CI)	(0.816 - 0.989)	(0.868 - 0.992)	(0.138 - 0.946)

EFFECT ON SIDE RATIOS OF ERECTOR SPINAE MUSCLE DURING ISOKINETIC TRUNK EXTENSION USING ABSOLUTE OR NORMALIZED EMG AMPLITUDES

Martin Wolter [1,*] Stephan Kopinski [1] Monique Wochatz [1] Steffen Mueller [1] Frank Mayer [1]

[1] Sport and Health Science, University Outpatient Clinic Potsdam, Potsdam, Germany

Introduction and Objectives: EMG is a valuable tool to assess neuromuscular impairments in patients e.g. suffering from chronic low back pain. Numerous studies have shown alterations in the neuromuscular activation of trunk muscles. Side differences in EMG amplitude between muscle pairs are present in patients as well as in healthy controls, though to a lesser degree. Usually normalization of EMG to maximum exertion (MVC) is used to account for confounding factors like differences in electrode placement. But normalization could also mask the distinctions that would be associated with pathology and it depends on maximum voluntary contractions (MVC). The aim of this study was to evaluate the effect of EMG amplitude normalization on calculation of contralateral side ratios in m. erector spinae (ES) in an isokinetic trunk extension.

Methods: In 42 healthy subjects (21 males/21 females, 27±3 years, 69±12 kg, 1.74±0.09 m) muscular activity of the lumbar ES (LES) at L3 level and thoracic ES (TES) at Th9 level were measured bilaterally via 4-lead-EMG during concentric isokinetic back extension at 45 °/s and a ROM of 45° flexion to 10° extension. Warm-up was followed by 5 maximum voluntary contractions (MVC). Afterwards each 5 isokinetic contractions were performed with 20, 40, 60 and 80% of the MVC peak torque. Root mean square (RMS) for the isokinetic phase of all 5 repetitions was averaged within each condition and normalized to MVC. Side ratios were calculated for raw RMS (Δ_{raw}) and normalized RMS (Δ_{norm}) with the formula $|1-(\text{left side/right side})|*100$. Differences of both calculations (Δ_{raw} vs Δ_{norm}) were tested for significance with a paired t-test ($\alpha=0.05$). Agreement between both was tested with Bland-Altman-Analysis (BAA) with bias ± limits of agreement (LoA; SD*1.96). Additionally repeated measure ANOVA (Bonferroni adjusted) was conducted to assess load dependency of the site ratios.

Results: Statistical significant differences between Δ_{raw} and Δ_{norm} were present for LES in 40, 60 and 80% with 18 vs 14%, 15 vs 11% and 14 vs 7%, respectively (Tab.1). ANOVA revealed significant differences for site ratios of the LES regarding load in both normalized and raw data. Post-hoc tests of Δ_{raw} showed just significant differences between 40 and 60%, whereas pair-wise comparisons of Δ_{norm} showed significant differences in 4 of 6 comparisons.

Figure:

Load	TES			LES			
	Raw RMS vs Normalized [%]		Bias±LoA	Raw RMS vs Normalized [%]			Bias±LoA
20%	24±17	25±21	-2±50	21±16	18±16		3±29
40%	22±21	23±19	-3±53	18±13	14±11	*	4±24
60%	23±22	21±16	1±43	15±11	11±7	*	4±20
80%	21±17	17±12	4±40	14±9	7±5	*	6±19

Caption: Side differences (mean ± SD) between left and right side of each muscle pair (* indicates significant differences between ∆raw and ∆norm with $p<0.05$) and BAA.

Conclusion: Side ratios calculated with normalized RMS data reveal lower values and LES site ratios were affected by the applied load. But Δ_{raw} seem to be more stable for load effects than Δ_{norm}. Whether the significant difference between both ways of calculating side ratios has practical relevance needs to be discussed. IfΔ_{norm} is more reliable than Δ_{raw} and able to distinguish between healthy and LBP patients needs to be investigated. Since EMG amplitudes can be influenced by several factors one should weigh carefully the advantages and disadvantages of raw RMS data.

PO-0069

EVIDENCE FOR MUSCLE-SPECIFIC PIPER RHYTHM OF LOWER LIMB MUSCLES DURING WALKING

Gregor Kuntze [1,*] Vinzenz von Tscharner [2] Cam Cummings [3] Carol Hutchison [3] Janet Ronsky [1]

[1]Mechanical and Manufacturing Engineering, [2]Kinesiology, [3]University of Calgary, Calgary, Canada

Introduction and Objectives: Electromyographic (EMG) signals of skeletal muscles display a temporal rhythmicity [1, 2] representing a cortical drive that tends to synchronize the activity of motor units. The Piper rhythm (30-60Hz) can be resolved during cyclic movements using wavelet analysis [3] and has been shown to be sensitive to changes in running speed [4]. While the general frequency range of the Piper rhythm has been defined, it is feasible that modulation of this rhythm occurs in response to task demands. Further, differences in activation rhythmicity may exist between different muscles of the lower limbs. However, there remains a lack of information concerning potential inter-muscular differences in this activation rhythmicity. The aim of this study was to investigate the Piper rhythm of seven lower limb muscles during a walking task. It was hypothesized that lower limb muscles display Piper frequencies between 30-60Hz and that significant inter-muscular differences in the Piper rhythm can be identified during a walking task.

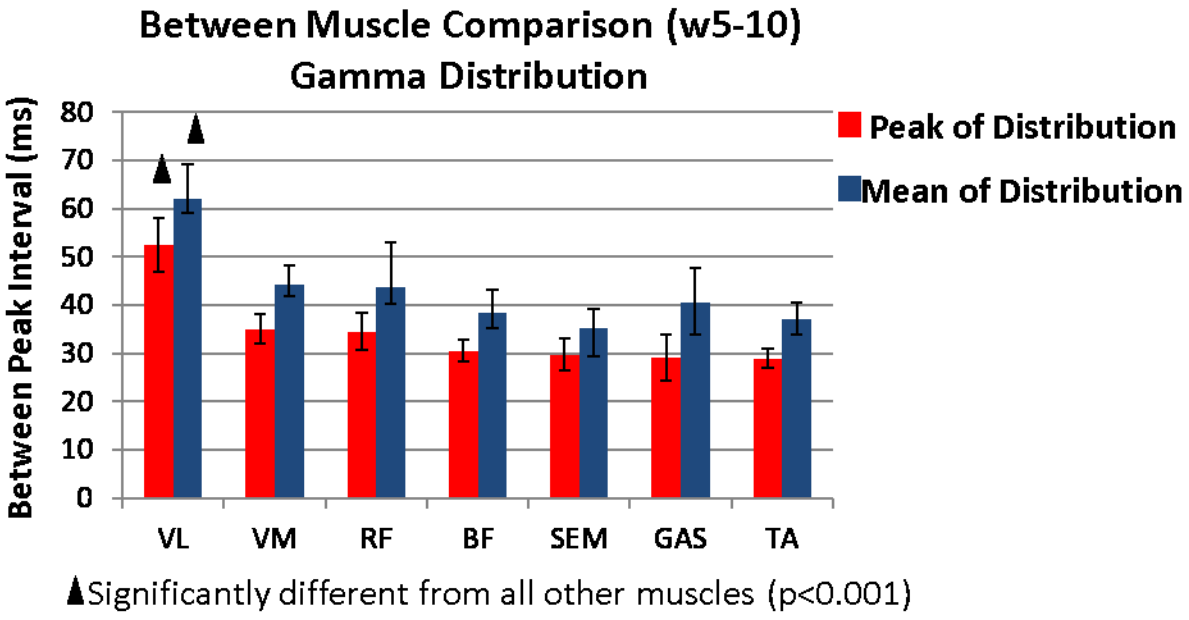
Methods: Nine healthy female subjects (61.4±7.4 years; BMI 25.6±2.4) volunteered for participation in this study. Approval was received from the local ethics board. Subjects walked at a self-selected pace on a raised wooden walkway. Gait velocity was recorded using a pair of timing lights (Banner, USA) positioned immediately before and after two forceplates (AMTI, OR6-6, USA; Kistler, 9286AA, Switzerland). Following recommendations by SENIAM (www.seniam.org) EMG data of seven lower limb muscles of a randomly selected limb were collected: vastus lateralis (VL), vastus medialis (VM), rectus femoris (RF), semitendinosus (SEM), biceps femoris (BF), lateral gastrocnemius (GAS) and tibialis anterior (TA). The skin was shaved, cleaned with rubbing alcohol and bipolar Ag/AgCl EMG electrodes (diameter 10mm, inter-electrode distance 20mm; Noraxon, USA) were affixed. All data were normalized to stance phase using force-plate measures. EMG signals were wavelet transformed [5], time normalized to 501 data points and visually inspected for movement artifacts. The lowest number wavelet was removed to minimize effects of signal noise. Five trials per subject were taken forward for analysis in Matlab (MathWorks, USA). Total intensity (TI) patterns were calculated for each muscle and trial by computing the sum of intensities of the wavelet pattern at each time point. Peaks, apparent in the TI patterns, were identified in Matlab and all peaks <5% of the maximum intensity were rejected. Between peak intervals (ms) were computed and histograms of all subject data were generated. Data distributions were obtained using a gamma fit. The peak and mean of each gamma distribution was computed for analysis purposes.

Data were tested for normality (Shapiro-Wilk) and log transformed if necessary. Multivariate ANOVA were performed in SPSS (IBM, USA) with Bonferroni correction ($p \leq 0.05$).

Results: Gamma distribution peak and mean data are presented in Figure 1. A significant effect of muscle was observed ($p<0.001$) with VL displaying longer between-peak intervals compared to all other muscles ($p<0.001$ throughout). These results indicate a Piper frequency range of 25-32Hz for VM, RF, BF, SEM, GAS, and TA and 16-19Hz for VL. Variations in frequency estimates based on peak and mean data may be explained by the distinct and consistent positive skew of the distribution curves. Peak data therefore would tend to result in a higher frequency estimate, while mean data would tend

to result in a lower frequency estimate. If the Piper frequency is modulated to meet exercise demands (Maurer et al. 2013) peak data may be more sensitive to such changes. However, this remains speculation at this time and will be investigated further in future studies.

Figure:



Caption: Figure 1. Peak (red) and mean (blue) distributions of intensity peak intervals of the activations of 7 superficial lower limb muscles.

Conclusion: The observations of this study indicate significant differences in the Piper frequency between muscles of the lower limbs. While the exact causes for these differences remain to be elucidated, this may be an indication that not all muscles receive the same cortical synchronization stimulus but that this input is indeed customized to the activity of the muscle.

This study was supported by Alberta Ingenuity Fund (AITF), NSERC, and AHFMR.

PO-0071

THE IMPORTANCE OF KNEE MUSCLE COORDINATION THROUGH DIFFERENT STAGES OF OSTEOARTHRITIS.

Aseel Ghazwan [1,*] Cathy Holt [1] Gemma Whatling [1]

[1]Arthritis Research UK Biomechanics and Bioengineering Centre, Cardiff University, Cardiff, Wales, United Kingdom

Introduction and Objectives: Literature has shown that people with knee Osteoarthritis (OA) tend to walk with greater muscle co-contraction to compensate for joint instability. This in turn increases knee contact load, and may contribute to the progression of OA. The ideal strategy to understand this scenario is to explore how the coordination between quadriceps, hamstrings, and gastrocnemii are affected at different stages of knee OA. Accordingly, this study was initiated which aims to determine the changes in co-contraction index with the severity of OA.

Methods: Fifteen, fully consented subjects formed three groups: five healthy subjects, five with medial OA awaiting high tibial osteotomy (pre-HTO), and five with late stage OA awaiting total knee replacement (pre-TKR). The mean and SD of weight and height for healthy, pre-HTO and pre-TKR cohorts were (81.7±8.7 kg, 88.5±11.4 kg, 91.6±17.7 kg), (173.2±3.4 cm, 169.3±8.2 cm, 161.9±4.5 cm), respectively.

Muscle electromyographic (EMG) data were collected bilaterally for seven muscles: Rectus Femoris, Vastus Lateralis, Vastus Medialis, Biceps Femoris, Semitendinosus, Gastrocnemius Lateralis, and Gastrocnemius Medialis. The electrodes were placed longitudinally over the muscle bellies after standard preparation of the skin.

Individuals were then asked to walk at their comfortable speed. Meanwhile, information regarding muscle EMG, ground reaction force and three dimensional movement were collected using motion analysis (Qualisys, Sweden). 6 trials of level gait were recorded for each subject.

EMG data, through stance phase, were analysed in Matlab version R2013a. The raw EMGs were band-pass filtered using a Butterworth 4^{th} order filter at 40_450 Hz to remove the movement artefacts, rectified and finally low-pass-filtered with a 4^{th} order Butterworth filter at 6 Hz, to create a linear envelope for each muscle. Linear envelopes were normalized to peak values obtained through the walking cycle by using the Peak Dynamic Method (PDM), as that adopted by Knarr et al 2012 [1]. The EMG data were normalized to 100 data points though the stance phase and an average of six trials for each participant were calculated, thus representing the mean muscle activity through stance. Finally, the co-contraction index (CCI) was calculated for each muscle through stance according to Rudolph et al.[2].

CCI was calculated for the following muscle sets: Vastus Lateralis- Gastrocnemius Lateralis (VLLG), Vastus Lateralis-Lateral Hamstring (VLLH), Vastus Medialis- Gastrocnemius Medialis (VMMG), and Vastus Lateralis-Medial Hamstring (VMMH).

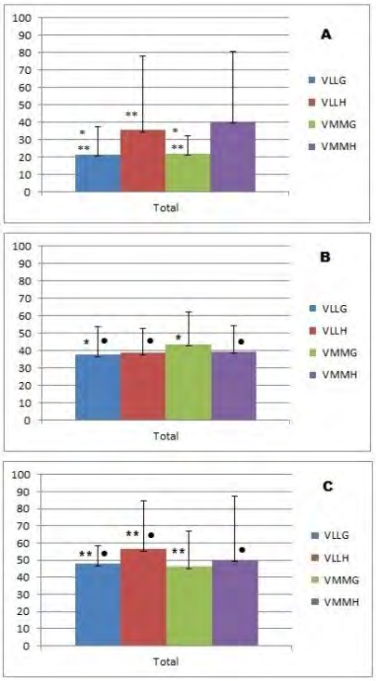
CCI was calculated for each subject during stance phase. Group means and standard deviations are presented in Figure1. One-way ANOVA was used to reveal statistically significant differences between the three cohorts ($p<0.05$).

Results: Figure 1(A, B, and C), shows the CCI for healthy, pre-HTO, and pre-TKR subjects, respectively. As expected, patients with OA (Figures 1-B and 1-C), have a higher CCI compared to healthy subjects (Figure 1-A). Significant differences in the CCI were identified between the three cohorts, as indicated in Figure 1.

Interestingly, this study shows an almost two-fold increase in gastrocnemii CCI in the pre-HTO group as compared to healthy subjects ($p<0.05$). For the pre-TKR group, the gastrocnemii indices are increased further. The hamstring muscle indices are also significantly increased compared to the pre-HTO cohort, indicating that they also have a potential to provide stability for the knee joint. The Hamstring indices increased almost 60% on the lateral side and 25% on the medial side, as compared to healthy individuals. The statistically significant increase in VLLH CCI for the pre- TKR group as compared to the healthy cohort, may contribute to a reduction in the medial contact force.

These findings are consistent with previous literature, where patients with OA co-contracted significantly higher than that of healthy individuals. It has found a strong relationship between CCI and the stage of OA, i.e., the index is higher among the pre-TKR group, which represent the end stage of OA, than for the pre-HTO group.

Figure:



Caption: Figure-1: Co-contraction index during stance-phase for healthy subjects - A, pre-HTO subjects – B, pre-TKR subjects - C. Values represent mean and standard deviation. (*) means the difference is significant ($p < 0.05$) between Pre-HTO and healthy groups. (**) means the difference is significant ($p < 0.05$) between Pre-TKR and healthy groups. (●) means the difference is significant ($p < 0.05$) between Pre-HTO and Pre-TKR groups.

Conclusion: In conclusion, hamstring and gastrocnemii muscles play a significant role in stabilizing the knee joint and they altered their coordination through different stages of OA.

PO-0072

IDENTIFICATION METHOD OF INNERVATION ZONE BY SURFACE ELECTROMYOGRAM DURING DYNAMIC CONTRACTIONS USING ELECTRODE ARRAYS

Aya Shirai [1,*]Tota Mizuno [1]Naoaki Itakura [1]Kazuyuki Mito [1]

[1]Graduate School of Informatics and Engineering, The University of Electro-Communications, Tokyo, Japan

Introduction and Objectives: During dynamic contraction, Innervation zone (IZ) shifts according to change muscle length in surface electromyogram (sEMG)[1]. Visual identification of IZ location is major method, but it is a matter of lack of objective assessment.

This study provided the new identification method of IZ location during dynamic contraction in order to identify that objectively, and compared with the traditional method.

Methods: 1. Experiment

Five healthy male subjects (mean of age was 21.6 years) maintained static (isometric) and dynamic contractions of right arm to the limit during 40% of maximum voluntary contraction (MVC). Isometric contractions were at right elbow joint angles 50°, 90° and 130°, and dynamic contraction was at the joint angle from 40° to 140° and the speed was set 10 °/s.

sEMG was recorded from the right biceps brachii muscle. Electrode arrays were composed of fifteen silver wires with diameter of 1 mm and a length of 10 mm, and attached on the muscle belly. The distance between neighboring electrodes was 5 mm. Fourteen sEMG signals were derived bipolarly from paired neighboring wires filtered by bandpass from 5 Hz to 1 kHz. The sEMG signals were digitized with sampling frequency of 10 kHz and stored on computer.

sEMG data for the isometric contraction (ISO) was analyzed at 0.4 seconds. sEMG data for the dynamic contraction was divided into concentric and eccentric contraction (CON, ECC), and each data analyzed at 0.4 seconds on the joint angles 50°, 90° and 130°.

2. New identification method

In visual identification, most of measurers focus on waves of large amplitude values. Thus in the new method, the waves were paid attention to similarly, and identification was conducted using sEMG data at 0.4 seconds and electrode arrays including fourteen channels.

First, sEMG data was divided in section between points of electrical potential crossing zero from negative to positive. For each section, maximum amplitude absolute values were calculated, and for each channel, sections which were ten of top the values or more were extracted. After that in any sections other than extracted sections, amplitude values were defined as 0 V.

Next for each channel, Cross-correlation Coefficient (CC) was calculated for extracted section and both neighboring channels. After that, rate of CC which was -0.7 or less (uRATE), and rate of CC which was 0.7 or more (oRATE) were calculate, and means of the rates between same channels were calculated.

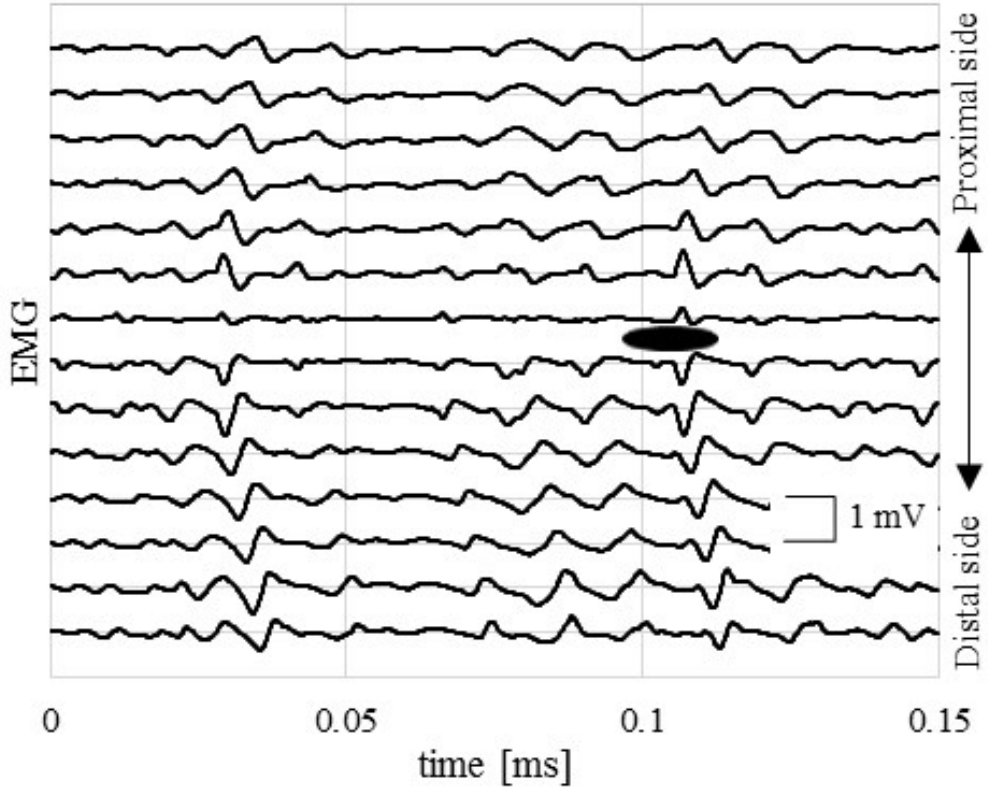
Finally IZ location was determined from the following two cases. In first case, if channels which the highest uRATE and the lowest oRATE were identical channels, IZ location was defined as the channels. In second case, if channels which the

highest uRATE and the lowest oRATE were consecutive channels, IZ location was defined as the middle channel. If there were not implement all the above cases, IZ locations were defined as impossible identification.

Results: In visual identification, IZ is located on reversed peak action potential of neighboring channel (Figure). Results of visual identification of IZ location by three experts were defined as correct result, and concordance rates of the new method and visual identification were calculated.

Table shows mean concordance rate of three experts in three contractions each five subjects. The mean was 80 % in all contractions of all subjects, and it is useful to identify IZ location by new method. Compared with contractions, concordance rates at CON and ECC in subject A were showed 50%. The result was related to sEMG amplitude values. With decreasing amplitude value, it was difficult to extract characteristic wave. Amplitude values of subject A were lower than other subjects, therefore it led to low rate.

Figure:



Caption: Example of IZ location by sEMG using electrode arrays, and ellipse shows IZ location in visual identification.

Conclusion: In identification of IZ location using sEMG, visual identification is major, and it is a matter of lack of objective assessment. Therefore, this study provided new objective identification method of IZ location. In the new method, characteristic waves were extracted, and similarities of the waves and neighboring channels were determined using CC. After that, by rate of CC was low and high each channel, IZ location was defined. Result of comparing the new method with visual identification, mean concordance rate was over 80 %, and it was useful to identify IZ location objectively.

Table:

	ISO		CON		ECC	
Subject	mean	±SD	mean	±SD	mean	±SD
A	83%	0%	50%	0%	50%	0%
B	83%	0%	72%	10%	78%	10%
C	78%	10%	10%	0%	10%	0%
D	83%	0%	10%	0%	83%	0%
E	67%	0%	83%	0%	89%	19%

PO-0073

EFFECT OF NUMBER OF TRIALS IN GROUND REACTION FORCES RELIABILITY DURING RUNNING

Andrea N. Onodera [1 2,*] Licia Cacciari [1] Ana Paula Ribeiro [3] Maria Isabel Roveri [1] Isabel C N Sacco [1]

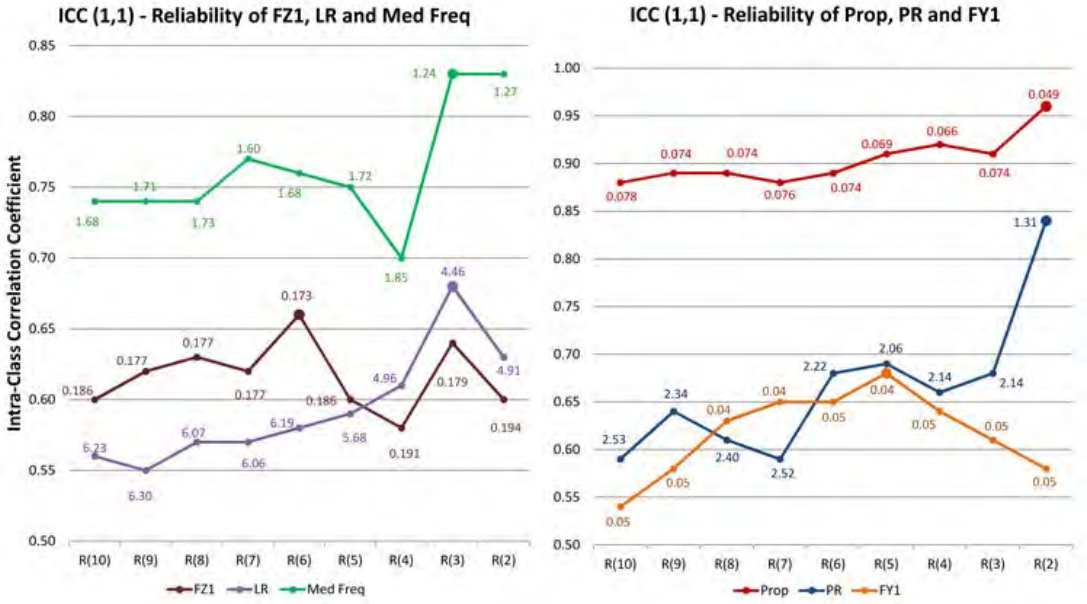
[1]Physical Therapy, Speech and Occupational Therapy Dept. School of Medicine, University of São Paulo, São Paulo, [2]Dass Nordeste Calçados e Artigos Esportivos Inc., Ivoti, [3]Universidade de Santo Amaro, Universidade de Santo Amaro - Campus I, São Paulo, Brazil

Introduction and Objectives: The ground reaction forces during running and its impact are very studied area especially for running shoes researches [1,2,3]. Particularly, the number of trials needed to reduce the variability has been questioned between researchers studying highly variable parameters, such as the human locomotion [4]. The Brazilian National Standards Organization [5] recommends 20 trials to determine shoe-cushioning rates during gait, what results in a long data acquisition time and a large amount of acquired data, delaying the development of sports shoes. It can also represent discomfort for the runners. Diss [6] compared the reliability of ground reaction force (GRF) data of running for one and 10 trials, predicting that 10 trials were enough to achieve high level of confidence. However, only the Intraclass Correlation Coefficients (ICC) score was analyzed. Our study purpose to analyze the ICC and the Standard Error of Measurements (SEM) along the series of tested trials for 6 GRF parameters in healthy runners, intending to optimize the biomechanical test protocols, yet assuring high confidence levels.

Methods: Ten healthy runners (39.0±9.3 years old, 70.0±6.1 kg, 170±6 cm) with rearfoot strike pattern ran over a 25 meters walkway in constant and natural velocity (2.64 to 2.92 m/s). All runners used the same commercially available sport shoes. Ten valid trials were acquired by a force platform sampled at 1200 Hz (AMTI BP600600, Watertown, USA), and data was filtered at 300Hz by Butterworth 4^{th} order zero-lag filter. The leg side was randomly chosen. Kinetic variables from vertical and antero-posterior GRF were analyzed. The Reliability tests were performed after confirming normal data distribution (Kolmogorov-smirnov). The Standard Error of Measurements (SEM = SD$\sqrt{}$1-ICC) were calculated along 2 to 10 trials, as well as the intraclass correlation coefficient (ICC(1,1) = (MSb-MSw)/(MSb + (k-1)MSw)) corresponding to the one-way model with single measurements reliability [7].

Results: All kinetic variables analyzed in this study presented the highest ICC scores for number of repetition with the lowest SEM, which means that the highest consistency of data is followed by the lowest absolute error in the measurements (figure 1). Biomechanical studies usually record 5 to 10 trials to guarantee data consistency. Our results show that for 10 subjects running 10 or 20 trials as recommended by the Brazilian National Standards Organization would be a waste of experiment time and also would reduce the consistency of the data, probably because the increasing chance of error. The first vertical force peak presented the highest reliability and lowest error at 6 trials. For loading rate and the median frequency of the first vertical force peak 3 trials corresponded to the optimal reliability rate and low SEM. On the other hand, variables related to the second vertical force peak presented optimal reliability rates and low SEMs for 2 trials. And lastly, the one variable related to the first antero-posterior peak presented higher reliability with 5 trials.

Figure:



Caption: Ilustration of Intraclass correlation coefficient (lines) and Standard Error of Measurement (numbers above or under each mark) of ground reaction force parameters during 2 to 10 trials.

Conclusion: The ideal number of trials needed in biomechanical studies differ according to the running event on focus. When studying the vertical GRF 3 trials seems to be enough, guarantying good reliability rates, except for the first peak. In cases in which horizontal GRFs are the main focus of the study, at least 5 trials are necessary to optimize the reliability and the standard error of measurements.

Table:

Variables	Mean	sd
First Impact Force (BW) - FZ1	1.66	0.29
Loading Rate (BW/sec) - LR	42.38	9.35
Median Frequency (Hz) - Med Freq	14.07	3.27
Propulsion Force (BW) - Prop	2.59	0.22
Propulsion Rate (BW/sec) - PR	17.92	3.98
Horizontal Breaking Force (BW) - FY1	-0.38	0.08

GROUND REACTION FORCE IMPULSES DURING FIRST ATTEMPT OF BAREFOOT RUNNING IN HABITUAL SHOD RUNNERS

Ana Paula D. S. Azevedo [1,*] Juliana Pennone [1] Bruno Mezêncio [1] Rafael Soncin [1] João Claudino [1] João Pinho [1] Alberto Amadio [1] Julio Serrão [1]

[1] Laboratory of Biomechanics, School of Physical Education and Sport - University of São Paulo, São Paulo, Brazil

Introduction and Objectives: Running has been a very important expression of movement. However, your practice has been related to an increasing injury rate [6,8]. Parameters of the vertical component of Ground Reaction Force (GRF), as the impulses, have been associated to these injuries [2,4,8]. Evidences suggest barefoot running decreases impact forces [3,5,7]. Thus, the belief that barefoot running could be an effective strategy to improve mechanical load control has been reinforced. Other evidences suggest barefoot running increases external load and could be harmful to human body [1,9]. Nevertheless, few studies analyzed the influence of barefoot running upon GRF in habitually shod athletes in their first attempt in this mechanical condition. Therefore, the purpose of this study was to analyze the effect of barefoot condition upon the impulse of the first 50ms and total impulse of GRF in habitually shod runners in their first attempt of barefoot running.

Methods: Fourteen habitually shod runners (12 men and 2 women; age = 28.4 ± 7.3 years; mass = 72.7 ± 7.8 kg; height 1.74 ± 0.06 m) ran during 10 minutes at 9 $km.h^{-1}$ on a treadmill in two conditions: using conventional running shoes and barefoot. An instrumented treadmill (GAITWAY Instrumented Treadmill System 9810S1; and TROTTER Treadmill Model 685, 01-06560201) with two piezoeletric force plates (KISTLER Inc.) was used to obtain the vertical component of GRF. Nine acquisitions (10 seconds each) of GRF were performed for each experimental condition at 2600 Hz. The impulse of the first 50ms (Imp50, area under the curve GRF x time of the first 50ms) and total impulse (ImpTot, area under the curve GRF x time) were calculated.

GRF data was low pass filtered by a Butterworth filter (4th order, 90 Hz cutoff frequency). The start and end of each left and right step was determined using 30N threshold. GRF data was normalized by individual body weight, while time was normalized by total support time. Statistical analysis of data was performed in SigmaStat 3.5 (Systat, Germany) software. Data normality was verified using the Kolmogorov-Smirnov test, while homoscedasticity was checked by Levene's test. For means comparison, an analysis of variance (ANOVA) for repeated measures was performed. The level of significance adopted was $p \leq 0.05$.

Results: Significant differences were observed between shod and barefoot running for the variables analyzed. The Imp50 was 29.2% higher ($p < 0.001$) for barefoot running (33.83 ± 11.20 BW.ms) compared to conventional shoe (26.19 ± 7.94 BW.ms). However, the ImpTot was 17.2% smaller for barefoot (328.30 ± 3.23 BW.ms) than conventional shoe (396.30 ± 4.12 BW.ms).

Conclusion: Habitually shod runners seem to have higher energy propagated through human body in the impact phase during running barefoot. When the entire stance phase is considered, barefoot running imposed less energy propagation than conventional shoe. This result can indicate a less efficient mechanical load control and higher external force in a

critical moment of gait cycle in habitually shod runners during their first attempt barefoot. Such results corroborate with evidences reported by literature [1,9]. Therefore, although barefoot running presents a smaller total impulse of GRF, the impulse of 50ms, related to the impact phase of running, seems to be increased in habitually shod runners in their first attempt in this mechanical condition. A cautious use of barefoot condition in habitually shod runners is suggested to minimize injury risk.

BAREFOOT AND SHOD WALKING IN VIRTUAL REALITY ENVIRONMENT WITH OXFORD FOOT MODEL

Craig R Childs [1,*] Vicki Cameron [2] Andrew J Murphy [1]

[1]Biomedical Engineering, University of Strathclyde, Glasgow, [2]StEPS Podiatry, Troon, United Kingdom

Introduction and Objectives: The Oxford Foot Model (OFM) [1] was developed to get accurate measurement of foot movement during gait as the bone pin method [2] is not practical for most clinical situations. It has been validated in adults [3] and children [4]. However, since barefoot walking on a treadmill is not recommended there is a question over whether the OFM can be usefully applied in facilities such as the Motek CAREN (Computer Assisted Rehabilitation Environment - motekmedical.com). Consequently, there is an interest to see if applying OFM markers to shoes can give useful results when measuring human walking on treadmills. This study looks at the differences in measurements using the OFM between walking over-ground (barefoot and with shoes) and on a treadmill (with shoes).

Methods: Nine boys (mean age 13.5±0.5yrs, height 1.59±0.09m, mass 47.8±8.3kg) were recruited. Retro-reflective markers were attached bilaterally following the Plug-in-Gait lower limb and OFM models. The over-ground (barefoot and with shoes) trials were recorded in a standard gait laboratory (12 camera Vicon T-Series). Barefoot trials were performed first to minimise the need to reattach markers. The treadmill walking trials were recorded in the CAREN immediately after the over-ground trials (12 camera Vicon Bonita10). The treadmill speed was set to match the speed of over-ground walking in the gait laboratory. Gait events were determined from force plate contacts. All the boys wore light indoor training shoes. Data was captured using Vicon Nexus 1.8.5 and processed using Plug in Gait and OFM models in Nexus 2.1.

Results: There was no difference in ankle kinematics between over-ground (barefoot and with shoes) and on a treadmill (with shoes). Although Forefoot-Hindfoot angles were comparable to the literature in the barefoot condition, this was not the case with shoes (Table 1). Barefoot, there was a steady dorsiflexing motion throughout stance until push off which was signified by a rapid plantar-flexing motion. With shoes on, the same model segments show rapid dorsiflexion, then plantar flexion during early stance followed by neutral position held until push-off.

Conclusion: Reinschmidt and colleagues [2] reported that the shape of the calcaneal motion curves was similar for shoe mounted markers and bone markers, but that the shoe-mounted markers overestimated joint angles. In this study, the shape of the curves was quite different. This paper will discuss the practicalities and limitations of this technique, and where it may be usefully applied.

Table: Forefoot-Hindfoot Model Segment Dorsiflexion during Stance

	range (degrees)	time of peak (% of stance phase)	rate of change (degrees per second)
Stebbins [4]	12	82	25
Barefoot	11	87	22
Shoe over-ground	9	11	150
Shoe treadmill	8	23	130

PO-0076

BIOMECHANICAL EVALUATION OF TWO SHOE DESIGNS FOR FOREFOOT OFFLOADING

Paolo Caravaggi [1] Alessia Giangrande [1] Lisa Berti [1] Giada Lullini [1] Alberto Leardini [1,*]

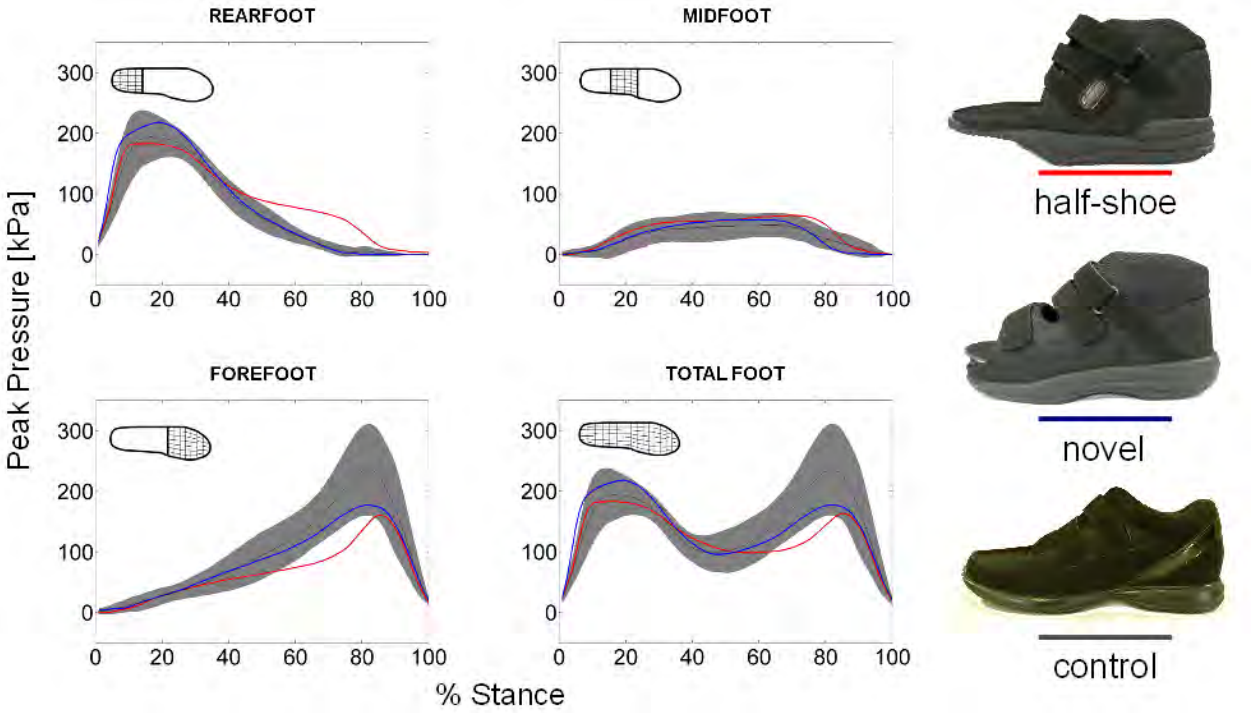
[1] Movement Analysis Lab, Istituto Ortopedico Rizzoli, Bologna, Italy

Introduction and Objectives: Forefoot offloading shoes (FOS) are special orthopedic footwear designed to protect and unload the injured part of the foot after surgery and for conservative treatments. While these shoes are intended to be worn only for short periods, a compromise must be found between offloading and comfort from one hand, lower limb functionality and stability on the other hand. In this study therefore, the traditional baropodometric measurements were integrated with joint kinematics and kinetics from standard gait analysis to assess the effects of a traditional half-shoe and a novel FOS (Podartis, Treviso, Italy), in a comparison to a standard comfortable shoe (control).

Methods: Ten healthy female participants (28.2±10.0 years; BMI 20.4±1.2 kg/m2) were asked to walk in three different footwear conditions for the left/right foot: control / traditional half-shoe, control / novel, and control / control. State-of-the-art gait analysis with three-dimensional rotations and moments at the hip, knee and ankle joints [1] was obtained from three walking trials for each participant in each condition. Simultaneously a sensor insole system (Pedar, Novel GmbH, Munich, Germany) recorded plantar pressure at 100 Hz. Rearfoot, midfoot and forefoot regions, along with the whole foot, were defined a-priori by selecting corresponding pressure capacitive sensors among the 99 available. Normalized root mean square error, determination coefficient, and frame-by-frame statistical analysis were used to assess differences between kinematic and kinetic time-histories.

Results: No significant differences were detected in walking speed and ground reaction force between the three shoes, nor in the spatio-temporal parameters with the exception of the stride length, this being on average 86 mm shorter in the half-shoe condition. From baropodometry, the time-histories of peak pressure (kPa) for each shoe condition at rearfoot, midfoot, forefoot and total foot (Figure 1) revealed different patterns between these three shoe conditions. Wearing the traditional and the novel FOS resulted in smaller peak pressure at forefoot (kPa, half-shoe 178±90; novel 186±45; control 244±75: $p<0.05$). The half-shoe showed also the smallest mean and maximum force and force-time integral at forefoot. At rearfoot, mean and peak pressure were the largest in the novel shoe. novel FOS design showed less compensation at the more proximal lower limb joints. Motion at the lower limb joints was similar to control for the two FOS designs, but at the pelvis the normalized root mean square error was 68% for the half-shoe, 27% for the novel design. At the ankle, sagittal-plane rotation in the novel FOS had a pattern more similar to control (half-shoe r2=0.85; novel r2=0.93). With respect to joint moments, the largest discrepancy from the control was observed in the sagittal and frontal planes at the ankle joint, the root mean square error being 16% for the half-show, 4% for the novel design.

Figure:



Caption: Patterns of peak pressure [kPa] at the three regions and at the entire footprint; mean values according to the color code shown on the right, grey bands showing standard deviation of the control.

Conclusion: The novel FOS appears capable, though less effective than a traditional half-shoe, in reducing considerably forefoot pressure. However, the good forefoot offloading provided by the traditional half-shoe was associated to more kinematic and kinetic alterations at the proximal lower limb joints with respect to the control, likely associated to the necessary compensation mechanisms for the peculiar shape of the outsole. The prescription of these forefoot offloading shoes should take into consideration both the required offloading and the overall restoration of normal gait function.

PO-0078

COMPARISON OF THE FOOT KINEMATICS DURING WEIGHT LOADING BETWEEN NORMAL FOOT AND THE FLATFOOT

Shintarou Kudo [1 2,*] Yasuhiko Hatanaka [3]

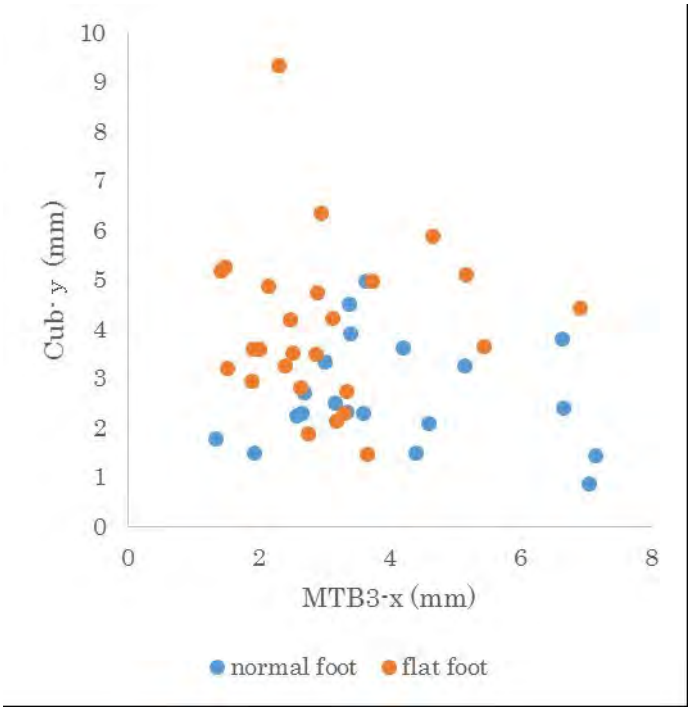
[1]Graduate school of Suzuka university of medical science, Mie, [2]physical therapy, Morinomiya university of medical sciences, Osaka, [3]physiotherapy, Suzuka university of medical science, Mie, Japan

Introduction and Objectives: The foot kinematic of the flat foot is important to make a foot orthosis. Three dimensional foot kinematics analysis during the gait is showed that forefoot abduction movement and rear foot pronation movement were increased, and peak plantar flexion moment were increased in the late stance phase using oxford foot model. However, forefoot is calculated as one segment in this model, although forefoot is consisted five metatarsals. Therefore, it has a limitation which can't be analyzed in detail forefoot movements. The purpose of this study is to be clarified difference the foot kinematics including mid- and forefoot between normal foot and the flat foot.

Methods: Sixty-one feet of fifty-two young normal volunteers were participated in this study. All subjects were categorized two groups which were normal foot group and flat foot group using both Foot Posture Index-6 and medical history of the pain were related to the flat foot. The fifteen color markers were mounted over the anatomical landmarks which were five metatarsal head and bases, navicular, the cuboid, the peroneal trochlea (cal-lat), the sustentaculum tali (cal-med), and posterior tip of the calcaneus (cal-p). The foot motion when measurement foot was stance forward, and body weight loaded on the forefoot as well as possible with lower leg forward inclined and whole plantar surface in contacted with the floor was recorded using the four hi-definition digital video cameras. And all markers were manually digitized using Flame DIAS4 software program. Three dimensional displacement of the each marker were calculated. And each directional markers movement were compared normal foot group with flat foot group using Man-Whitney test. Moreover, discriminant functional analyses were performed on all combinations if significant differences existed between the normal foot and the flat foot using SPSS statistics ver.18 (IBM).

Results: In the medial direction, flat foot is significant smaller than normal foot at the first, third, fourth metatarsal head, first to third metatarsal base, navicular and cuboid. In the forward direction, flat foot is significant larger than normal foot at the first metatarsal head and base, second and third metatarsal base, cuboid and cal-p. In the vertical direction, flat foot is significant smaller than normal foot at first, fourth and fifth metatarsal head, fifth metatarsal base, navicular and cuboid, and it was larger second metatarsal head and cal-p. In the discriminant analysis between the groups the Cub-y and the MTB3-x were the most powerful variables in distinguishing between normal foot and flat foot (fig.1). Based on these two variables 90.48% of the patients were correctly classified (Wilk's lambda 0.3; kai square 37.7; $p<0.01$). If the step height was additionally included in the discriminant analysis, 70% of the flat foot were correctly classified.

Figure:



Conclusion: In the normal foot, some anatomical makers showed larger medial movement than that of the normal foot. While, some anatomical makers of the flat foot showed larger forward movement than those of the normal feet. Therefore we considered that normal foot showed medial inclination with maintaining the arch structure, however flat foot showed that forward splaying with collapsed arch structure. Moreover, it may be key movements which are forward movements of the cuboid and medial movement of the third metatarsal base. Lundgren[1] showed that the mobility of the lateral side of the foot was greater than medial side of the forefoot such as medial cuneiform and first metatarsal. Therefore, results of this study were indicated that it might be important for the treatment of the flatfoot to control the stability of the lateral longitudinal arch.

INFLUENCE OF FOOTWEAR IN POSTURAL BALANCE OF YOUNG WOMEN

Estele C. W. Meereis [1,*] Patrícia Dorneles [1] Gabriel Panke [1] Carlos Mota [2]

[1]Federal University of Rio Grande do Sul, Porto Alegre, [2]Federal University of Santa Maria, Santa Maria, Brazil

Introduction and Objectives: Postural balance involves a complex connection mechanism of the afferent and efferent pathways and their integration into the central nervous system (CNS). Postural balance is influenced by proprioceptive, vestibular and visual sensory inputs [1]. The proprioceptive affereces and the cutaneous-plantar discrimination mechanism facilitate CNS to detect the center of gravity projection, and thereby, seems to decrease body sway in posture maintenance [2]. The aim of this study was to analyze the body balance of young women in three situations: barefoot, with sport shoe and with high heel shoe, to identify possible influences of using different shoes.

Methods: The study included 16 women with mean age of 22,94 ± 1,91 years. The postural balance was assessed through the center of pressure (CoP) displacements with a force platform in all three situations: for the subject barefoot, wearing sport shoe, and wearing high heel shoe. ANOVA with post hoc Bonferroni test was used to perform statistical analysis, $p < 0.05$ was considered significant.

Results: Regarding the postural sway, statistically significant differences were found between situation using high heel shoes and the others in the three CoP variables analysed: antero-posterior amplitude os displacement (CoPap), medial-lateral amplitude displacement (CoPml), and mean velocity (CoPmv). The subjects showed higher postural sway when using high heel shoes.

Conclusion: It was ound that high heel shoes negatively affected the postural balance of the partipants of the study. It were found larger displacements amplitudes and velocity of CoP in the high heel shoes situation. It suggests that high heel shoes affect the postural control performance.

Table:

	Barefoot (n=16)	Sport shoe (n =16)	High heel (n=16)	*p*-valor	*f*
CoPap (cm)	1.77 ± 0.53 [a]	1.86 ± 0.62 [ab]	2.33 ± 0.64 [c]	0.030	3.76
CoPml (cm)	1.01 ± 0.37 [a]	0.92 ± 0.32 [ab]	1.37 ± 0.44 [c]	0.003	6.45
CoPmv (cm/s)	0.86 ± 0.20 [a]	0.89 ± 0.20 [ab]	1.41 ± 0.29 [c]	0.001	9.01

THE RELATIONSHIP BETWEEN ARCH FLEXIBILITY AND MEDIAL-LATERAL GROUND REACTION FORCES

Regina Parker [1,*] Rebecca A. Zifchock [1] Willahelm Wan [1] Howard Hillstrom [2] Jinsup Song [3] Michael Neary [4]

[1]Civil & Mechanical Engineering, United States Military Academy, West Point, [2]Leon Root, MD Motion Analysis Laboratory, Hospital for Special Surgery, New York, [3]School of Podiatric Medicine, Temple University, Philadelphia, [4]Keller Army Hospital, United States Military Academy, West Point, United States

Introduction and Objectives: Several authors have analyzed extrinsic causes of foot and leg injuries, such as the relationship between the magnitude of vertical impact force and susceptibility to bone fracture. However, few have analyzed the role of intrinsic biomechanical factors on the magnitude of ground reaction forces, which may be indicative of injury susceptibility. Foot structure may be described by a number of features, such as arch flexibility. Greater three-dimensional flexibility of the foot may facilitate force redistribution from the vertical to the medial-lateral or antero-posterior directions. It is plausible that medial-lateral ground reaction force (GRF) may contribute to injuries in the knee joint [1]. Therefore, the purpose of this study is to examine the relationship between arch flexibility and the relative proportion of medial-lateral to vertical GRF impulse. We expect that there will be a difference in the distribution of medial-lateral GRF between individuals with flexible and stiff arches. In order to characterize the entire stance phase, the impulses of the GRFs were used to describe the distribution of force in each direction.

Methods: Ten subjects have participated in this ongoing study (all male, 19±1yrs, 176.5±6.4 cm, 73.5 ± 13.4 kg). All participants were injury-free, and wore the same clothing and shoes during testing. Participants ran for 8 minutes on a single belt of an instrumented treadmill (Bertec Corp; Columbus, OH) at 7 mph. Kinetic data were collected at 1000 Hz during the final 10 seconds of running. From these data, the medial, lateral and vertical impulses were determined for each of ten sequential left foot strikes. These impulses were related to participants' left foot arch height flexibility (AHF), which was determined a year prior (as part of a larger study). AHF is defined as the difference between arch height in the seated and standing positions normalized to body weight [2]: AHF = (AH(standing) – AH(sitting))/(40%BW)

Participants were categorized into one of two groups—stiff (AHF<14.9 mm/kN) and flexible (AHF>14.9 mm/kN). The criterion of 14.9 mm/kN was based upon the median value of AHF for a large sample size (n = 1124). According to this categorization method, 6 participants had stiff arches and 4 had flexible arches.

The ratio of medial-lateral to vertical GRF impulse was calculated for each participant, and an independent t-test was used to detect a difference in the measure between the stiff and the flexible groups. Additionally, the ratios of medial to vertical GRF impulse and lateral to vertical GRF impulse were calculated independently for each participant. A mixed-effect ANOVA model was used to analyze the difference between the directional ratios, and between the stiff and flexible groups. All analyses were conducted in SPSS (IBM SPSS Statistics, v19).

Results: The independent t-test suggests that there is no significant difference in the ratio of medial-lateral to vertical GRF impulse between groups ($p = 0.27$). However the calculated moderate effect size of 0.77 suggests that there may be a significant difference between the groups given a larger sample size.

The results of the mixed-effect ANOVA model suggests that there is no interaction between the direction of GRF impulse (medial vs lateral) and between group membership (stiff vs flexible) ($p = 0.25$). Further, neither the main effect of direction nor group membership were significant ($p = 0.22$ and $p = 0.27$, respectively). However, there was a moderate effect size of 0.66 for the main effect of direction and 0.55 for the main effect of group. Descriptive statistics are shown in Table 1.

Conclusion: While this study does not support any statistically-significant findings, the moderate effect size for all analyses suggests that the hypotheses may have merit. The descriptive statistics demonstrate that individuals with flexible arches have a greater portion of impulse in the medial-lateral direction than the individuals with stiff arches. Further analysis of the data suggests that this disparity is due to the medially-directed force, and not the laterally-directed. Individuals with flexible arches have twice the GRF impulse in the medial direction as compared to individuals with stiff arches. However both groups have similar magnitudes of lateral GRF impulse.

With only ten subjects, this study does not have the power to support our hypothesis. However, with a larger data set, there may be evidence to suggest that individuals with flexible arches may direct a larger proportion of their GRF medially. This may suggest a mechanism for injury susceptibility based upon foot structure.

Table:

	T-Test	ANOVA	
	Medial-Lateral : Vertical	Medial: Vertical	Lateral : Vertical
	Mean ± SD	Mean± SD	Mean± SD
Stiff	0.06± 0.03	0.02± 0.01	0.04± 0.02
Flexible	0.07± 0.02	0.04± 0.02	0.04± 0.02

CAN FOOT STRUCTURE PREDICT RUNNING KINETICS?

Willahelm Wan [1,*]Rebecca A. Zifchock [1]Regina Parker [1]Howard Hillstrom [2]Jinsup Song [3]Michael Neary [4]

[1]Civil & Mechanical Engineering, United States Military Academy, West Point, [2]Leon Root, MD Motion Analysis Laboratory, Hospital for Special Surgery, New York, [3]School of Podiatric Medicine, Temple University, Philadelphia, [4]Keller Army Hospital, United States Military Academy, West Point, United States

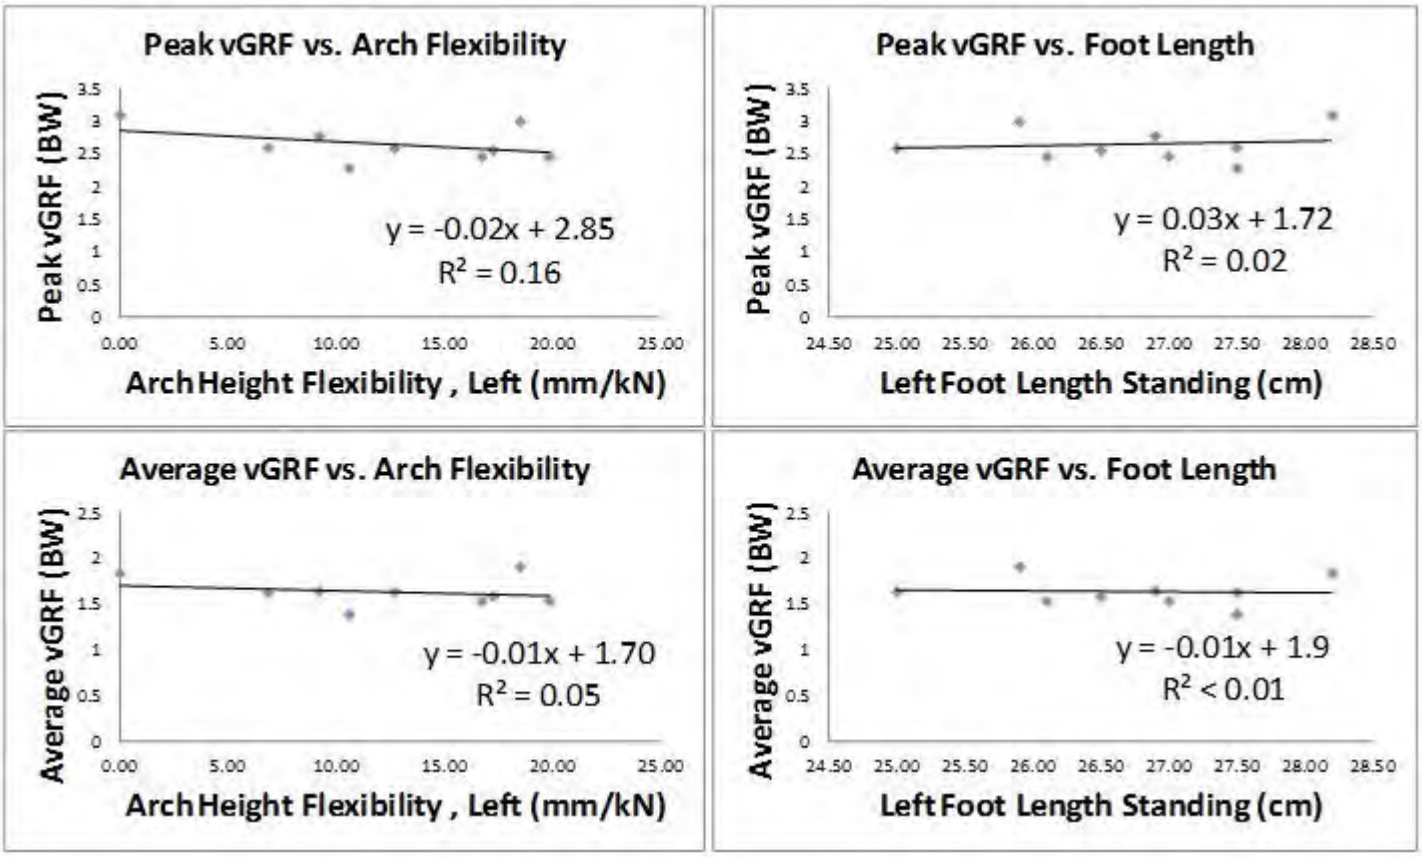
Introduction and Objectives: Stress fractures are one of the most common lower extremity injuries – accounting for 4 to 16 percent of running injuries [1]. While our bones are built to adapt to strains, there are extrinsic risk factors such as training changes and inappropriate footwear, and intrinsic risk factors such as muscle inflexibility that may increase the incidence of stress fracture. There is evidence to suggest a relationship between stress fracture and elevated values of the vertical ground reaction force (vGRF) [2]. However, very few studies have examined the intrinsic foot characteristics that may be related to those elevated values. In their study of the relationship between arch mobility and GRF, Williams et al. found that runners with high arch structure but differing arch mobility exhibited differences in select lower extremity movement patterns and forces [3]. However, their description of foot characteristics was limited to arch mobility in high-arched individuals.Therefore, the goal of this study was to examine the relationship of foot length and flexibility with vGRF during running. In order to characterize the vGRF, both the overall peak and the average value over the entire stance phase were considered. It was hypothesized that longer and more flexible feet would have lower average and peak vGRF.

Methods: As part of a larger ongoing study, the foot structure data on over 1100 individuals have been collected. A subset of that cohort was invited to participate in the current study. To date, 9 volunteers have been included in this sub-study (all male, 19±1 year, 176.5±6.4 cm, 73.5±13.4 kg). Participants were asked to run on an instrumented treadmill (Bertec FIT; Bertec Corp; Columbus, OH) at 7mph for 8 minutes. All participants wore the same shoes and clothing while running. Kinetic data were collected at 1000 Hz from the final 10 seconds of the run. The average and peak vGRF from the left-side stance phase of 10 sequential foot strikes were extracted from the raw data using a custom-written Python program (Python Software Foundation). These data were then compared to the participants' left foot length and arch flexibility, AHF: AHF = AH(standing) – AH(sitting)/(40%BW)

Step-wise regression, with a backward elimination method, was used to identify the foot structure variable(s) that best predicted the peak and average vGRF (Microsoft Excel). The model was generated separately for peak and average vGRF.

Results: When both foot structure measures were entered into the model, the R^2 value was calculated to be 0.21 and 0.14 for peak and average vGRF, respectively. The models were then re-run, entering the foot structure measures independently to predict both peak and vGRF, as shown in Figure 1. Both kinetic variables only showed weak relationships with foot structure. The relationships suggest that increased arch flexibility may lower the peak vGRF and increased foot length may increase the peak vGRF but neither structural variable has an effect on the average vGRF.

Figure:



Caption: Figure 1. Relationship between individual foot structure measurements and vGRF

Conclusion: With the inclusion of both foot structure measures into the model, they were able to account for 21% of the variance in peak and 14% in average vGRF. On their own, arch flexibility accounted for 16% of the variance in peak vGRF and only 5% of the variance in average vGRF. Foot length showed a weaker relationship, accounting for only 2% of the variance in peak vGRF and less than 1% of the variance in average vGRF. These results suggest that intrinsic characteristics of a runner's foot can have a moderate influence on the magnitude of their ground reaction forces. There may be additional foot structural measurements that could account for additional variability in the measure. Further, with the inclusion of additional participants, the predictive capacity of these structural measures on vGRF, and the relationship between kinetics and foot structure, may be strengthened.

PO-0082

VERTICAL IMPACT PEAK OCCURRENCE IN HABITUALLY SHOD RUNNERS UNDER DIFFERENT CONDITIONS OF RUNNING.

Juliana Pennone [1,*] Ana Paula Azevedo [1] Bruno Mezêncio [1] Rafael Soncin [1] João Claudino [1] João Pinho [1] Alberto Amadio [1] Júlio Serrão [1]

[1] School of Physical Education and Sport - University of São Paulo, São Paulo, Brazil

Introduction and Objectives: Running can be most injurious at the moment the foot collides with the ground [6]. Patellofemoral pain, plantar fasciitis and tibial stress fractures are examples of injuries that have been associated with a high vertical impact peak of ground reaction force (GRF), as well as to its load rate [7].

Previous studies that compared barefoot and shod running showed increased mechanical loads in barefoot condition [2,3,4]. Nevertheless, barefoot running has been suggested as a means to reduce impact forces, since habitually barefoot runners presents a suppression of the first vertical peak (Fy) of GRF[6]. However, it is not known if habitually shod runners also present this pattern when running barefoot. For many runners, barefoot running may be impractical due to unsafe running surfaces and potential performance limitations [1,5,7]. The minimalist shoes were designed to allow runners to employ the same mechanics of barefoot running, but minimizing the risk of injury due to direct contact of the foot with the ground. Thus, the aim of this study is to investigate the incidence of vertical peak of GRF in subjects not adapted to barefoot condition during shod, barefoot and minimalist running and to verify if the minimalist shoe provides the same mechanical condition of barefoot running.

Methods: Fourteen habitually shod runners (12 men and 2 women; age = 28.4 ± 7.3 years; mass = 72.7 ± 7.8 kg; height 1.74 ± 0.06 m) ran during 10 minutes at 9 $km.h^{-1}$ on a treadmill in three conditions: using conventional running shoes, using minimalist shoes and barefoot. An instrumented treadmill (GAITWAY Instrumented Treadmill System 9810S1; and TROTTER Treadmill Model 685, 01-06560201) with two piezoeletric force plates (KISTLER Inc.) was used to obtain the vertical component of GRF. Nine acquisitions (10 seconds each) of GRF were performed for each experimental condition at 2600. The mean occurrence of the first vertical peak of GRF (Fy1) was calculated.

GRF data was low pass filtered by a Butterworth filter (4th order, 90 Hz cutoff frequency). The start and end of each left and right step was determined using 30N threshold. Statistical analysis of data was performed in SigmaStat 3.5 (Systat, Germany) software. Data normality was verified using the Kolmogorov-Smirnov test, while homoscedasticity was checked by Levene's test. For means comparison, an analysis of variance (ANOVA) for repeated measures was performed. The level of significance adopted was $p \leq 0.05$.

Results: No significant difference was observed between shod and minimalist running, while barefoot running was significant different from both conditions for first peak occurrence. Barefoot condition showed 39,6% ($p<0,001$) and 34,75% ($p<0,001$) lower Fy occurrence when compared to shod and minimalist conditions, respectively.

Conclusion: Barefoot running seems to induce a decrease in Fy1 occurrence even in subjects not adapted to this condition. The lower occurrence is probably related to changes in running technique and foot strike pattern, providing reductions in GRF as observed in habitually barefoot runners [5,6]. Corroborating with other studies, the minimalist shoes

was not capable to induce the same mechanical condition found in barefoot running for Fy occurrence [1,7]. These results suggest a less mechanical load and reduced risk of injury in barefoot running.

PO-0083

IS PLANTAR PRESSURE A GOOD INDICATOR OF FOOT JOINT MOBILITY?

Paolo Caravaggi [1,*] Alberto Leardini [1] Claudia Giacomozzi [2]

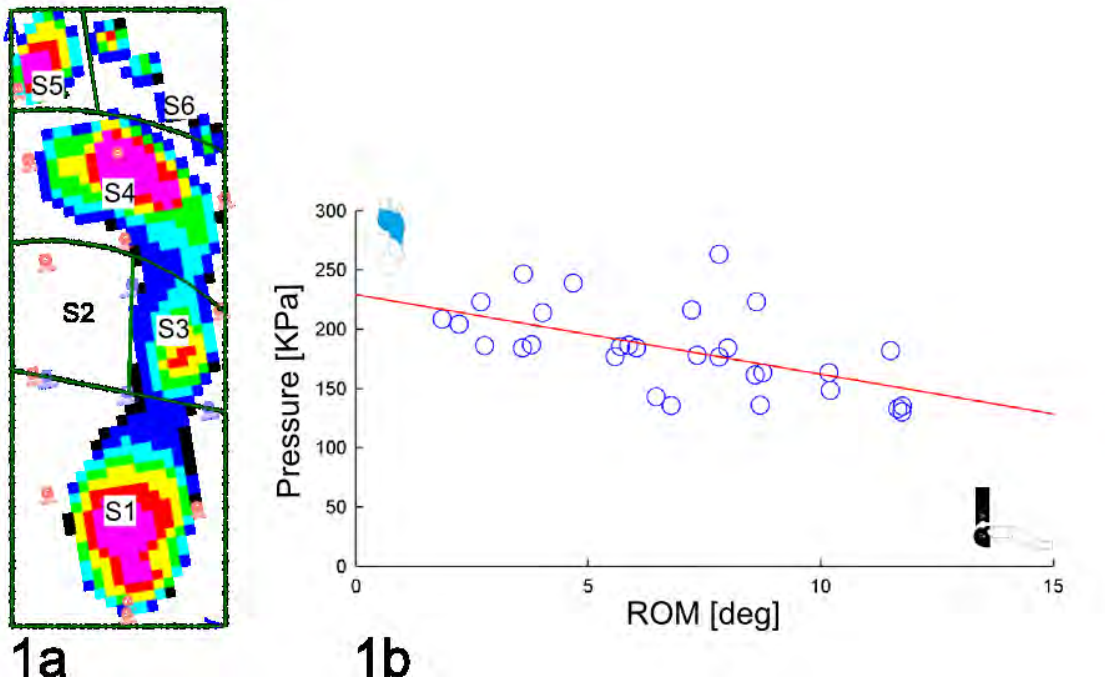
[1]Movement Analysis Laboratory, Istituto Ortopedico Rizzoli, Bologna, [2]Department of technology and health, Istituto Superiore della Sanità, Rome, Italy

Introduction and Objectives: The foot is generally regarded as a flexible structure which can adjust its flexibility in response to various external conditions and variable dynamic states within the motor tasks of daily living. In gait, both joint kinematics and plantar pressure have shown to be affected by functional and structural factors [1]. In fact, pressure distribution can be seen as the effectiveness of the musculoskeletal system in absorbing the ground reaction forces and managing propulsion via the foot and its joints. Excessive repetitive load may develop into calluses, which become sites of peak pressure and pain. While an association between limited joint mobility and increased plantar pressure has been shown in the diabetic foot [2,3], no study has hitherto investigated the relationship between in-vivo joint mobility and pressure in the normal foot. Aim of this study was to combine a multi-segment kinematic model [4] with advanced baropodometric analysis based on anatomical masking [5], to investigate correlations between intersegmental kinematics and regional baropodometric parameters in the normal-arched healthy foot.

Methods: Ten able-bodied subjects (26.8 ± 6.9 years; 67.5 ± 12.6 Kg; BMI 22.0 ± 2.7) with normal-arched feet (foot arch index 0.15 ± 0.02) volunteered in the study. An eight-camera motion system (Vicon, UK) was used to track foot segments during the stance phase of level walking, according to an established protocol [4]. This implied tracking fourteen 10mm reflective spherical markers attached to relevant anatomical landmarks of the shank and foot over three walking trials. Simultaneously, a pressure plate (Novel Gmbh, Germany) recorded foot plantar pressure. An anatomical-based masking [5] was employed to divide the pressure footprints in six subareas (Fig. 1a). Maximum of mean and peak pressure, of vertical force, contact-area and -time, and pressure- and force- time integrals, were determined for each subarea. The relationship between range of motion (ROM) of the foot joints in each anatomical plane and baropodometric parameters in each subarea was investigated using Pearson's and Spearman's coefficients.

Results: Walking speed was consistent across subjects and trials (1.41±0.14 m/s). Most of the statistically significant correlations between foot joints ROM and baropodometric parameters were moderate (Pearson's $|r| = 0.36 – 0.67$). In general, motion at the foot joints was negatively correlated with pressure and pressure-time integral at rearfoot and forefoot (see Fig. 1b) and positively correlated at midfoot.

Figure:



Caption: 1a. A typical footprint pressure image from a walking trial of one of the subjects. Where S1-S6 are the six subareas according to the projection of the foot anatomical landmarks on the footprint image. 1b Negative correlation (r=-0.57, p=0.001) between between peak pressure at the forefoot and frontal-plane ROM at the ankle joint across all walking trials.

Conclusion: According to the sample of normal feet analyzed in this study, those feet presenting smaller joint mobility are associated with larger pressure at the rear- and fore-foot. A trend for decreased pressure at the midfoot was also detected in those feet presenting a stiffer medial longitudinal arch. A more flexible foot may allow better distribution of pressure at the plantar foot surface during gait, with greater involvement of the midfoot region. Additional factors worsening joint mobility, such as age, weight and foot pathologies, may even magnify the impact on plantar pressure and increase the tissue damage; therefore they should be carefully considered in the identification of at-risk subjects.

SOCCER SHOES STRUCTURE AND ITS CORRELATION TO PLAYERS INJURY RISKS : A LITERATURE REVIEW

Sylvain blanchard [1] Jerome Palestri [2] Jean-Luc GUER [2] Marta-Catalina Harnagea [2] Benoit Cheyrou [2] Michel Behr [1,*]

[1] Laboratoire de Biomécanique Appliquée, IFSTTAR/Aix-Marseille Université, [2] Wizwedge SARL, Marseille, France

Introduction and Objectives: Soccer is the most popular sport in the world, the one generating greatest financial incomes, and whose practice has evolved the most in terms of intensity and commitment, with a particularly high inherent risk of injury [1]. The cleated shoe seems to play a major role in this high exposure to injury [2]. Despite the increasing interest of the scientific community in this regard, soccer shoes have experienced small changes in their design and mechanical structure, as compared to other sports such as running, tennis, basketball.

Based on an in-depth literature review, an analysis of the modern soccer shoe design and its adequation with regards to injuries protection is proposed.

Methods: The articles were selected by a review of the literature conducted on PubMed and ScienceDirect research gates between 1970 and october 2014, focusing on 6 different aspects of the structural characteristics of the shoe, in order to identify possible links between biomechanical characteristics and sport-specific pathologies. These axes are:

(1) Ankle dorsiflexion

(2) Medio-lateral plantar constraints

(3) Ergonomics, comfort and proprioception

(4) Types of ground surfaces and studs

(5) Uppers height of cut

(6) Minimalism and weight of the shoe.

Results: (1) Fitting and outsole configuration should help ensure sufficient range of motion of the ankle dorsiflexion, minimizing exposure to the many pathologies associated with the limitation of this parameter.

(2) The geometry and material used for the outsole should reduce the harmfulness of mediolateral stresses observed in soccer-specific movements.

(3) Adding plantar arch supports and systematic customized outfit would significantly improve the ergonomics of the soccer shoe. In addition, cushioning materials integrated in the outsole could reduce peaks of potentially pathogenic stress and improve comfort.

The integration of proprioceptive stimulation elements should also help preventing instabilitiesrelated accidents.

(4) Given the conflicting data in the literature, those cleats offering moderate resistance to rotational movements should be preferred. In addition, counseling strategies must be developed to help players to choose a reliable type of footwear and cleats type corresponding to the specifics of their practice.

(5) A low-cut shoe model does not seem to induce increased risk of ankle injury, while ensuring sufficient lightness and freedom of movement. This trend is in a certain way supported by the fact that even basket-ball seems to come back to low cut shoes. New high-cut soccer shoe models have appeared on the market, but authors are not aware of any previously published scientific evaluation of their efficiency.

(6) There is no major argument in favor of drastic reduction of the soccer shoe weight. On the opposite, many authors tend to prefer heavier products as long as they would integrate technical devices to enhance protection, comfort and performance. As such, one should seek the right balance between weight and technicality.

Conclusion: This study underlines the possible link between characteristics of the soccer shoe in its current design and the specific injuries related to the practice of this sport. It also reveals the sometimes contradictory developments proposed by some soccer shoe manufacturers. From this analysis, some possible technical solutions to design a safer soccer shoe were also identified.

PO-0085

THE RELATIONSHIP BETWEEN THE FLEXIBILITY OF THE TRANSVERSE ARCH OF THE FOREFOOT AND GAIT IN HEALTHY SUBJECTS

Takashi Kondo [1,*] Tsutomu Fukui [1 2]

[1]Sports Management Center, [2]Health Care Science, Graduate School, Bunkyo Gakuin University, Tokyo, Japan

Introduction and Objectives: To measure the transverse arch of the forefoot (; TAF) is important, because a low transverse arch may lead to forefoot deformity (hallux valgus) and decrease balance ability of elderly people. TAF have been examined by plantar pressure measurements [1], ultrasonography [2], and X-ray photography [3]. Recently, using 3D foot-scanner [4] has been getting easy to measure TAF. As the evaluation of foot posture is complicated by the existence of both static foot posture and foot mobility, it has been still unclear how to evaluate the foot posture. Therefore, the relationship between flexibility of TAF and human movement has not been revealed. Clinically, it is important to establish a simple method of the foot evaluation. The purpose of this study is to investigate the relationship between the flexibility of TAF and gait in healthy subjects.

Methods: Fifteen healthy subjects (8 men and 7 women) participated in this study. Their mean age was 23.4 ± 3.2 years, body weight was 60.5 ± 12.5 kg, height was 165.2 ± 9.7 cm. Foot posture evaluations were recorded using a 3D foot-scanner INFOOT (I-Ware Laboratory, Osaka, Japan). Three conditions of TAF were measured. Condition1: sitting. Condition2: standing. Condition3: foot forward and lower leg tilting anteriorly to the maximum position with heel contact. Width and height of TAF of dominant foot were measured in respective condition. Rates of the width (%width) and height (%height) of TAF among three conditions were calculated. Gait kinematics was recorded using a Vicon motion system (Vicon Motion Systems Ltd, Oxford, UK) and a force plates (AMTI, MA, USA). Reflective markers were attached by the definition of the Vicon Plug-in Gait (full body). Subjects were asked to walk at self-selected speed for 5 trials to detect the gait variables (gait speed, stride length, hip, knee, ankle angles, moments, and ground reaction forces). Firstly, the peak values of the joint angle, moment in the sagittal plane and ground reaction force were calculated during last half of mid-stance, terminal stance, and pre-swing phases. Secondly, the averages values of the five repetitions of peak values were analyzed. Partial correlation coefficients between the flexibility of TAF and the gait variables adjusted for gait speed and stride length were used to evaluate. The statistical significance was set at the level of p <0.01.

Results: In the case of the differences in between condition2 and condition3, there was a significant correlation between the gait variables and the flexibility of TAF. The flexibility of TAF width(%) significantly related to anterior component of ground reaction force (r = 0.53) and TAF height(%) significantly also related to vertical component of ground reaction force (r = 0.61) and ankle plantar flexion moment (r = 0.60) .

Conclusion: We found that the relationship between the differences in standing and foot forward and lower leg tilting anteriorly and some gait variables. When the body moved anteriorly, abilities of both mobility and stability of TAF might be crucial for gait performances. These results indicated that evaluation of TAF might be useful for patients with hallux valgus and the elderly people with impaired balance ability. The evaluations of TAF in the differences standing and foot forward and lower leg tilting anteriorly to the maximum had some relationships with gait variables.

FOOT CHARACTERISTICS OF INDIAN RURAL SCHOOL CHILDREN

Rajani Mullerpatan [1,*]Yuvraj Singh [1]Stacey Pinto [1]Anila Paul [1]Amit Maurya [2]Robert VanDeursen [3]

[1]Physiotherapy, MGM Insitute of Health Sciences, Navi Mumbai, [2]Mechanical Engineering, Indian Institute of Technology Bombay, Mumbai, India, [3]Physiotherapy, Cardiff University, Cardiff, United Kingdom

Introduction and Objectives: Foot anthropometry varies across populations. Limited information on morphological characteristics of feet among tribal children walking bare foot motivated this study. The objective was to study foot characteristics of Indian rural school children using a foot-print based approach.

Methods: This study was approved by the Institution Review Board of MGM Institute of Health Sciences. Consent was sought from all parents by the school. A convenience sample of 112 healthy children aged 5-15 yrs with no history of foot pain was studied. 55 rural children (24 females and 31 males) were matched on marginal distributions for age and body mass with 57 urban children (24 females and 33 males) for comparison.

Bilateral static footprints were obtained for all subjects resulting in a total of 224 feet for analysis. Foot characteristics were studied in terms of foot surface area and medial longitudinal arch height (Cavanagh & Rodgers, 1987). A foot-print based approach was used to calculate total surface area of foot (sq.cm), forefoot, mid-foot and hind-foot and medial longitudinal arch height using Arch Index (AI). Foot prints were scanned and MATLAB software was used for image processing and further computation. Arch height was also calculated with Staheli's Index (SI) (Staheli & Chew, 1997) and Chippaux-Smirak Index (CSI) (Forriol &Pascual, 1990) for comparison using a standard protocol.

Following an overall one-way Anova, independent sample t-test was used for between group comparisons.Paired t-test was used for within group analyses to compare left and right side.

Results: Arch height increased with advancing age on AI ($r=-0.247$; $p=0.020$).Total foot surface area ($p=0.001$), fore-foot area ($p=0.000$) and mid-foot area ($p=0.043$) were greater for the right foot compared to left foot in all children (pooled).Total surface area in males was greater compared to females on both right ($p=0.027$) and left side ($p=0.006$). Total foot surface area of rural children was greater than urban children on both sides. Forefoot and hind foot area was significantly greater on right side; however differences on left side were not significant.Medial longitudinal arch height did not differ between rural and urban children as measured by all 3 indices on both sides.

Conclusion: Increasing arch height with advancing age from 5 yrs to 15 yrs suggested continued development of medial longitudinal arch in both rural and urban children. All children presented with wider right foot compared to left side and males presented with wider foot compared to females.

Rural children presented with wider feet compared to urban children, particularly the forefoot which may relate togreater demand on prehensile function of feet to adapt to uneven terrain while walking barefoot. Whereas in urban children the presence of footwear leads to less interaction between the feet and irregular walking surfaces. In the absence of longitudinal studies, clinical judgments on implications of such foot characteristics of rural children on lower limb function are difficult.

Table:

Foot characteristics	**Rural children (n=55)** Mean (S.D.)	**Urban children (n=57)** Mean (S.D.)	**p value**
Right Total surface area (sq.cm)	86.9(20.9)	74.7(19.1)	0.006 *
Right Fore-foot area (sq.cm)	43.4(11.4)	34.9(8.6)	0.000 *
Right Mid-foot area (sq.cm)	20.5(6.2)	19.1 (8)	0.345
Right Hind-foot area (sq.cm)	22.9 (5.3)	20.7 (4.6)	0.036 *
Right Arch index (AI)	0.24 (0.04)	0.25 (0.05)	0.16
Right Chippaux-Smirak Index (CSI)	0.45 (0.12)	0.49 (0.19)	0.29
Right Staheli's Index (SI)	0.75 (0.24)	0 .80 (0.29)	0.31

$p \leq 0.05$ significance level

THREE-DIMENSIONAL KINEMATIC ANALYSIS OF THE HUMAN CADAVER FOOT IN WEIGHTBEARING CONDITION USING BIPLANAR X-RAY FLUOROSCOPY

Kohta Ito [1,*]Koh Hosoda [2]Masahiro Shimizu [2]Shuhei Ikemoto [2]Takeo Nagura [3]Hiroyuki Seki [3]Masateru Kitashiro [3]Nobuaki Imanishi [3]Sadakazu Aiso [3]Masahiro Jinzaki [3]Naomichi Ogihara [1]

[1]Department of Mechanical Engineering, Keio University, Kanagawa, [2]Graduate School of Engineering Science, Osaka University, Toyonaka, [3]School of Medicine, Keio University, Tokyo, Japan

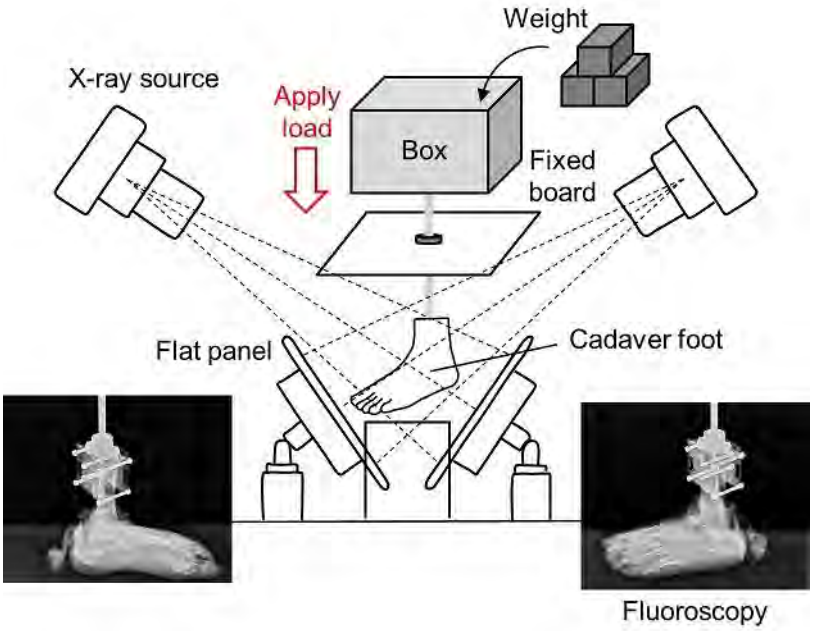
Introduction and Objectives: The human foot is a complex musculoskeletal structure consisting of many bones, muscles, ligaments, and soft tissues that directly interact with the ground during locomotion. In attempt to clarify the behavior and internal loading of the human foot for biomechanical, orthopedic and ergonomic applications, finite element (FE) models are employed recently as foot bone kinematics and internal forces are generally difficult to measure experimentally. However, the predictive ability of the FE model certainly depends on experimental validation. A method to comprehensively and quantitatively validate the FE model is essential for realistic emulation the human foot behavior that mechanically interacts with the ground. In the present study, therefore, we developed an experimental framework to precisely measure three-dimensional bone kinematics of the human cadaveric foot under a variety of loading conditions using biplanar X-ray fluoroscopy.

Methods: We developed a custom-made X-ray biplanar fluoroscopy system, consisting of two sets of X-ray sources and flat panels positioned in a quasi-orthogonal arrangement (Shimadzu, Kyoto, Japan). A human cadaveric foot was fixed to a vertical shaft supported by a linear motion rolling guide and 10 levels of axial force up to 60kg were applied by putting weight. Paired radiographic images of the foot under different axial loading conditions were obtained using the biplanar fluoroscopic system. We determined the motion of the tarsal and metatarsal bones by a model-based registration technique. Specifically, 3D surface models of foot bones were generated prior to motion measurement based on computed tomography, and the bone models generated were registered to fluoroscopic images such as to maximize similarity measures between occluding contours of the bone surface models with edge-enhanced fluoroscopic images, while avoiding mutual penetration of bones. The accuracy of bone registration was evaluated as 0.27 ± 0.19 mm and 0.24 ± 0.19 degree (mean ± standard deviation) in translation and rotation, respectively. To describe the change in the relative positions and orientations of each of the bones due to axial loading, a local coordinate system was defined by anatomical landmarks. In the present study, two fresh frozen cadaveric feet were investigated.

Results: By automatic registration technique, three-dimensional movements of the tarsal and metatarsal bones under axial loading conditions were precisely quantified. With higher axial loads, larger downward displacement of the talus, plantar flexion of the calcaneus with respect to the talus and overall flattening of the medial longitudinal arch were observed. The 1st and 5th metatarsals were everted and abducted, respectively, with increasing the axial loading. The change in the length of plantar aponeurosis, defined as the distance between metatarsal heads and calcaneal tuberosity, was also measured. The strain of the PA due to 60 kg of axial loading was found to be 6.9 and 1.1 % in the medial side

and 2.0 and 0.6 % in the lateral side, suggesting that the mechanical property of the human foot has considerable individual variability as suggested elsewhere [1-3].

Figure:



Caption: Biplanar X-ray fluoroscopy system and loading system

Conclusion: We developed an experimental framework to precisely measure human foot kinematics in weight bearing conditions using a biplane fluoroscopy for rigorous validation of foot FE model.

PO-0088

CHARACTERIZING FOOT TOTAL DEFORMATION USING HELICAL ANGLE: REPEATABILITY OF THE METHOD.

Claude Pothrat [1,*]Laurent Vigouroux [1]Marvin dufrenne [1]Elke Viehweger [2]Eric Berton [1]Guillaume Rao [1]

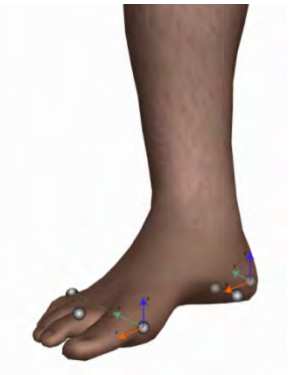
[1]Institute of Movement Sciences, Aix Marseille Université, MARSEILLE cedex 09, [2]Pediiatric orthopedic department, APHM La Timone Hospital, 13005 MArseille, France

Introduction and Objectives: The foot specific architecture gives this segment high adaptive skills that allow handling both long-term locomotor solicitation as well as sudden direction or support changes(1). As the foot motion results from the combination of motions coming from numerous intrinsic joints, a global approach is necessary to investigate the solicitations while respecting its anatomy. This study aims to propose a global approach to characterize the total intrinsic foot motion during walking, running, lateral cutting, and 180° U-turn movements. The helical angle has been calculated to express the movement between forefoot and rearfoot segments(2). The outcomes have been analyzed in terms of repeatability(3) and relevance of the results. We hypothesized that the helical angle (HA) would be representative of foot solicitation to give consistent clues in the understanding of its behavior. In this line, HA should differ depending on the movements.

Methods: Twelve subjects, 6 men and 6 women volunteered for this study. Each subject performed 5 repetitions of each movement along a 12m pathway, equipped with embedded force plates and an optoelectronic 8 cameras system (Vicon, Oxford UK). Six retro-reflective markers were placed on the forefoot and rearfoot segments of the right foot (Fig. 1) to calculate local coordinate systems.Twelve subjects, 6 men and 6 women volunteered for this study. Each subject performed 5 repetitions of each movement along a 12m pathway, equipped with embedded force plates and an optoelectronic 8 cameras system (Vicon, Oxford UK). Six retro-reflective markers were placed on the forefoot and rearfoot segments of the right foot (Fig. 1) to calculate local coordinate systems.

Results: Results concerning the maximum and the amplitude of the helical angle are presented in table 1 (values and ICCs), with repeated measure ANOVA showing significant differences in between all the movements. ICCx on the HA patterns for walking, heel running, and forefoot running were respectively 0.66±0.21, 0.69±0.15, and 0.61±0.20 whereas sport movements showed much smaller ICCx coefficients (90° cutting: 0.33±0.29 and 180° U-turn: 0.0±0.0).

Figure:



Caption: . Marker placement on the forefoot and rearfoot. Local coordinated systems definition.

Conclusion: The purpose of the study was to assess foot deformation by quantifying the helical angle, representative of the total intrinsic foot motion through the stance phase, for five sport movements. This measure is less prone to error than cardan angles can be, as it is free from sequences resolution. Maximum and amplitude values of the HA were representative of foot intrinsic solicitations and are sufficiently sensitive to statistically differentiate movements between them. As expected, cyclical locomotor movements that require more flexibility from the foot reached the highest values of HA. Opposite to that, non-cyclical movements as 90° cutting and the U-turn got less amplitude in HA, related to a more stiff foot. According to our results, the chosen movements allowed to obtain different foot solicitations that are fairly represented by a significantly different maximum and amplitude values of HA. The use of HA is then a suitable method when studying foot function in a global approach.

The ICCx methods allows considering the variables behavior over the entire time course of the dataset. From this perspective, ICCx performed on the helical angle can be used as a signature of the movement expertise. Repeated measure ANOVA confirmed these differences, as cutting and U-turn movements were reported with significant poorer repeatability compared to daily movements. The use of over time ICCx on the HA brought out a new and objective tool for the understanding of foot response to different solicitations. Indeed, a well-mastered movement will lead to a higher repeatability of the foot deformation pattern.

Table:

	Walking	Heel impact run	Fore foot impact run	90° cutting	180° U-turn
	Value (°)± sd	Value (°)± sd	Value (°)± sd	Value (°)± sd	Value (°)± sd
Maximum	20.8±6.7°*	13.0±6.7°	16.4±8.4°*	12.54±7.8°	4.4±4.6°*
Amplitude	26.5±5.2°*	20.2±4.1°*	23.6±5.5°*	16.5±5.0°*	9.9±4.1°*
	ICC	ICC	ICC	ICC	ICC
Maximum	0.8	0.9	0.8	0.8	0.5
Amplitude	0.7	0.7	0.8	0.8	0.3

EVALUATION OF THE MEASUREMENT OF REARFOOT MOTION USING DIFFERENT MARKER PLACEMENT TECHNIQUES

Yousef Shanib [1,*] Anmin Liu [1] Andrew Findlow [1] Richard Jones [1]

[1]Health Sciences, The University of Salford, Salford, United Kingdom

Introduction and Objectives: Quantifying rearfoot motion in barefoot and shod using loose skin/shoe mounted markers can lead to artefacts and inaccurate tracking of the segment. Therefore, an optimal method that allows both to be obtained without the need for removal of markers is required. A rigid heel cup cluster with three markers attached firmly to the skin of the heel has frequently been utilised to track the 3D movement of the heel in barefoot biomechanical studies (Nester *et al.*, 2014). In addition to this, a skin mounted 4-marker heel pin cluster secured to the lateral aspect of the rearfoot (fig. 1) has also been utilised (Schultz and Jenkyn, 2012). If there is agreement in these two methods of estimating rearfoot motion during barefoot, then it may be possible to use a heel pin cluster through an aperture in footwear (to prevent shoe interference); thus allowing the motion of the rearfoot in a shod experimental condition to be compared to the barefoot data directly. The aim of this study was to investigate the difference in rearfoot motion using two different attachment methods; the heel cup cluster and a heel pin cluster.

Methods: Fifteen healthy participants (7 male, 8 female) were recruited to take part in this study in the gait laboratory at The University of Salford using sixteen OQUS infrared cameras (Qualysis AB, Sweden) sampled at 100Hz. Three retro reflective markers were attached to the heel cup and four were fixed on to a heel pin cluster, both attached independently of each other to the skin of the heel with double sided tape (fig. 1). A cluster was attached to the leg for the calculation of rearfoot motion. Five walking trials were conducted for each participant with the data captured simultaneously for both attachment methods.

The error between the heel cup cluster and the heel pin cluster was determined by root mean squared deviation (RMSD) in the three planes of motion relative to the tibia. Paired t-tests were undertaken to determine significant difference at the 95% confidence interval.

Results: The angular movement of the heel about the tibia indicated no significant difference ($P>0.05$). The RMSD differences were identified as less than ±1.5 degrees between the two methods.

Figure:

Caption: Figure 1 – Heel cup cluster and heel pin cluster markers.

Conclusion: The heel pin cluster marker was identified as a reliable and non-invasive method to capture rearfoot kinematics during walking. The small difference that was identified may be due to skin movement artefact. Therefore, either method could be used for the collection of rearfoot motion during barefoot walking. Rearfoot motion is difficult to quantify in shod conditions without modifying the heel counter extensively, therefore using a heel pin cluster with a small hole appears to be a potential solution for comparison studies of barefoot to shod experimental conditions.

The findings of this study will be of benefit to investigations into rearfoot motion whilst wearing footwear and its part in the lower limbs function, particularly to those during the assessment of orthotic interventions.

Table:

R_Relative_Tibia	Mean					
Barefoot	Heel Cup	Pin Cluster	STD Cup	STD Pin	P value	RMSD
Plantar Flex (X)	-1.21	-2.01	2.29	2.86	0.133	0.88
Eversion (Y)	-2.35	-2.43	2.43	2.13	0.897	1.37
Abduction (Z)	-0.75	-1.11	5.26	4.44	0.662	1.21
Dorsi Flex (X)	15.31	15.30	3.45	3.41	0.984

PO-0091

INVESTIGATION OF BENCH METHODS FOR DETERMINING STIFFNESS OF SOLID ANKLE-FOOT ORTHOSES

Dimitrios Sokratis Komaris [1,*] Stephanos Solomonidis [1] Andrew James Murphy [1]

[1] Biomedical Engineering, University of Strathclyde, Glasgow, United Kingdom

Introduction and Objectives: The prescription of ankle-foot orthoses (AFOs) is one of the most common and effective treatments for the compensation of neuromuscular disorders, for example stroke and spinal cord or peripheral nerve injuries (Bregman et al., 2010). The biomechanical functions of plastic AFOs are determined by their thickness, the material selection and their geometry. The geometry, also known as trim-line, reflects the stiffness in relationship to the range of motion that the AFO allows at the talocrural joint (Lin and Bono, 2010). Their design, however, is mainly empirical due to a lack of evidence-based research on their geometrical characteristics (Papi, 2012). Therefore, experimental data are critical for the optimization of AFOs' characteristics.

This project aimed to investigate the different experimental methods currently utilized for determining the stiffness of homo-polymer and co-polymer polypropylene AFOs with different trim lines.The experimental procedure had two aims.

1. To design and fabricate an artificial leg suitable for the stiffness testing of an AFO.
2. To measure and compare the stiffness of an AFO with/without the presence of the artificial leg by means of different stiffness-measuring methods.

Methods: The strengths and weaknesses of eight experimental bench testing methods were analysed and two different techniques (Figure 1) were implemented in order to determine the relationship between the AFOs' mechanical properties and their geometry: the bending test by Ross et al. (1999) in a custom-made rig and the mechanical test by Major et al. (2004) in the Instron ElectroPuls E10000 testing machine. Three AFOs were tested in total: a 4.6mm black co-polymer solid AFO (4.6BCP), a 6mm homo-polymer solid AFO (6HP) and a 4.6mm co-polymer solid AFO with carbon fibre shape corrugations (4.6CP).

Results: Table 1 demonstrates the different dorsiflexion angles when a constant moment of 20Nm about the ankle joint is applied to the AFOs. During the Instron test and when a moment of 20Nm about the ankle joint was applied, adopting the mathematical equations that were described by Major et al. (2004), an error equal to 1.05° was found when the distance between the lower jig and the medial malleolus prominence of the 4.6BCP AFO and the distance connecting the medial malleolus and the upper jig were considered as constants.

Figure:

Caption: Figure 1 Left, the mechanical testing of the 4.6 BCP AFO in the Instron E10000 as described by Major et al. (2004), and (right) the dorsiflexion test of the 4.6CP AFO in a custom-made rig with the presence of the artificial leg as described by Ross et al. (1999).

Conclusion: The results of this investigation indicates, particularly in relation to the 4.6CP AFO, that the difference in stiffness when a leg is introduced in an AFO is noteworthy and it is suggested that the outcomes of a study utilizing an artificial leg cannot be compared with the results obtained when testing isolated AFOs. Additionally, comparing the 4.6BCP and the 4.6CP, and as suggested by Ross et al. (1999), colour additives in the copolymer polypropylene sheets will affect the stiffness of the AFO resulting in a more flexible orthosis.

The difference between the two methods is also considerable and it is believed that the cause of this variation is that the manual methods are more sensitive to creep and thus the AFO seems to be more flexible when measured manually than in materials testing machines.

Finally, the mathematical data processing of the Instron testing that exists in the literature (Major et al., 2004) was found to be imprecise and it is suggested that a camera system (such as the Bluehill software) should be used in order to measure accurately the deformation of the AFOs.

Table:

AFO	With the artificial leg		Without the artificial leg	
	Custom-made rig/ Dorsiflexion Angle (°)	Instron E10000/ Dorsiflexion Angle (°)	Custom-made rig/ Dorsiflexion Angle (°)	Instron E10000/ Dorsiflexion Angle (°)
4.6BCP	3.49	3.35	3.84	3.56
6HP	3.28	1.81	3.30	2.19
4.6CP	4.20	1.96	5.29	3.48

COMPARATIVE FUNCTIONAL MORPHOLOGY OF THE HUMAN FOOT BASED ON THREE-DIMENSIONAL FINITE ELEMENT ANALYSIS

Tomoya Nakamura [1] Ryo Suzuki [1,*] Kohta Ito [1] Naomichi Ogihara [1]

[1] Department of Mechanical Engineering, Keio University, Yokohama, Japan

Introduction and Objectives: The anatomy of the human foot complex is distinctive from that of the apes owing to specialized morphological adaptations for habitual bipedal locomotion. However, the functional significance of the human unique morphological features that differentiate the human foot from those of apes and other primates still remains unclear due to the complexity of structure and mechanics of the foot. In this study, we developed three-dimensional finite element models of the human and chimpanzee feet in order to comparatively investigate the functional morphology of the human foot.

Methods: Each bone and the whole foot surfaces were extracted from computer tomography images. The volume enclosed by each surface was meshed with tetrahedral elements. The bones were represented as a linear elastic material. The articular cartilage was also assumed to be linear elastic and the contact between the articular surfaces was considered frictional. The encapsulated soft tissue was defined as a hyperelastic Ogden material. Ligaments and plantar fascia were represented by tension-only spring elements. The foot-ground contact was modeled using rigid contact surfaces. The mechanical interactions of the human and chimpanzee feet with the ground during balanced standing were simulated by applying compressive force on the tibia and tension along the Achilles tendon due to muscle contraction. The size of the foot is normalized by the total volume of the foot bones for comparisons between the human and chimpanzee feet.

Results: Our results demonstrated that the center of pressure was situated more anteriorly in the human foot because of the presence of the longitudinal arch. It was also demonstrated that the calcaneocuboid joint was less mobile in the pronation-spination direction in the human foot due to locking mechanism of the articular morphology. Furthermore, the human foot is probably more capable of storing elastic energy during foot-ground contact for effective generation of propulsive force in the late stance phase.

Conclusion: We developed a computational framework for comparatively investigating the causal relationship among the morphology, behavior, and internal loading of the human foot, leading to a better understanding of morphofunctional relationships between the foot architecture and human bipedal walking.

THE INFLUENCES OF THREE-TYPES OF FOOT STRIKE PATTERNS ON THE MECHANICAL ADVANTAGE AND THE FORCES APPLIED TO FOOT

Satoru Hashizume [1 2,*] Toshio Yanagiya [1]

[1]School of Health and Sports Science, Juntendo University, Chiba, [2]Japan Society for the Promotion of Science, Research Fellowship for young Scientists, Tokyo, Japan

Introduction and Objectives: Distance running sometimes induces musculoskeletal injuries. One of common injured parts of running-related musculoskeletal injuries is foot and ankle, such as the Achilles tendon (AT) and the tibia. Effective prevention method, therefore, is required to reduce the rate of running-related musculoskeletal injuries occurring at foot and ankle.

The influence of different foot strike patterns on the risks of running-related musculoskeletal injuries occurring at foot and ankle was previously discussed. Lieberman et al [1] reported that the smaller vertical ground reaction force (GRF) was found for fore-foot strike than for rear-foot strike during early stance phase. They suggested that fore-foot strike may reduce the risk of running-related musculoskeletal injuries occurring at foot and ankle as compared with rear-foot strike. However, the GRF does not coincide with the forces applied to common injured parts of foot and ankle such as the AT and the tibia. The influence of different foot strike patterns on the forces applied to common injured parts should be confirmed to prevent running-related musculoskeletal injuries occurring at foot and ankle.

The mechanical advantage, which is defined as the ratio between the AT moment arm and the moment arm of the GRF influences on the relationships between the GRF and the AT force and between the GRF and the joint reaction force. The mechanical advantage varies depending on ankle angles [2], suggesting that the AT and joint reaction forces may also vary among foot strike patterns even if the GRF is constant. The purpose of this study, therefore, was to confirm the influences of the different foot strike patterns on the mechanical advantage and the forces applied to foot.

Methods: Seven male runners voluntary participated. Reflective markers were attached to skin overlaying the medial and lateral malleoli, the calcaneal tuberosity, the distal muscle-tendon junction (MTJ) of the soleus, the heads of first and fifth metatalsal bones and the toe. Subjects were asked to perform barefoot running along a 15 m runway at 3.33 ± 0.16 m/s by using fore-foot strike, mid-foot strike and rear-foot strike. The three-dimensional coordinate of each marker and the GRF were recorded by using the motion capture system (250 Hz) and the force platform (1000 Hz), respectively. The position of the center of mass of foot was calculated by using the three-dimensional coordinate of markers attached to the calcaneal tuberosity, the heads of first and fifth metatalsal bones and the toe. The talocrural joint axis was defined as the line passing through the markers attached to the medial and lateral malleoli. The line of action of the AT force was defined as the line passing through the markers attached to the calcaneal tuberosity and the distal MTJ of the soleus. The AT moment arm and the moment arm of the GRF were calculated as the shortest distance between the talocrural joint axis and the line of action of each force, respectively. The mechanical advantage was calculated as the ratio of the two moment arms. The AT and joint reaction forces were calculated by solving the equations of motion of foot.

Results: The means and standard deviations of each parameter were represented in Table. The AT moment arm was not different among each foot strike pattern. Meanwhile, the moment arm of the GRF was significantly greater for fore-foot strike than for others foot strike patterns, and greater for mid-foot strike than for rear-foot strike. The mechanical advantage was significantly smaller for fore-foot strike than for others foot strike patterns, and smaller for mid-foot strike than for rear-foot strike patterns. The GRF was not different among each foot strike pattern. Meanwhile, the AT and joint reaction forces were significantly greater for fore-foot strike than for others foot strike patterns, and greater for mid-foot strike than for rear-foot strike.

Conclusion: Present results showed that the mechanical advantage was significantly different among foot strike patterns, and this induces in the significant differences in the AT and joint reaction forces among each foot strike pattern. The largest AT and joint reaction forces were found for fore-foot strike, suggesting that the risks of running-related musculoskeletal injuries occurring foot and ankle may be higher than others foot strike patterns.

Table:

	fore-foot strike	mid-foot strike	rear-foot strike
AT moment arm (mm)	55 ± 3.8	54 ± 3.7	54 ± 4.1
GRF moment arm (mm)	111 ± 4.7	98 ± 8.1	83 ± 3.9
mechanical advantage	0.491 ± 0.037	0.552 ± 0.038	0.648 ± 0.058
GRF (N)	1085 ± 151.3	1064 ± 112.0	1037 ± 108.5
AT force (N)	2318 ± 236.1	1995 ± 249.0	1599 ± 128.3
joint reaction force (N)	3292 ± 364.6	2971 ± 342.7	2565 ± 150.3

DEVELOPMENT OF A LARGE-SCALE SUBJECT-SPECIFIC FINITE ELEMENT MODEL OF HUMAN FOOT COMPLEX

Mohammad Akrami [1,*] David Howard [2] Chris Nester [2] Zhenmin Zou [1] Lei Ren [1]

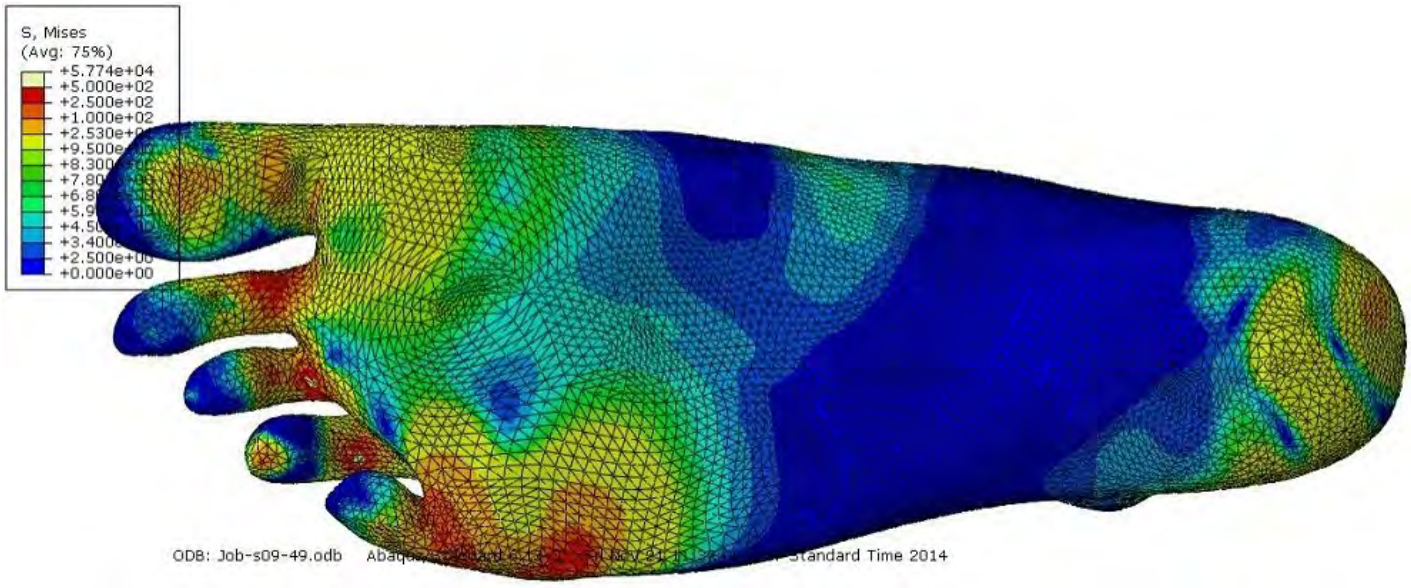
[1]School of Mechanical, Aerospace and Civil Engineering, University of Manchester, [2]School of Health Science, University of Salford, Manchester, United Kingdom

Introduction and Objectives: Human foot, as the only component of the human body in contact with the ground during locomotion, has different roles in absorbing the shocks, bearing body weight and generating propulsive powers during locomotion [1]. In the past years, a large amount of experimental and computational studies have been conducted to investigate the biomechanical structures and functions of the human foot complex. However, due to the complexity of the foot musculoskeletal structure, our current understanding of the fundamental biomechanical mechanism of the human foot structure is still very limited. The objective of this study is to develop a large-scale subject-specific finite element model of the human foot complex with high bio-fidelity so that the delicate foot structure and function interplay during different activities could be investigated.

Methods: The anatomical and geometrical structures of the model were constructed based on the individualised Magnetic Resonance Images (MRI) of the right foot of a healthy male subject (age: 27 years, weight: 75 kg; no history of the foot abnormalities or lower limb injuries). Totally 28 foot bones and also tibia and fibula were modelled. All the possible relative motions among the 28 foot bones have been modelled as connecting joints constrained by contacts between 52 cartilage layers and 80 ligament groups. A three dimensional (3D) plantar fascia structure was constructed to represent the load transfer between rear foot and phalanges. All the bones, cartilages, ligaments and the plantar fascia structure are embedded into a 3D structure of the encapsulated soft tissues. In this study, 3D gait measurement for the same subject used for modelling, was conducted to record the major foot bone motions, ground reaction forces and moments and plantar pressure distribution during normal level walking. The in vivo force data of 12 major ankle/foot muscles around talocrural, subtalar and metatarsophalangeal joints were calculated using a scaled OpenSim foot musculoskeletal model driven by the gait measurement data.

Results: FE simulations were conducted to analyse the mechanical behaviour of the foot complex in the mid-stance of normal level walking. The simulations were driven by the in vivo muscle forces of 12 major foot muscles and also the bone-to-bone contact forces between tibia and talus calculated based on gait measurement data. The model simulation results were rigorously validated against the measured region specific peak plantar pressure data, and also the relative 3D orientations and positions of major foot bones. The simulated peak plantar pressure data showed a good agreement with the pressure plate data. The predicted relative 3D angle changes of the major foot bones agreed reasonably well with the in vivo measurement data. The experimental validation results indicated that the developed FE foot model is capable of predicting the plantar pressure distribution, load transfer and foot bone motions reasonably well.

Figure:



Caption: Fig 1: Plantar pressure distribution of the human foot (Von Mises stress)

Conclusion: A large-scale subject-specific 3D FE musculoskeletal model of the human foot complex was developed to represent the bio-realistic behaviour of the foot during in the stance phase of normal walking. The peak pressures were found in the heel region and the area underneath the five metatarsal bones in the middle stance. This pattern is reasonable considering the ankle joint force role in transmission the force from rear foot to the fore foot through talonavicular and cuneonavicular joints in which showing high stress values in the heel region and under the five metatarsal bones. Future works involve the investigation of the contribution of different foot structure components to the weight bearing, load transmission and power generation capacities of the human foot complex during different motor activities.

PO-0095

A CORRELATION STUDY BETWEEN THE DYNAMIC FOOTPRINT AND STATURE USING PEDOGRAPHY

Raghad Mimar [1,*] Hossien Nabavi Nik [2] Hadi Mohammadi [1]

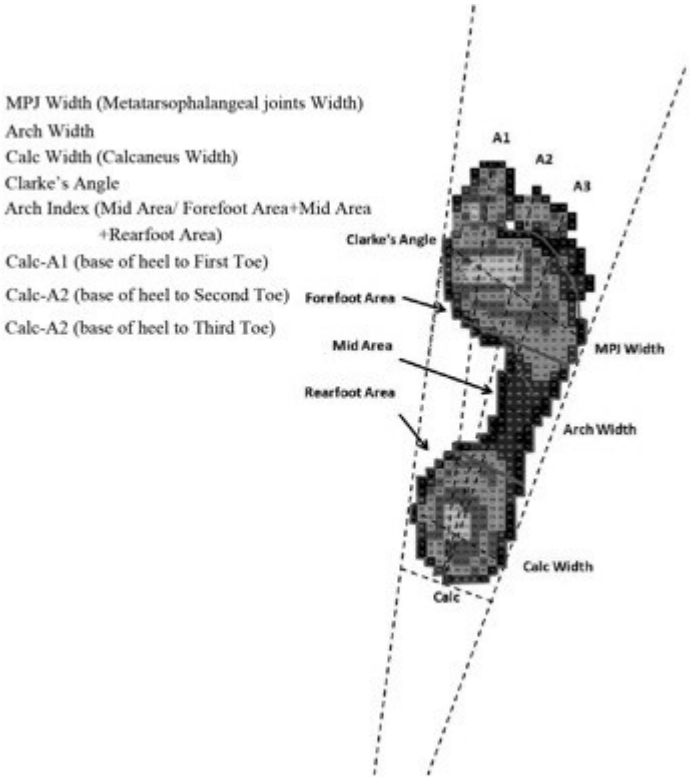
[1]Biomedical Engineering, University of British Columbia, Kelowna, Canada, [2]Physical Education and Sport Sciences, Kharazmi University, Tehran, Iran, Islamic Republic Of

Introduction and Objectives: One of the established methods to effectively assess the size of the human body is using anthropometric techniques. The objective of this study is to estimate standing height or stature by pedography using a dynamic footprint.

Methods: Measurements of the dominant footprint of 40 subjects were assessed using pedography. In order to collect data, a two-step protocol in which the participant walked barefoot at a self-selected pace was implemented. Five trials of the right foot were recorded and the average was calculated for the analysis (Fig. 1). The Pearson correlation coefficient was then used to determine the relationship between the variables followed by the implementation of the linear regression test to estimate the subject's stature.

Results: Results showed a high correlation between standing height and foot length from heel to the second toe ($p < 0.01$, $R = 0.472$) and a low correlation with the width of the foot in metatarsal phalangeal area ($p < 0.05$, $R = 0.016$). As to the models available to predict the stature, the foot length equation from the base of the heel to the tip of the second toe offered the highest coefficient of determination ($R^2 = 0.48$), (Tbl. 1).

Figure:



Conclusion: Results of this study showed a strong correlation between the different footprint sizes and stature. Thus, a person's height can be estimated by different footprint sizes left at a crime scene with different regression models. Depending on the quality of the footprints recovered at a crime scene, the regression models developed in this study may effectively estimate the stature with an error of the order of a few millimeters.

Table:

Variables	Maximum (mm)	Minimum (mm)	Mean (mm)	Standard Deviation	Correlation Coefficient
MPJ Width	11.3	9.1	10	0.46	0.174
Arch Width	7.6	1.9	3.47	1.04	0.172
Calc Width	7	4.8	6	0.45	0.016
Arch Index	0.29	0.18	0.24	0.02	0.171
Clarke's Angle	61	22.8	46.38	9.26	-0.063
Calc-A1	27.1	23.3	25.01	0.76	0.440*
Calc-A2	26.1	22.8	24.78	0.75	0.472**

USING TOPOLOGY OPTIMISATION TO GENERATE PERSONALISED FOOTWEAR MIDSOLE GEOMETRIES

Iain Hannah [1,*] Andy Harland [1] Dan Price [2] Tim Lucas [2]

[1]Sports Technology Institute, Loughborough University, Loughborough, United Kingdom, [2]adidas AG, Herzogenaurach, Germany

Introduction and Objectives: Studies have shown that adding mass to a runner's shoes increases oxygen uptake [1] and thus the metabolic cost of running. However, further studies have also suggested that shod running may provide an energetic advantage over a barefoot condition for habitual rearfoot runners [2]. As a result of these findings, lightweight performance footwear that still offers some degree of cushioning represents a large segment of the running shoe market [3].

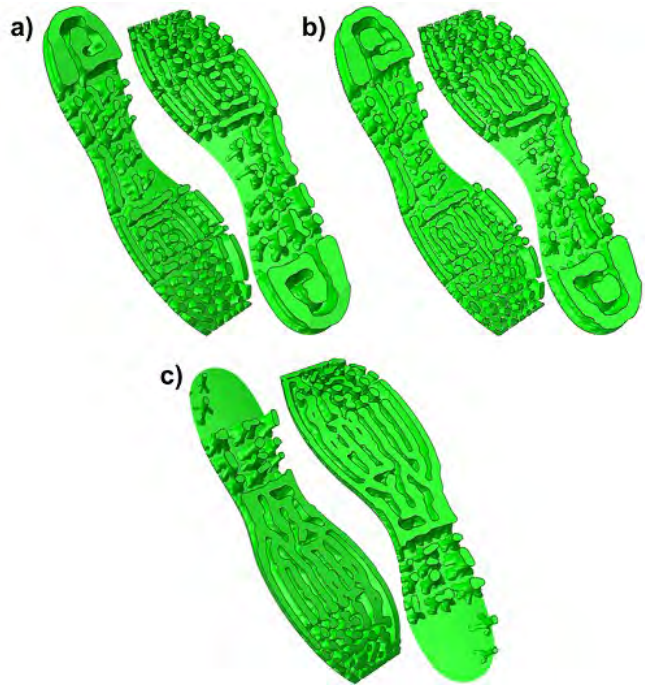
Lieberman et al. [4] have conducted a significant number of studies into different running footstrike styles and concluded that "…runners who forefoot or midfoot strike do not need shoes with elevated cushioned heels to cope with [the] sudden, high transient forces that occur when you land on the ground." This suggests that footwear could be optimised to a runner's individual footstrike pattern, providing support under the areas of the foot that are highly loaded with material omitted elsewhere. Based on the "Material Distribution Method" [5], this paper details the use of finite element analysis and topology optimisation to output lightweight footwear midsole geometries optimised for an individual subject's personal footstrike loading profile.

Methods: Biomechanical running trials were performed by three healthy, male subjects (two habitual rearfoot strikers, one habitual forefoot striker) whilst wearing a pair of simple athletic shoes. The plantar surface of the foot was segmented into 20 discrete regions with the triaxial loads exerted on each sub-area of the foot estimated by combining the data output by the force platform and pressure insole using an "assumption of proportionality" [6].

A generic finite element midsole geometry was created, meshed with linear hexahedral elements and assigned an isotropic linear elastic material model. The 20 sub-sections of the foot's plantar surface were represented by rigid plates with the maximum 3-D load predicted to occur in each area applied to its respective plate. The objective function of the optimization task was to minimise strain energy whilst satisfying a constraint defined to ensure the midsole volume remained below a defined threshold. This approach resulted in a robust model capable of outputting midsole geometries optimised to be stiff but lightweight.

Results: As expected, material was retained in areas of high loading but removed in areas that experienced lower strains. This is highlighted by the clear differences in the optimised geometries output for the rearfoot (Subject A and Subject B) and forefoot (Subject C) strikers. The midsole geometries output for Subject A and Subject B were similar but Subject B exhibited comparatively greater loading in the lateral rearfoot and under the metatarsal heads. This is reflected by a higher level of material retention in these areas. Geometric restrictions were also applied in subsequent analyses.

Figure:



Caption: Optimised midsole geometries output for each subject. a) Subject A (rearfoot striker), b) Subject B (rearfoot striker), and c) Subject C (forefoot striker).

Conclusion: This study demonstrated that topology optimisation methods could potentially be employed to automatically generate lightweight midsole geometries optimised for a subject's individual footstrike loading pattern. However, the primary role of the midsole is to dissipate footstrike impact forces but the task was defined such that the stiffest structure was considered optimal. To address this, some degree of "engineered compliance" [7] should be introduced in future optimisation tasks. Furthermore, significant advances in manufacturing technology would also be required before the mass customisation of functional footwear midsoles could become a feasible reality.

FOOT ANTHROPOMETRY AND SHOE SIZE OF BRAZILIAN ELDERLY: A LONGITUDINAL STUDY

Thais R. Aurichio [1,*] Eliane Manfio [2] Alessandra Castro [3] Juliana Ansai [1] José Rubens Rebelatto [1]

[1]Federal University of Sao Carlos, Sao Carlos, SP, [2]FEEVALE, Novo Hamburgo, RS, [3]Federal University of Espirito Santo, Vitória, ES, Brazil

Introduction and Objectives: The use of unsuitable shoes is a common problem among elderly and has been highly associated with deformities in toes, presence of calluses, symptoms of pain and falls in this population. An appropriate shoe is composed of functional qualities, aspects related to comfort and safety and according to trends of current fashion. The purpose of this study was to identify foot anthropometry parameters in order to highlight the importance of manufacturing different profiles for each size; to verify influence of aging on foot anthropometry of elderly women over four years.

Methods: 101 community-dwelling elderly women with a mean age of 69.4 (±6.1) years were assessed in two moments within a range of four years. Foot anthropometric variables (foot length (FL), instep circumference (IC), foot breadth (FB), dorsal arch height (DAH) and height of top of ball girth (HTBG)) were measured through analog instruments, such as caliper, fiberglass tape and height gage. Body weight and height were measured to calculate body mass index (BMI). The volunteers were questioned about their shoe size. To investigate the relationship between FL and other anthropometric variables, they were transformed into discrete variables, according to the French system (each size corresponds to intervals of 6.666mm of FL) and previous studies of anthropometric characterization (perimeters and widths change every 5mm and height every 2.5mm). The highest concentration of subjects for FL was in intervals of 240.0mm, 246.7mm and 253.3mm, corresponding to 36, 37 and 38 brazilian size, respectively. These subjects were kept in these subgroups for longitudinal analysis. Paired t-test and its corresponding nonparametric test (Wilcoxon) were used to assess differences in anthropometric variables in each size over four years and a 5% significance level was used.

Results: At baseline 65 (64.3%) elderly were at FL intervals corresponding to 36 (26.7%), 37 (17.8%) and 38 (19.8%) shoe sizes. After four years, only 61.4% volunteers were at FL intervals corresponding to the 36 (22.8%), 37 (20.8%) and 38 (17.8%) sizes. At baseline, for 36 size there was a change of 30mm (217 to 247mm) in IC and three IC profiles (235 to 245mm) were required to attend 59% volunteers in this subgroup. After four years, this variability remained (220 to 253mm) and three IC profiles were also required. The biggest change (41mm) occurred for 37 size, in both assessments, and three profiles (230 to 240mm) were required to attend 57.2% elderly. For 38 size, the IC variation was initially 34mm and two profiles (235 and 240mm) were required to attend 55% elderly. After four years, the variation was 29mm and two profiles (245 and 250mm) were required to attend most volunteers. At baseline 52.3% used unsuitable shoes according to FL and after four years the use of unsuitable shoes reduced to 50.8%. There was a decrease of FL over years for 36, 37 and 38 sizes. Also, the FB for 37 size and the HTBG for 38 size reduced in aging. The BMI reduced only for elderly with 37 and 38 sizes.

Conclusion: These results suggest the need of manufacturing different profiles for each size in order to provide a comprehensive and more suitable shoe for Brazilian elderly population. The constant adjustment of shoe models and sizes are needed in elderly population to prevent injuries and falls.

PLANTAR PRESSURE AND FOOT TEMPERATURE RESPONSES AFTER BAREFOOT RUNNING

J I Priego [1,*] M R Kunzler [2] E S da Rocha [2] A S Machado [2] F P Carpes [2]

[1]University of Valencia, Valencia, Spain, [2]Federal University of Pampa, Uruguaiana, Brazil

Introduction and Objectives: Benefits or inconveniences of barefoot running still are controversial in the literature. Barefoot running was associated to higher plantar pressure in forefoot region (Squadrone and Gallozzi 2009), which can result in more friction therefore impacting foot temperature. However, the relationship between plantar pressure and skin temperature still is unclear. Skin temperature helps to investigate the efficiency of thermoregulatory system during exercise. Foot temperature can help to understand the effect of footwear insulation. Here we examined the immediate effects of barefoot running on foot plantar pressure and temperature.

Methods: Eighteen participants (age 23.9 ± 3.6 years, body mass 64.8 ± 16.6 kg, and height 1.70 ± 0.11 cm) completed two protocols of running (shod and barefoot) following two days. They ran during 15 min at preferred and comfortable speed in a treadmill. Preferred speed was determined in the first trial and kept constant for the second. Plantar pressure during bipedal standing was recorded before and after running using a pressure mapping system (Matscan, Tekscan Inc). Foot temperature was quantified using an infrared thermography (camera E60, FLIR). Pressure and temperature were analyzed for whole foot, forefoot, midfoot and rearfoot regions. Plantar pressure in each foot region was normalized by the total pressure. Skin absolute temperature and its percentage variation between pre and post running were quantified. A 2x2 analysis of variance for repeated measures was applied to analyze the differences in plantar pressure and temperature before *vs* after running and barefoot *vs* shod. Pearson correlation was used to verify the relations between skin temperature and plantar pressure. Significance level was set at 0.05 using SPSS.

Results: The average speed was 7.3 ± 1.6 km/h. No significant differences were found in plantar pressure after running barefoot and shod ($p>0.9$). Regardless of the shoe condition, pressure in midfoot increased ($p=0.003$, 95%CI [0.8-3.1%]) whereas pressure in rearfoot decreased ($p=0.004$, 95%CI [0.8-3.7%]), after running. Shod running resulted in higher temperature in forefoot ($p=0.003$, 95%CI [0.5-2.2°C]) and midfoot ($p<0.001$, 95%CI [0.9-2.4°C]). Barefoot running resulted in higher variation of temperature in rearfoot ($p=0.04$, 95%CI [0.1-10.4%]). Any significant correlations were observed between skin temperature and plantar pressure ($p>0.05$ and $r<0.5$ or $r>-0.5$)

Conclusion: The main findings in our study were the lack of difference in static plantar pressure distribution after barefoot and shod running, higher temperature in forefoot and midfoot regions after shod running, larger variation of temperature in rearfoot after barefoot than shod running, and finally, no correlation between skin temperature and plantar pressure. Changing running technique towards a barefoot running may change rearfoot landing strategy to a midfoot and forefoot technique, producing higher dynamic plantar pressure in forefoot (Squadrone and Gallozzi 2009). We did not find differences in static plantar pressure after running between shod and barefoot running. Despite this, running in any of the conditions increased plantar pressure in the midfoot and decreased plantar pressure in the rearfoot, which is also in accordance with previous findings (Willems et al. 2012). These changes in plantar pressure may result from fatigue of plantar musculature (Willems et al. 2012). Shod running produced higher temperature in forefoot and midfoot than

observed for barefoot running, which may result of the footwear insulation. No significant correlation between plantar pressure and temperature were observed. These results could mean that the effect of footwear insulation can be greater than possible higher dynamic forefoot pressure produced by barefoot running. It was observed a higher variation of temperature in rearfoot after barefoot running. One possible reason to explain these results is that barefoot running can produce more vascularization due to activation of foot musculature, and higher mechanical work and stride frequency (Divert et al. 2008). More vascularization in one region can lead to higher temperature variation.

EFFECTS OF FALLING WITH AND WITHOUT KNEE PROTECTION: AN IN-VITRO STUDY

Michael Schwarze [1,*] Bastian Welke [1] Christof Hurschler [1]

[1] Laboratory for Biomechanics, Hanover Medical School, Hannover, Germany

Introduction and Objectives: Falling on the knees is a hazard prevalently occurring during various sports or in the elderly. For some sports the usage of protective devices such as pads is mandatory. In the elderly, special padding on the hips can reduce the effect of an unexpected fall [1]. To our knowledge, the mechanics of such padding was not investigated in high-force real life scenarios to date. The presented study illustrates the effect of wearing knee pads compared to unprotected impact on a hard surface.

Methods: Eight human knee cadaver specimens were acquired (mean age: 68y). The skin and subcutaneous soft tissue were removed at the proximal and distal end leaving the muscles, articular capsule, tendons and ligaments intact. The tibia and femur were embedded and fixed with a flexion angle of 90 deg in a custom made drop testing device (75kg including the knee). A commercially available knee pad was attached to the knee when required. Specimens were lifted 10, 20, 30 and 40mm from a force sensor and subsequently released to fall along guiding rods onto a rigid, even aluminium plate. Falling speed was continuously monitored by a displacement transducer at 1000Hz.

Results: The usage of a knee pad lead to an average attenuation of peak forces on impact by about 15% (Fig.1). As contact time on the plate was higher with a knee pad, the observed impulse was also increased. The effect diminished with increasing falling height. Energy dissipation, defined as the difference between kinetic energy pre-impact and peak potential energy post-impact, was slightly higher without a knee pad. The difference between pad or no pad was negligible at 10mm height, while difference was 75% at 40mm falling height.

Figure:

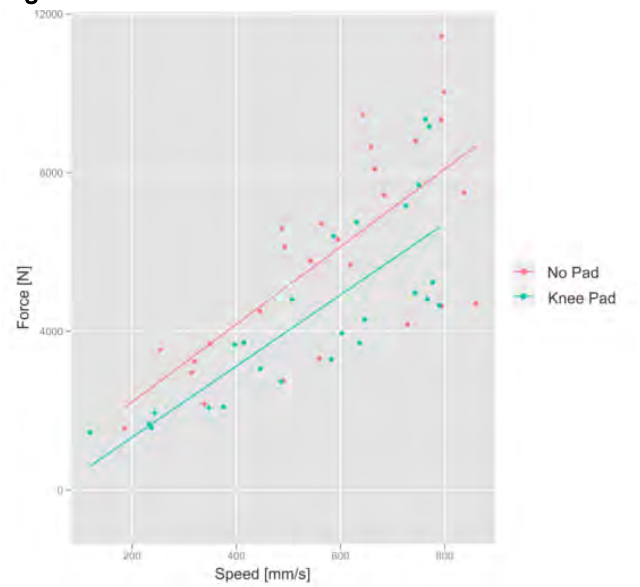

Fig.1: Maximum forces at impact over maximum falling speed of the specimen. Specimen with pads are colored in blue, specimen without pads are colore in red.

Conclusion: Despite several limitations, the results from this study illustrate the magnitude of influence of knee pads on peak forces, transmitted impulse and energy transfer. Contrary to expectations, the knee pad did not act as a mechanical damper. The mechanical behavior was more closely to a spring that temporarily stored energy and therefore reduced peak forces on impact. Possible indications for development of innovative pad designs will be the subject of further research.

THE PARAMETERISATION OF THE CAVITY FORMATION IN SUBSTITUTE MATERIALS FOR NORMALISED AND SPECIAL MILITARY AMMUNITION

Richard Billich [1,*] Ondrej Fanta [1] Frantisek Lopot [1] Petr Kubovy [1] Pavel Stursa [2] Karel Jelen [1]

[1]Department of Anatomy and Biomechanics, Faculty of Physical Education and Sport, Charles University in Prague,

[2]Department of Radiology, Na Homolce Hospital, Prague, Czech Republic

Introduction and Objectives: The issues of gunshot injuries and their consequences are at the forefront of the interest of a wide spectrum of various fields of science – medical and technological. Our study sets the goal of giving precision and accuracy to the description of bullet behavior in the human organism. Among parameters crucial for the assessment of the effect of a gunshot is not only the shape of the bullet path after the stabilization of the whole process, but also during the penetration of the material by the bullet. The bullet path with its permanent cavity defined by its shape, proportion and orientation within tissue is unique for every penetrating gunshot. Tissue damage provokes a wide range of reactions in the affected organism. The main nature of biological material is its reactibility through innervation.

Methods: Experimental shooting uses 20% gelatine blocks kept at the temperature of 4°C and glycerine soap. The size of blocks used in our experiment is 20x20x35 cm. Weapon systems used to shoot through the substitutive material were of 9 mm calibre for a pistol cartridge. Impact velocity was determined using optical light gates (LS-04 Intelligent Light Gates). Exiting velocity of bullets was measured with a radar (DRS-1 Doppler Radar System). Parameterization of shape transformations within the test blocks was done methods of computed tomography (CT) and magnetic resonance imaging (MRI). Experimental data was acquired using computer software CURVE EXPERT DATA.

Results: Most substantial changes happened on bullet .357 Magnum-GOLD DOT. During the penetration of the substitutive material it passed on 91% of its kinetic energy. Diagnostic methods calculated for this weapon system a difference of more than 48,2 mm in diameter between the entry and exit hole. While preserving its original weight the bullet reached its maximal average temporary cavity in the distance of 142 mm.

Conclusion: The weight of a bullet, the impact speed, bullet shape and construction constitute the determinating characteristics of a bullet's wounding effect. Specific profiles of the bullet path help constitute an image of what gunshot wound can be anticipated of each respective weapon system. It is apparent from the performed comparison that advantages and disadvantages of both substitutive materials used are approximately balanced. The results of these experiments have further significance also for the construction of ballistic protective systems.

MODELING THE INFLUENCE OF PAD STIFFNESS AND DAMPING PROPERTIES ON SKULL-BRAIN MOTION DURING BALLISTIC IMPACTS

Wenming Chen [1] Melanie Franklyn [1] Peter Vee Sin Lee [1,*]

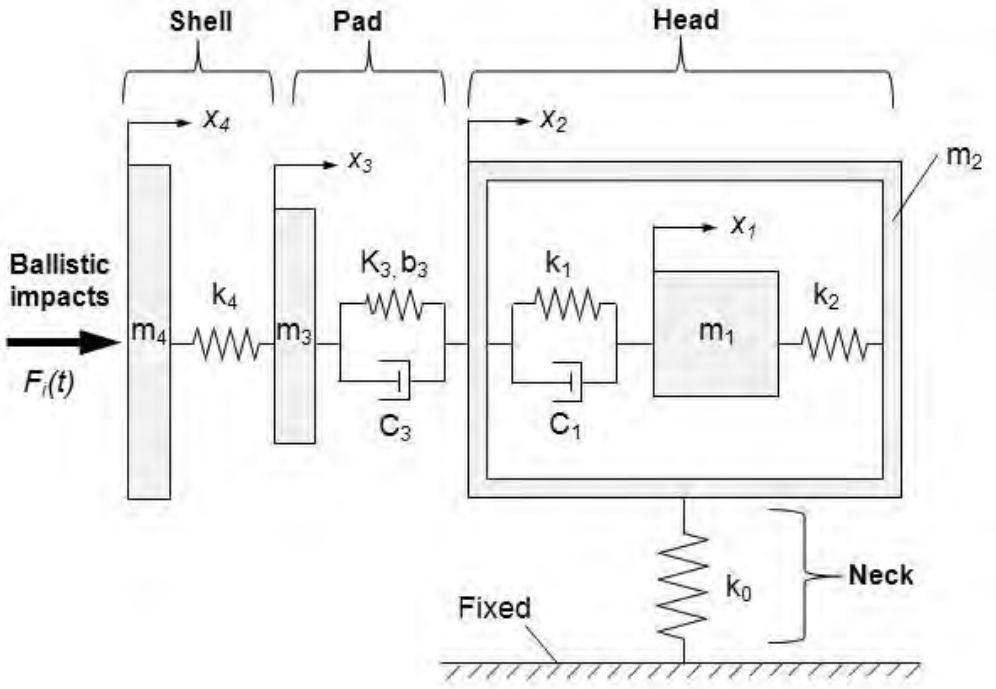
[1] Department of Mechanical Engineering, University of Melbourne, Melbourne, Australia

Introduction and Objectives: Brain injury studies involving military helmets have primarily focused on the effects of head acceleration; however, recent findings support the idea that Traumatic Brain Injury (TBI) is more likely to be caused by rapid deformation of the brain tissue [1]. To date, experimental approachs for military helmet evaluation have predominately been limited to tests using standard headforms, for example, the Hybrid III dummy head. However, the Hybrid III headform does not give a sufficient or realistic view of the intrinsic brain responses; hence there are limitations to the changes which can be made to enhance helmet performance and improve head protection.

Methods: The aim of this study was to develop a simplified mathematical model of the combined helmet/head system and then simulating a ballistic impact loading scenario. Firstly, a model of the human head represented by a spring-damper-mass system was developed by modifying Stalnaker's head model [2] where an additional soft tissue mass known as the "wobbling mass" was added to include the effect of brain oscillation within the skull under impact load. Secondly, a bi-layered subsystem consisting of nonlinear spring-damper units was constructed to model the helmet's shell and padding. The physical properties of contact between the pad and the skull were described by the Hertz type contact law, and experimentally obtained using an impact test to determine the stiffness and damping parameters of the helmet pad (ZAP PADs, Zorbium Foam, Cleveland, USA). The helmet subsystem was then coupled onto the head model to form an integrated helmet/head system (Fig. 1). The system governing equations were derived by applying the Newton's Second Law of motion and implemented using Matlab/Simulink (MathWorks Inc).

Results: Typical traces of the helmet-head contact force predicted by the model exhibited double peaks, i.e. forces peaked rapidly at 1~2 ms, then followed by a second peak with slightly a lower magnitude. This force trace resembled those measured contact forces reported in the literature. In addition, the movement pattern of the wobbling mass was also similar to a recent study on tagged magnetic resonance images (MRI) which demonstrated that the brain matter shifts relative to the skull and ''wobbles'' in a complex damped manner upon impact. A parametric analysis further revealed that the maximum displacement of the brain varies from 1.23 to 2.52 mm at different padding conditions simulated. The maximum brain acceleration decreased from 372.5 to 192.4 m/s^2 when padding properties were altered from hard to soft conditions.

Figure:



Caption: Figure 1. The schematic of the head model with a bi-layered subsystem attached.

Conclusion: In this study, a mathematical model to investigate impact biomechanics of the head-helmet system was developed and validated. The model facilitates efficient evaluation of military helmet designs on helmet-head contact forces and intrinsic brain responses under ballistic impact conditions. It was shown that brain motions were strongly influenced by the padding stiffness properties, which should therefore be considered as an essential parameter in helmet designs.

Table:

Helmet parameters		Predicted responses by the model		
Shell (K4)	**Padding (K3/C3)**	**Fc (N)**	**Ds (m)**	**Acc (m/s^2)**
550 kN/m	Soft	1480	0.0015	245.8
	Hard	2490	0.0024	451.4
4400 kN/m	Soft	2150	0.0012	192.4
	Hard	3620	0.0025	372.5

Caption: Table 1. Model predicted helmet-head contact force (Fc), maximum skull-brain displacement (Ds), and maximum brain acceleration (Acc) as a function of different helmet properties.

THE INFLUENCE OF IMPACT DIRECTION ON BRAIN TISSUE RESPONSE FROM REAL-WORLD HUMAN PCS INJURY RECONSTRUCTIONS

Marshall Kendall [1,*] Andrew Post [1] Janie Cournoyer [1] Thomas Blaine Hoshizaki [1] Michael D. Gilchrist [2] Susan Brien [3] Shawn Marshall [4]

[1]Human Kinetics, University of Ottawa, Ottawa, Canada, [2]University College of Dublin, Dublin, Ireland, [3]Hull Hospital, Gatineau , [4]Ottawa General Hospital, Ottawa, Canada

Introduction and Objectives: Persistent post-concussive syndrome (PCS) is a major concern as it leads to long term disability and lost productivity. In a clinical setting, PCS is characterized by long term symptoms (6 weeks +) that are representative of mechanical damage to tissues in regions of the brain that are responsible for the affected brain functions. It is possible that PCS injury is affected by impact direction as brain tissue is anisotropic and inhomogenic by nature and directional dependency of brain tissue damage in anatomical research has been shown [1]. This anatomical research has yet to be quantified in real-world human PCS cases. Thus, the purpose of this study is to investigate the influence of impact direction on the location of the peak magnitude of strain within the brain for real-world human PCS reconstructions cases.

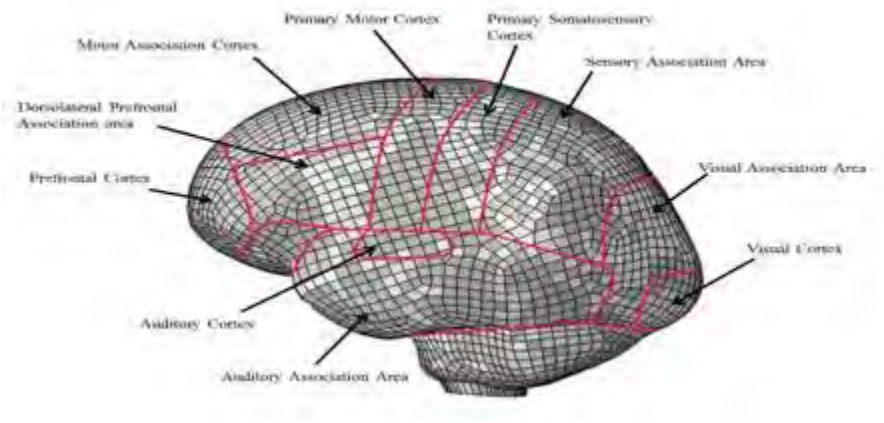
Methods: Subject data collection for the PCS cases took place at three hospitals in Canada. Fourteen PCS cases were used for reconstruction of which: eight were in the rear direction, four in the frontal direction, and two in the side direction. Subject inclusion criteria for this study required; PCS symptoms lasting longer than six weeks with no lesions evident on medical imaging. The injury cases in this study resulted from three mechanisms of injury (falls, collisions, and projectiles) and were thus reconstructed using a monorail for falls, linear impactor for collisions, or pneumatic ball launcher for projectiles. A Hybrid III headform instrumented with a 3-2-2-2 accelerometer array was impacted under conditions as described. The three-dimensional linear and angular acceleration loading curves were used as input for the University Dublin Brain Trauma Model (UCDBTM) in order to calculate brain tissue responses (MPS). The UCDBTM was analyzed according to nine regions of the brain linked to PCS symptomology. The influence of impact direction was characterized in MPS and compared using an ANOVA.

Results: The largest magnitude MPS value for each impact direction occurred in a different location of the cerebrum (Table 1). Statistical analysis for the frontal impacts reported no significant differences between location of the largest magnitude MPS and values in the other locations of the cerebrum. Significant differences were found in rear impact direction where the peak magnitude MPS were larger than those values reported in the other areas of the cerebrum ($p<0.05$). Significant differences were found between the location of the peak MPS for side impacts (Primary somatosensory cortex) and the values in the Prefrontal cortex and Visual cortex ($p<0.05$). Overall, there was no significant difference between the peak MPS in the cerebrum between the three impact directions ($p>0.05$).

All PCS cases clearly demonstrated brain tissue deformation values above the 50% risk of concussive injury threshold for the entire cerebrum (MPS 0.19) [3]. This result may be characteristic of PCS in these cases, where large strain fields in

the brain would cause a multitude of symptoms, and the large strains may indicate severity in terms of duration of ill effects.

Figure:



Caption: Figure 1. Image of the UCDBTM segmented into regions for analysis.

Conclusion: This study investigated whether impact direction influenced the location of MPS in the brain from real-world PCS injury reconstructions. Maximum principal strain between impact directions was not found to be significantly different. In addition, while where the peak MPS was located in the brain was different, this was inconsequential in terms of risk of injury because the strain levels were so high throughout the entire cerebrum. These results suggest that for these PCS cases, the characteristics of the impact were so severe that factors such as impact direction may not have been influential in the location of peak strain that might have been able to indicate symptoms of PCS.

Table:

	MPS for nine requions of the cerebrum								
Impact Direction	*1*	*2*	*3*	*4*	*5*	*6*	*7*	*8*	*9*
Front	0.454 (0.199)	**0.488 (0.254)**	0.435 (0.214)	0.454 (0.222)	0.423 (0.049)	0.332 (0.056)	0.234 (0.034)	**0.488 (0.126)**	0.289 (0.072)
Back	**0.531* (0.074)**	0.441 (0.054)	0.405* (0.038)	0.431 (0.071)	0.401* (0.134)	0.334* (0.061)	0.247* (0.058)	0.440 (0.085)	0.269* (0.036)
Side	0.261* (0.131)	0.430 (0.231)	0.342 (0.161)	0.458 (0.235)	**0.519* (0.269)**	0.369 (0.240)	0.302 (0.197)	0.333 (0.202)	0.186* (0.108)

COURT SURFACE EFFECT AND PLANTAR LOADING ASYMMETRY DURING A BASKETBALL JUMPSHOT LANDING

Darren Z. Nin [1,*] Raymond Quek [1] Pui Wah Kong [1]

[1]Nanyang Technological University, Singapore, Singapore, Singapore

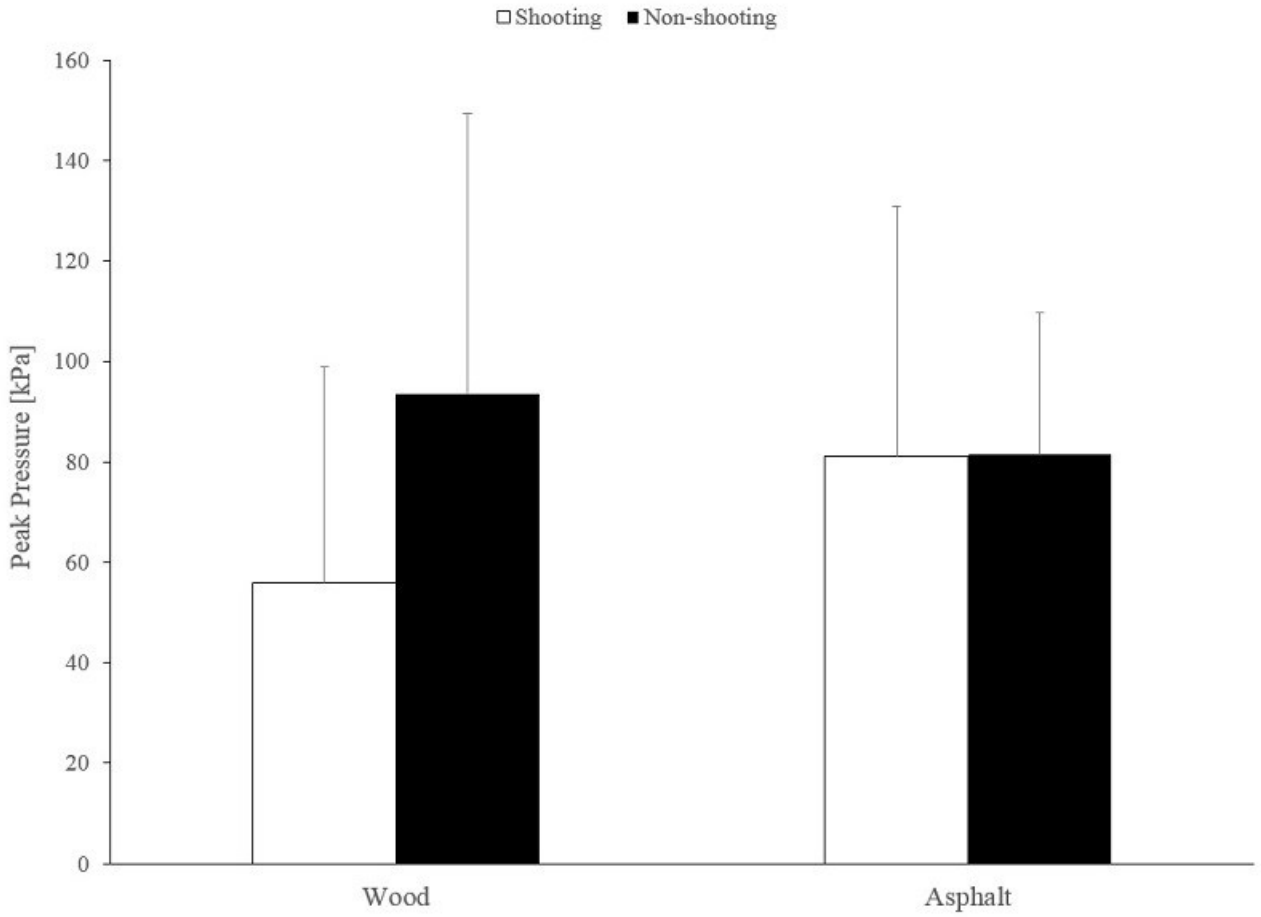
Introduction and Objectives: Basketball is a sport which places a considerable amount of stress on the lower extremities of players and an inability to attenuate these forces might lead to injury[1]. Outdoor (asphalt) and indoor (wood) playing surfaces have different cushioning properties which might affect the level of attenuation from impact forces during landing movements. Previous studies have examined the impact attenuation properties of different playing surfaces (e.g. grass, artificial turf) for a variety of sports[2, 3] but less is known about basketball court surfaces.

Movements such as the jumpshot result in a double-leg landing and it has been assumed that the bilateral symmetry of such a landing reduces the risk of lower limb injury.[4] There are, however, no available data of plantar loading between the two feet in basketball-specific movements. Therefore, the purpose of this study was to investigate the court surface effect and bilateral asymmetry in plantar loading variables during the landing of a basketball jumpshot.

Methods: Thirteen university basketball players (23.0 ± 1.4 years, 1.75 ± 0.05 m, 68.4 ± 8.6 kg) were recruited for this study. The Novel Pedar-X system (Novel GmbH, Munich, Germany) with 99 sensors within each insole was used to measure plantar loading. A randomised cross-over design was used. Each participant performed 10 trials of a basketball jumpshot on an ashpalt- and wood-surface basketball court from the free-throw line. Trials were considered valid if (i) the shot was successful, (ii) the ball made contact with the rim or (iii) the ball made contact with both the back-board and the rim. The jumpshot landing steps were analysed using the Novel Pedar-X Step Analysis software (Novel GmbH, Munich, Germany). The shooting side was defined as the leg on the same side of the shooting arm. The three variables recorded from the software were peak force (PF), peak pressure (PP) and pressure-time integral (PTI). A predefined mask of eight regions, created using the Novel Multimask software was applied to obtain the values of each region for PF, PP and PTI. Variables were compared using a two-way repeated measures ANOVA (court surface × side) ($\alpha = .05$). Post-hoc analysis was conducted with Bonferroni-correction for significance level.

Results: When landing from a jumpshot, there was no difference in any plantar loading variables between the asphalt- and wood-surface courts. Bilateral asymmetry was observed in some variables. PF was higher at the medial forefoot (21.8%, $p = .038$) and heel (39.1%, $p = .002$) in the non-shooting than shooting sides. PP was higher at the heel (10.8%, $p = .001$) while PTI was higher for the whole foot (35.5%, $p = .021$), at the hallux (47.8%, $p = .021$), lateral arch (50.6%, $p = .009$) and heel (62.1%, $p = .020$) in the non-shooting side. A significant court surface × side interaction (show p-value) for PP was found at the lateral arch (Figure 1). Post-hoc analyses did not reveal any significant pairwise comparisons.

Figure:



Conclusion: The foot loading associated with landing from a jumpshot did not differ between asphalt and wood surfaces. This suggests that playing surface does not have an effect on impact force attenuation during landing. Players and coaches should be aware of the loading asymmetry between the shooting and non-shooting side, predominantly at the heel region. Future studies could investigate whether this asymmetry is associated with lower limb injuries.

PO-0104

LEG DOMINANCE DIFFERENCES EXIST IN MUSCLE ACTIVATION PATTERNS IN PRE- OR EARLY-PUBESCENT SOCCER PLAYERS PERFORMING UNANTICIPATED SIDE-CUTS: RELEVANCE TO NON-CONTACT ACL INJURIES.

M J Del Bel [1,*] M L Jones [1] A K Fairfax [1] K Steele [1] S C Landry [1]

[1] Acadia University, Wolfville, Canada

Introduction and Objectives: It has been well established that female athletes have an increased risk of sustaining a non-contact ACL injury in sport compared to males. The increased occurrence of ACL injuries in females may be influenced by neuromuscular patterns at the knee joint that are not yet fully understood. Studies examining sex/leg differences in the muscle activity of muscles surrounding the knee joint have typically focused on athletes competing at the high school or collegiate level (1). This study set out to identify if sex and/or leg dominance differences exist in male and female soccer players under the age of 12 years, while performing unanticipated side-cut maneuvers on artificial turf.

Methods: Neuromuscular patterns during the stance phase of 45o side-cut maneuvers were analyzed under unanticipated conditions to closely emulate a true game-like scenario where non-contact ACL injuries most likely occur. Thirty-four youth soccer players (17 male and 17 female) with no history of lower limb injuries had muscle activity measured for the following muscles: lateral and medial gastrocnemii, lateral and medial hamstrings, and vastus lateralis and medialis. Mean muscle activation waveforms during the stance phase of the cutting stride were amplitude normalized to a series of maximal voluntary isometric contractions. Principal component analysis was performed on the individual mean waveforms of each athlete, with PC1 and PC2 capturing differences in overall magnitudes and phase shifts, respectively. A two-way mixed model ANOVA was used to test for sex, leg or interaction effects.

Results: Significant findings ($p \leq 0.05$) were found in five of the six muscles tested. All significant differences found were leg effects with both sexes displaying i) greater activation magnitudes in their dominant leg compared to their non-dominant leg for the lateral gastrocnemius, lateral and medial hamstrings, and vastus lateralis muscles and ii) earlier peak activations in their non-dominant leg compared to their dominant leg for the lateral and medial gastrocnemii, medial hamstrings and vastus lateralis muscles. No differences were observed in the vastus medialis or between sexes.

Conclusion: Few studies have evaluated neuromuscular differences between legs in athletes performing unanticipated side-cut maneuvers. It has been demonstrated that in older populations (ages 14-38), females are more at risk of injuring the ACL in their non-dominant leg, while males are more likely to injure the ACL in their dominant leg (2). Both males and females in this study displayed similar differences with respect to leg dominance, suggesting that leg differences are not influenced by sex in a young population. Furthermore, it has generally been reported that female collegiate athletes, compared to males, display greater activation magnitudes in the vastii muscles, potentially putting them more at risk of sustaining an ACL injury. However, in the population in this study, there were no sex differences found in neuromuscular patterns of muscles crossing the knee joint. Conclusion: Completing further studies considering sex and leg dominance differences could provide additional insight into the mechanisms behind non-contact ACL injuries. It is essential to determine how muscle activity across the knee joint occurs in a population that rarely experiences non-contact ACL

injuries and where no sex-bias is present (3) to help improve injury prevention programs aimed at reducing the rate of non-contact ACL injuries.

PO-0105

SEX AND AGE EFFECT ON MUSCLE ACTIVITY PATTERNS IN THE DOMINANT AND NON-DOMINANT LEGS OF EARLY PUBESCENT AND POST-PUBESCENT SOCCER ATHLETES DURING THE PERFORMANCE OF UNANTICIPATED SIDE-CUT MANEUVERS: IN RELEVANCE TO NON-CONTACT ACL INJURIES

Kendal Steele [1,*] Michelle Jones [1] Michael Del Bel [2] Alana Fairfax [1] Scott Landry [1]

[1]School of Kinesiology, Acadia University, Wolfville, [2]School of Human Kinetics, University of Ottawa, Ottawa, Canada

Introduction and Objectives: Recent studies regarding non-contact ACL injuries show that female athletes have a significantly increased risk of sustaining this injury in sport compared to their male counterparts (1). During puberty, it has been suggested that females undergo unfavorable alterations in their neuromuscular control patterns that can lead to an increased risk of ACL injuries (5). Previous research has also shown that female athletes are twice as likely to tear their ACL in their dominant leg as opposed to their non-dominant leg (2). This study set out to identify if sex differences exist in male and female soccer athletes at two different age groups: under 12 year old male and female athletes (U-12), and above 17 year old male and female athletes (AB-17) in unanticipated side-cutting conditions.

Methods: All athletes, 20 males and 16 females (U-12) and 20 males and 19 females (AB-17), had no history of major lower limb injuries. Participants performed 45 degree unanticipated side-cut maneuvers, at 75% of their maximum speed, on an artificial turf surface. Unanticipated conditions were used to simulate a true game-like scenario, where non-contact ACL injuries are most likely to occur. Neuromuscular control patterns were recorded and analyzed during the stance phase of the side-cut maneuvers for the vastus lateralis (VL) and medialis (VM), lateral (LH) and medial hamstrings (MH), and lateral (LG) and medial gastrocnemius (MG). A series of maximal voluntary isometric contractions were used to normalize the magnitude of muscle activation waveforms during the side-cut maneuvers. A separate principal component analysis (PCA) was performed on each of the different muscle groups, with a two-way ANOVA being used to test for a sex, age and interaction effect on both the dominant and non-dominant leg of the athletes.

Results: Significant differences ($p \leq 0.05$) were identified in all six muscles tested for the dominant leg. AB-17 athletes had greater magnitudes (PC1) than U-12 athletes for all six muscles. AB-17 athletes had earlier peak muscle activity (PC2) compared to U-12 athletes in the MH. All female athletes demonstrated greater magnitudes in the VM and earlier peak activity in the VM and VL compared to males. For the VL of the dominant leg, there was an interaction effect for phase shift, where AB-17 males peaked earlier than AB-17 females.

Significant differences ($p \leq 0.05$) were found in four of the muscles tested for the non-dominant leg. AB-17 athletes had greater magnitudes than U-12 athletes in the LG, MG, and MH. AB-17 athletes had earlier peak muscle activity compared to U-12 athletes in the LG and MG. U-12 athletes had earlier peak muscle activity compared to AB-17 athletes in the VL. AB-17 female athletes, and U-12 male athletes peaked earlier than their sex counterparts for the VM. Both groups of female athletes showed greater magnitudes than male athletes for the LG and VL.

Conclusion: Research has shown that female athletes display greater magnitudes of activation in the vastus medialis and lateralis than their male counterparts (4). In this study, AB-17 athletes displayed greater magnitudes for all muscles in the dominant leg and in three of the muscles for the non-dominant leg. This finding requires further investigation but the

increased activity level required to execute the cutting maneuvers in post-puberty athletes could lead to greater strains on the ACL in this population who are at greater risk of injury. A sex effect was apparent as females demonstrated significantly greater magnitudes in the VM of the dominant leg and in the LG and VL of the non-dominant leg. These findings combined with joint loadings and body positioning during the maneuvers could help explain the higher incidence of ACL injuries seen in the AB-17 female athletes. Activation of both the gastrocnemii and vastii muscles without appropriate activation of the hamstring muscles has previously been shown to increase the strain on the intact ACL, while a balanced synergistic activation between muscle groups is essential in protecting the ACL from injury (3).
Future studies considering each of the factors presented in this study (sex, age, leg dominance) will provide additional and important insight into the mechanisms behind non-contact ACL injuries and why collegiate female athletes are more prone to injuring their ACL. It is essential to determine what neuromuscular patterns are occurring in a population before puberty, allowing researchers to further understand how neuromuscular patterns change as an individual ages and how prevention programs can be developed to help reduce the incidence of this devastating injury post-puberty.

FATIGUE PROGRESSION CAUSES A TRANSITION FROM SOFT TO STIFF LANDING

Mianfang Ruan [1,*] Qiang Zhang [2] Xie Wu [3]

[1]Physical education, Ningbo University, Ningbo, [2]Kinesiology, Shanghai University of Sport, [3]kinesiology, Shangh University of Sport, Shanghai, China

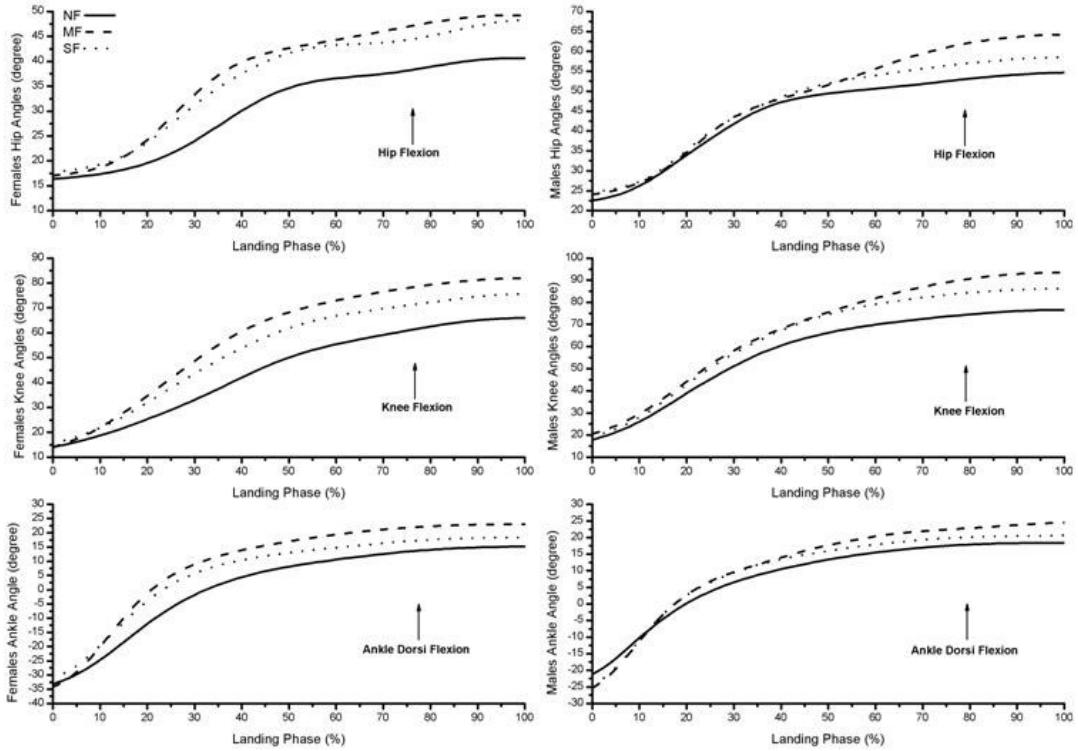
Introduction and Objectives: Although tremendous research efforts have been made to understand risk factors for noncontact ACL injuries [1] and a few prevention programs have been developed, the annual incidence of ACL injuries has increased by 1.3% in jump-landing sports [2] and the magnitude of the difference between male and female athletes has remained constant or even widened [3], which suggests that critical risk factors in ACL injury may have been ignored [4]. Most ACL injuries occur in the late phase of the match [5] and landing biomechanics showed significant changes throughout fatiguing. However, the changes in landing biomechanics associated with fatigue are inconsistent in the literature which may be due to distinct fatigue protocols. Considering that the neuromuscular fatigue is a progressive process and there is no standardized fatigue level in studies, the prefatigue-postfatigue testing model, which was used in most studies, may be another factor contributing to controversial results in the literature. This study aimed to investigate the progressive changes in landing biomechanics during a fatiguing exercise protocol.

Methods: Nine females and nine males were recruited to perform landing tasks throughout the fatigue protocol. A variety of movements including sidestep cutting, running, pivoting and jumping were incorporated in the fatigue protocol. The subject was requested to stand in the center of a 6 m diameter circular region and six lights were equally placed on the circle. When a light was illuminated randomly by a program, the subject ran to touch the active light to turn it off and trigger illumination of next lights. Males chased a series of 35 lighting intervals and females completed a series of 25 lighting intervals, followed by 8 CVJ trials to complete one fatigue drill cycle. Pilot testing revealed this would ensure both male and female subjects achieve the severe fatigue (SF) level in approximately 9 sets, which would take approximately 40 minutes. The average jumping height of the last 3 jumps was used to calculate the reduction of jumping height compared to the pre-fatigue (NF: no fatigue) jumping height. The medium fatigue (MF) level criterion was a reduction of 20% in jumping height and the severe fatigue (SF) criterion was a reduction of 30%. The fatigue drill was repeated until that threshold was met. At that point, the drop landing test was applied. Three-dimensional lower-limb-joint kinematics and kinetics during the drop landing testing were recorded by a 16-camera motion analysis system (100 Hz, Vicon Motion Analysis Inc., Oxford, UK) and two force platforms (1000 Hz, Kistler Instruments AG Corp., Winterthur, Switzerland) simultaneously during the testing. A 2-way (fatigue level × gender) mixed-design analysis of variance (ANOVA) was performed to determine any significant effects and interactions of fatigue levels and gender. A Bonferroni *post hoc* analysis was applied for further evaluation when a main effect was present. The αlevel was set at .05.

Results: Non-progressive patterns were observed: landing duration time (main fatigue effect, P= .007), peak knee flexion angle (main fatigue effect, P= .001) and peak hip flexion angle (main fatigue effect, P= .039) increased, and knee joint stiffness (main fatigue effect, P= . 033) decreased from NF to MF and all remained unchanged from MF to SF. Reversal patterns were observed: peak ankle dorsiflexion angle (main fatigue effect, P= .001) increased and then decreased from

NF to MF to SF, whereas peak VGRF (main fatigue effect, P= .001) and peak hip extension moment (main fatigue effect, P= .001) decreased and then increased across fatigue levels. Peak hip abduction angle (fatigue *gender, P= .021) in female subjects at SF was less than it at NF and MF, but this parameter in male subjects was not influenced by fatigue.

Figure:



Caption: Figure 1.The time history of hip, knee, and ankle joint in sagittal plane during landing for females (left) and males (right).

Conclusion: Over all, we observed non-progressive or reversal patterns in landing biomechanics during fatigue progression. The results indicated that fatigue progression would cause a transition from soft to stiff landing, which could eventually increase ACL injury risk. Additionally, fatigue may potentially further increase females' risk in ACL injury.

Table:

PO-0107

INVESTIGATION OF THE BIOMECHANICS OF BRUISING

Heather Black [1,*] Niamh NicDaéid [2] Philip Riches [1]

[1]Biomedical Engineering, University of Strathclyde, Glasgow, [2]Centre for Anatomy and Human Identification, University of Dundee, Dundee, United Kingdom

Introduction and Objectives: In legal cases involving physical injury, assessment of bruising can prove vital. Yet the mechanics of bruise formation and whether force of impact or age of injury can be inferred from bruise appearance, are not completely understood. One study is currently known to have focussed on the mechanical parameters of bruise formation [1]. Impact stresses of 1720 kPa to 5560 kPa were applied to one person, finding that increased tissue stiffness did increase the likelihood of bruising. Red, green and blue (RGB) value tracking has been used to quantify bruise analysis with little success, although showing potential [2, 3]. Infrared (IR) and ultraviolet (UV) wavelengths have also shown limited success [4]. Such colour analyses have not yet been related to the stress required for bruise formation, thus this study investigates the biomechanics of bruise initiation, RGB value tracking and use of IR and UV for bruise analysis.

Methods: Using custom built apparatus, three impact forces were generated by dropping a 2.7 kg mass from heights of 3, 4 and 5 cm onto an impactor resting on the forearm of 5 volunteers. An accelerometer (MicroStrain®, G-Link®, Wireless Node) was attached to the mass and its recordings used to derive the impacting pressure, displacement and tissue stiffness for each impact. Colour, IR and UV images were taken prior to impact and then daily for up to 2 weeks. The colour images were standardised and RGB values for each bruise obtained.

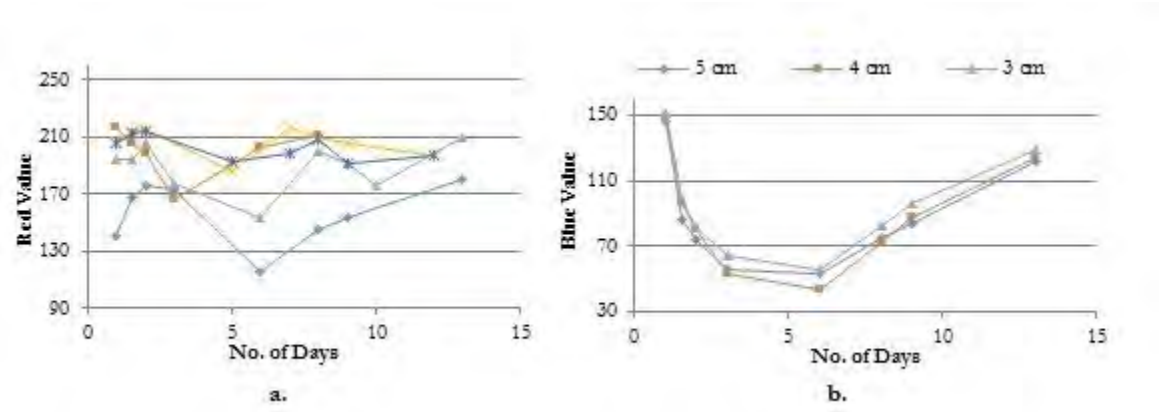
Results: Average impact stresses were 679.24±115.94 kPa, 577.61±95.98 kPa and 619.99±76.25 kPa for the 5 cm, 4 cm and 3 cm drop heights respectively. Unexpectedly, constant pressures were not recorded for each drop height. This was primarily due to the anatomical variation of impacting location.

Displacement varied with drop height and position with significant intra- and inter-subject variation. Skin displacement generally decreased from proximal to distal areas while tissue stiffness increased. Increased tissue stiffness was also observed as drop height increased.

For each drop height, both red (Fig. 1a) and green values followed a similar pattern inter- and intra-person. Blue values followed an intra-person pattern only (Fig. 1b). These patterns indicate colour timelines may be reproducible and comparable.

Colour photography provided clearest contrast between skin and bruise. IR failed to provide positive results while UV showed minor contrast between skin and bruise. Neither IR nor UV detected bruising once no longer visible to the naked eye. Skin tone influenced all imaging techniques and bruise appearance differed for all individuals.

Figure:



Caption: Figure 1. a. Example of red inter-person pattern b. Example of blue intra-person pattern

Conclusion: This study found that the mechanics of bruise formation and how impacting conditions influence bruising, could not be determined. RGB values could not be linked to impacting conditions, though did show potential. IR and UV imaging were not successful in bruise analysis.

Future work will aim to develop a repeatable and reliable method of bruise initiation, then use a larger group of volunteers to investigate bruise characteristics. If bruise biomechanics and colour development can be successfully understood, their use as evidence would cease to be subjective, thus having a major impact on forensic injury investigations.

KINEMATIC AND DYNAMIC BIOMECHANICAL VALUES IN RELATION TO MUSCLE ACTIVITY DURING CONTACT HEAD IMPACT

Ondrej Fanta [1,*] Karel Jelen [1] Daniel Hadraba [1] Richard Billich [1]

[1]Department of Anatomy and Biomechanics, Faculty of Physical Education and Sport, Charles University in Prague, Praha 6, Czech Republic

Introduction and Objectives: For the evaluation of neck injury the relative distance was observed between a marker placed on the forehead and a marker placed on the shoulder and also by change of the angle. To compare the severity of head injury a value of maximum head acceleration was used, HIC and a 3 ms criterion. All criteria were related to the activity of musculus sternocleidomastoideus and musculus trapezius in a situation of expected or unexpected contact impact.

Methods: The situation was recorded using a Qualisys system, head acceleration of probands in three axes was recorded using the accelerometer, activity of neck muscles was monitored by a mobile EMG.

Results: Maximum head acceleration was 5.61 g for non-visual and 5.03 g for visual. HIC36 was 6.65 non visual and 5.97 for visual. 3-ms criterion was 5.37 g for non-visual and 4.89 g for visual and max. force was 291 N for non-visual and 314 N for visual. The average time of muscle activation of the observed group without visual perception is 0.355 s after hitting an obstacle, with visual perception 0.085 s before the crash.

Conclusion: Kinematic values indicate more favourable parameters for neck injuries for visual. Head injury criteria show an average decrease of about 10% for visual. We can conclude that the visual perception means a significant increase in pre-activation of the observed muscle group of almost 745 % and lower activation in following phase of approximately 90 %.

IS THE 45 DEGREE LAB-BASED SIDE-CUT TASK EVER ACHIEVED? IMPLICATIONS FOR ACL INJURY RISK SCREENING

Grace Smith [1,*] Mark Robinson [2] Jos Vanrenterghem [2]

[1]Sport and Exercise Sciences, University of Chester, Chester, [2]Research Institute for Sport and Exercise Sciences, Liverpool John Moores University, Liverpool, United Kingdom

Introduction and Objectives: The side step cutting manoeuvre has been used extensively as a screening tool for ACL injury risk in laboratory-based biomechanical research. Rapid decelerations in single-leg support, combined with a change in direction, generate high joint loading and have been identified as a common mechanism of noncontact ACL injury in athletes during game situations. A variety of approach speeds and cutting angles have been reported, possibly reflecting the diverse range that athletes will perform during a game [1]. Whilst the 45 degree side step cut has been used more extensively than other angles, there has been little evidence that this task is actually being achieved in a lab-based environment. However, a clear trade-off between task achievement and mechanical loading with increasing running speed in a 45 degree cut has been reported previously [2]. The purpose of the present study was to investigate task achievement of a side cut at different cutting angles: 45, 90, 135 and 180 degrees.

Methods: Ten male footballers (20.6 ± 0.8 years; 182.0 ± 6.5 cm; 73.9 ± 4.3 kg) performed five trials of an anticipated side cut in each cutting angle condition. Angles of 45, 90, 135 and 180 degrees were marked on the floor with tape and subjects were asked to follow these lines. A run-up speed of 3.45 – 4 ms^{-1} was required, monitored using timing gates/ Kinematic data were recorded using 10 opto-electronic cameras (Oqus 300, Qualisys, 250 Hz) and 44 reflective markers [3]. Each side cut was completed on a Kistler force platform (9287C, Kistler Instruments Ltd, 1500 Hz). Marker and force data were filtered using a 4th order low pass Butter-worth filter with a cut off frequency of 18 Hz and analysis was undertaken in Visual 3D (v.4.83, C-Motion). For the evaluation of task achievement, a one-way repeated measures ANOVA (α=0.05) was used to determine statistical differences between COM velocity, transverse plane angle of progression, contact time, and peak horizontal and medio-lateral ground reaction forces [2].

Results: Only the 45 degree cutting task was performed at the prescribed touchdown running speed, other cutting angle tasks were performed significantly slower (Table 1). The prescribed change in angle was not achieved during the observed support phase by any of the four tasks, with the actual cutting angle deviating from the prescribed angle by up to 34 degs. The inability to achieve the required change may be explained by the significantly lower contact times. For side cuts that require a larger change of direction, this comes with a clear trade off in the velocity of the athlete. As participants had to slow down substantially before touchdown, they were unable to perform a 180 degree turn at high velocities. Peak posterior GRFs were significantly lower for the 45 degree cutting task, but peak medial GRFs were different between all cutting task conditions, demonstrating that each task elicited different GRF loading responses.

Conclusion: In none of the conditions was the task achieved, both in terms of obtaining the required velocity and change, in agreement with some previously reported data on task achievement [2]. This questions whether these lab-based tasks can suitably mimic the changes in directions experienced in real-time competition situations, which likely occur at higher

and varying approach velocities. Previous studies have failed to standardize cutting angle or speed of task execution, raising questions about the legitimacy about the task.

The successful execution of a side stepping task is dependent on cutting angle, however for a 45 degree side cut, the change in angle achieved is far from 45 degrees. If clinicians are to move towards a gold-standard method of ACL injury risk screening, which will inevitably require a task which mimics competition situations, they must be aware that the side cutting protocol needs standardizing and task achievement needs assessing.

Table:

Variable	45°	90°	135°	180°	*F*	*p*

PO-0110

ACL RECONSTRUCTION RESULTS IN INCREASED INSTABILITY DURING VISUAL FEEDBACK OF MULTIDIRECTIONAL FORCE PRODUCTION.

Amelia A. Lanier [1 2,*] Thomas Buchanan [2 3]

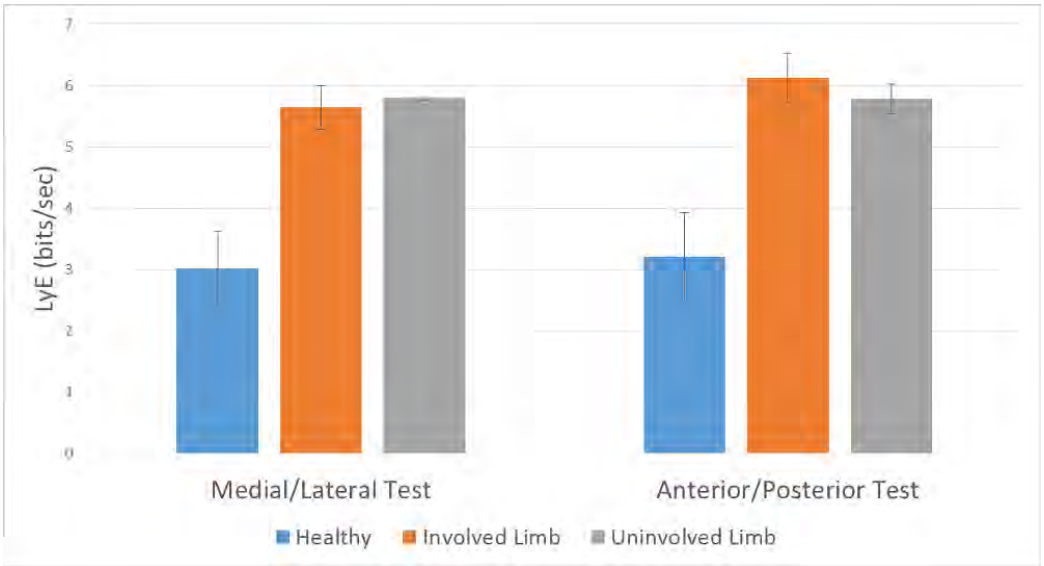
[1]Biomechanics & Movement Science, University of Delaware, [2]Delaware Rehabilitation Institute, [3]Mechanical Engineering, University of Delaware, Newark, United States

Introduction and Objectives: After anterior cruciate ligament (ACL) rupture most will undergo reconstructive surgery. Within the first year after surgery 25% of patients will re-tear their ACL. Most of those injured attempt to return to sports which include running and cutting. The ability to produce appropriate ground reaction forces may be crucial for the successful return to sports without re-injury. Understanding stability of multidirectional ground reaction force (mGRF) production in healthy and ACL reconstructed (ACL-r) patients can lend insight to the high instance of re-injury. Typically, stability has been measured using linear analyses, but these analyses cannot capture the subtle time varying changes that can occur. Recently, research using nonlinear techniques, such as the Lyapunov exponent (LyE), have been able to overcome these issues. Recent studies using this measure to quantify the stability of knee flexion during gait found that there are significant increases in LyE measured after ACL injury and reconstruction when compared to healthy control subjects [1, 2]. The purpose of this study was to understand the ability of those with ACL reconstruction to produce specific mGRFs stably. We hypothesized that there would be more instability, noted by greater LyE values, after ACL reconstruction when compared to healthy uninjured controls. Secondarily, we hypothesized that LyE values measured during the medial/lateral (ML) task would be greater compared to the anterior/posterior (AP) task.

Methods: Our study included 7 (2M) healthy uninjured individuals and 2 (1M) who have undergone ACL reconstruction. We provided visual feedback of GRF production in the AP and ML direction to the subjects. Subjects stood on two force plates (AMTI OR-6) with a foot on each plate. Subjects were instructed to alternatively and continuously produce ±50 % of their max force in the AP or ML direction to the beat of a metronome set at 60 beats per minute. For the LyE analysis, AP and ML GRFs were the variables of interest. Calculating LyE requires two input parameters time lag (tau) and embedding dimension (m), used to transform the AP and ML GRF into phase space. Tau & m were calculated using an average mutual information (AMI) algorithm and global false nearest neighbor (GFNN) algorithm respectively. Once in this format maximum LyE was calculated using the Wolf algorithm. Detailed descriptions of the AMI, GFNN, and Wolf algorithms can be found in previously published work [3, 4]. Largest LyE in bits/sec was reported as it indicates maximum divergence/instability of force production.

Results: ACL-r subjects had larger LyE values when compared to healthy uninjured controls (Fig.1). Additionally, the uninvolved limb of ACL-r subjects exhibited larger LyE values when compared to healthy uninjured controls. When comparing the ML and AP task there were no differences in all three limbs: healthy, involved, and uninvolved (Fig.1). While there was instability between groups there was no instability specific to direction of force production.

Figure:



Caption: Figure 1: Avg. LyE ± SD (bits/sec) for healthy uninjured and ACL-r subjects. Lower values for LyE imply greater stability.

Conclusion: After ACL reconstruction, patients produce less stable multidirectional ground reaction forces when compared to healthy controls. Instability is present in both the AP and ML directions, suggesting this phenomena is not limited to a single direction. Given that the ACL primarily limits anterior tibial translation we initially predicted the AP direction would exhibit greater instability, however, this was not the case. Instability in both AP and ML directions may be a result of reduced proprioception and neuromuscular control commonly seen after ACL injury. Previous studies have observed reduced stability in ACL injured [1]and reconstructed[2] populations during gait using LyE analysis of knee flexion/extension, when compared to healthy controls. Interestingly, increased LyE values are present in both the involved and uninvolved limbs during both gait[2] and for the mGRF task performed in this study. For those who have undergone ACL reconstruction and plan to return to sport instability during GRF production may be an important factor contributing to re-injury. Approximately, 70% of ACL tears are noncontact which include activities like landing or cutting maneuvers. Instability when generating ML ground reaction forces may lead to reductions in performance and subsequent injury. Overall, after ACL reconstruction patients are unable to produce stable ground reaction forces, but this is not confined to the involved limb or direction (AP & ML). Instability during force production may be contributing to ACL injury as it may affect performance during cutting maneuvers.

PO-0111

MECHANOMYOGRAPHIC DETECTION CAPABILITIES POST FATIGUE IN THE BICEPS BRACHII AGAINST THE BICEPS FEMORIS: A COMPARATIVE STUDY

Christian A. Than [1,*] Mark Gorelick [2] Mark Brown [1]

[1]School of Biomedical Science, The University of Queensland, Brisbane, Australia, [2]Department of Kinesiology, San Francisco State University, San Francisco, United States

Introduction and Objectives: Mechanomyography (MMG) is a developing analytical technique with the ability to assess the contractile properties of muscle non-invasively. Its capacity to quantify changes in muscle contractile performance suggests it might have utility as a clinical diagnostic tool. The aim of this study was to determine whether the MMG technique was sensitive to changes in muscle contractile properties following eccentric muscle injury in an upper (biceps brachii) and lower (biceps femoris) limb muscle.

Methods: 12 subjects (6 male and 6 female; mean age 24.3 ± 3.7yrs) were recruited and performed an eccentric exercise protocol to volitional cessation using their biceps brachii. A further 12 subjects (9 male and 3 female; mean age 21.1 ± 1.1yrs) performed a similar exercise protocol using their biceps femoris muscle. Subjects were monitored for 5 days total post exercise using MMG and psychological measurements of pain (VAS scores) to follow the onset of fatigue and recovery between the two groups.

Results: VAS scores in both groups significantly changed on day 2 post exercise, with resolution on day 4 for the biceps brachii group and no resolution in the biceps femoris group by the 6th and final day of the experiment ($P<0.05$). Contraction time of the biceps brachii was found to be significantly slowed post exercise on days 2 and 3 ($P<0.05$) while those in the biceps femoris group showed no significant change despite similar trends of slowing. Relaxation time of the biceps brachii group was found to be significantly slowed post exercise on days 2, 3 and 4 ($P<0.05$) while relaxation time in the biceps femoris group showed no significance.

Conclusion: MMG was able to detect changes in contractile properties in the biceps brachii group during the onset and resolution of muscular fatigue, but was not able to detect significant changes in the biceps femoris group. This could be in part attributed to the different fiber compositions of the two muscles, with the biceps femoris group consisting of a substantially higher number of slow twitch fibers that are fatigue resistant. Nevertheless, the MMG technique continues to show potential for clinical application in detecting muscular changes that may be beneficial for predictive, diagnostic or rehabilitative purposes.

THE FATIGUE EFFECT IN ANTECIPATORY AND COMPENSATORY POSTURAL CONTROL IN FEMALES INDOOR SOCCER ATHLETES WITH ANKLE INSTABILITY

Thiago T. Teruya [1,*]Alex Sandra Oliveira Cerqueira [1]Vinicius Andre Soares [1]Julio Cerca Serrão [1]Luis Mochizuki [2]Alberto Carlos Amadio [1]

[1]School of Physical Education and Sport, [2]School of Arts, Sciences and Humanities, University of São Paulo, São Paulo, SP, Brazil

Introduction and Objectives: The ankle sprain a common injury in indoor soccer. This injury affect a sports and locomotion performance. Despite widely studied in biomechanics and motor control areas, the postural adjustments in people with a history of ankle sprain were few studied. The purpose of this pilot study was to analyze the anticipatory and compensatory postural control in female athletes soccer athletes.

Methods: 8 female college indoor soccer athletes were divided into 3 groups: functional instability (3 subjects), mechanical instability (2 subjects) and control (3 subjects). Before and after a fatigue protocol, 20 inversion movements were simulated on an inversion platform [1] on both legs and the electrical activity of the mm. tibialis anterior (TA), fibularis longus (FL), fibularis brevis (FB) and gastrocnemius lateralis (GL) were recorded. The root mean square (RMS) from two EMG epochs (the anticipatory, APA; and compensatory postural, CPA, adjustments) were calculated. The APA was defined as the interval between 200 ms before and 51 ms after start of the fall of the inversion platform. The CPA was defined as the interval between 51 and 251 ms after start of the fall of the inversion platform. The movement start of the inversion platform was measured with a 3D accelerometer. The raw EMG signal was demeaned, filtered (4^{th} order 200hz Butterworth low-pass filter), and rectified. The analysis of variance (ANOVA) was applied to check de differences among the groups. The level of significance was 5%.

Results: APA: TA: There was not effect of fatigue ($F_{2,191}$=0.3 p=0.74), group ($F_{2,191}$=2.4 p=0.09) and interaction ($F_{4,191}$=1.9 p=0.10). FL: There was effect of group ($F_{2,191}$=43.4 p<0.001). The post hoc Tukey test showed that the control group showed the highest RMS; and it decreased after the fatigue protocol. FB: There was effect of group ($F_{2,191}$=17.2, p<0.001). The post hoc test Tukey showed that the mechanical instability presented the highest RMS. GL: There was effect of group ($F_{2,191}$=12.6 p<0.001), fatigue ($F_{2,191}$=4.7 p=0.01) and interaction ($F_{4,191}$=5.7 p<0.001). The post hoc test Tukey showed that for the mechanical instability presented the lowest RMS; and fatigue increased the RMS at the functional group.

CPA: TA: There was effect of group ($F_{2,191}$=8.3 p<0.001) and interaction ($F_{4,191}$=3.0 p=0.01) between group and fatigue. The post hoc test Tukey showed that the functional instability showed the highest RMS. FL: There was effect of group ($F_{2,191}$=4.8 p=0.009), fatigue ($F_{2,191}$=4.7. p=0.01) and interaction ($F_{4,191}$=2.9 p=0.02). The post hoc test Tukey showed that the RMS was higher in control group than mechanical instability group; and the RMS was lower in dominant leg after the fatigue protocol for the mechanical and functional instability group. FB: There was effect of group ($F_{2,191}$=5.3 p=0.006). The post hoc test Tukey showed that the mechanical instability showed the highest RMS. GL: There was effect of group ($F_{2,191}$=28.5 p<0.001). The post hoc test Tukey showed that the functional instability presented the highest RMS.

Conclusion: The ankle sprain simulation induces different muscle activation before and after the mechanical stimulus. The results suggest that postural control during APA and CPA is instability-dependent. For APA, the functional instability group presented the lowest activity of FL and FB; and the mechanical instability presented the lowest activity of GL. The fatigue decreased FL activity and increased GL activity at the functional group. For CPA, the ankle instability groups presented the highest TA (functional) ,GL (functional) and FB (mechanical) activities; and presented the lowest FL activity. The fatigue decreased the FL activity in the dominant leg for the mechanical and functional instability groups.

Table:

Epoch	Group	Leg	RMS (% maximal activity)			
			Tibialis Anterior	Fibularis Longus	Fibularis Brevis	Gastrocnemius Lateralis

DOES A HALF TIME RE-WARM UP INFLUENCE THE MARKERS OF ANTERIOR CRUCIATE LIGAMENT INJURY RISK DURING MULTI-DIRECTIONAL SIMULATED SOCCER MATCH-PLAY?

Raja Mohammed Firhad Raja Azidin [1,2,*] Sean Sankey [2] Ruth Cabeza-Ruiz [2,3] Fransiska Bossuyt [2] Barry Drust [2] Mark A Robinson [2] Jos Vanrenterghem [2]

[1]Faculty of Sport Science and Recreation, Universiti Teknologi MARA, Shah Alam, Malaysia, [2]School of Sport and Exercise Sciences, Liverpool John Moores University, Liverpool, United Kingdom, [3]Department of Physical Education and Sports, University of Seville, Seville, Spain

Introduction and Objectives: An inactive (passive) half-time interval during soccer matches has been shown to impair physical performance, imposing an increased risk of injuries during the early stages of the second half [1,3]. The main aim of this study was to investigate markers of anterior cruciate ligament (ACL) injury risk related to knee and hip mechanics and isokinetic muscle strength imbalance during a soccer match simulation, and the effect a half-time re-warm up has to reverse increased risk in the second half of play.

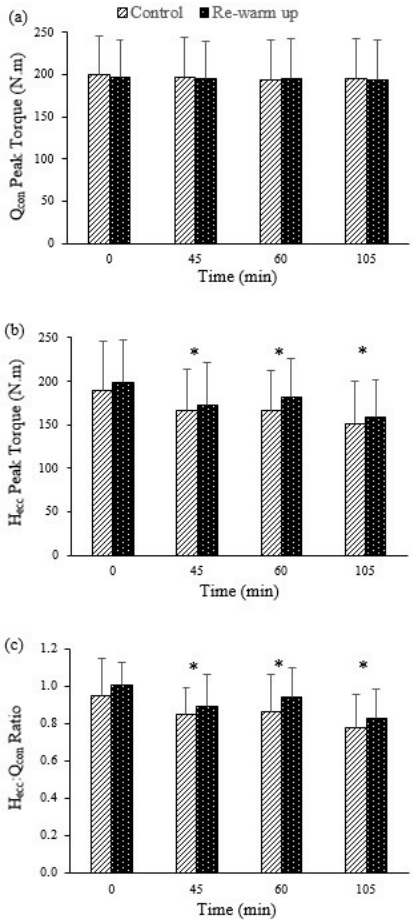
Methods: In a single-group repeated measures design, 14 male recreational soccer players completed a 90-min lab-based multi-directional overground match-play simulation, comprising two 45-min halves separated by a 15-min half-time interval. During the half-time period, players either remained seated (passive, CON), or performed an intermittent agility exercise at ~70% of maximal heart rate during the last 5-min of half-time (re-warm up, RWU). Kinematics and kinetics of the support leg during unanticipated 45° side cutting manoeuvres were recorded as part of the simulated match-play, providing multiple trials over the 45 minutes which were subsequently grouped into 15 minute blocks. Participants also performed five maximal dominant-limb isokinetic contractions for concentric quadriceps (Q_{con}) and eccentric hamstrings (H_{ecc}) prior to exercise (time 0 min), at the beginning and end of half-time (time 45 min and 60 min), and post-exercise (time 105 min). A two-way ANOVA was used to identify significant differences, with $\alpha=0.05$.

Results: Significant reductions in H_{ecc} ($P < .010$) and functional H_{ecc}:Q_{con} ratio ($P < .020$) were observed at all times during match-play compared to pre-exercise values, for both conditions, with no significant difference observed between conditions (Figure 1). Similarly, significant increases in Q_{con} angle of peak torque at all times ($P<.030$), compared to pre-exercise values and H_{ecc} angle of peak torque ($P=.037$) in the last 15 minutes of match-play were observed. A trend towards increased hip extension angles at initial contact ($P=.076$) was observed in the last 15 minutes of simulated match-play. No significant differences between conditions or over time for Q_{con}, knee abduction moments and knee extension angles were observed.

The main findings revealed RWU did not offset impairments in all the markers of ACL injury risk. Reduced eccentric hamstrings strength and muscle imbalances, a shift in angle of peak torques and a trend towards more erect hip landing posture at initial contact, suggested a greater risk of ACL injury during the latter stage of match-play, supporting epidemiological observations [2]. A reduced muscle temperature due to passive rest during half-time has been associated with a reduction in physical performance during the second half of match-play [3]. Whilst RWU has been shown to

increase muscle temperature, increased nerve conduction rate, and increased contraction velocity [3], RWU had no reversal effects on markers of ACL injury risk in this study.

Figure:



Caption: Quadriceps concentric peak torques (a) hamstrings eccentric peak torques (b) and functional hamstring eccentric: quadriceps concentric strength ratio (c) during simulated match-play. *Indicate significant difference from pre-simulation (time 0 min).

Conclusion: Despite the growing evidence of physical performance improvement after RWU in soccer players, the efficacy of this intervention towards reducing ACL injury risks remains unknown and requires further investigation.

PO-0114

AGE AND GENDER EFFECT ON MUSCLE ACTIVATION PATTERNS IN THE DOMINANT AND NON-DOMINANT LEGS OF SOCCER PLAYERS DURING UNANTICIPATED SIDE-CUTS: RELEVANCE TO NON-CONTACT ACL INJURIES

Michelle L. Jones [1,*] Kendal Steele [1] Michael J Del Bel [1] Alana K Fairfax [1] Scott Landry [1]

[1] Acadia University, Wolfville, Canada

Introduction and Objectives: Recent literature demonstrates that females are more susceptible to non-contact anterior cruciate ligament (ACL) injuries compared to males, though muscle activity differences in age and gender are not yet completely understood. While a number of studies exist examining gender effects on non-contact ACL injury risk, very few consider gender as well as the effect of age (1). The purpose of this study was to determine if gender and age differences exist in lower limb muscle activation patterns between pre-pubescent and post-pubescent male and female soccer players while performing maximum effort unanticipated side-cutting maneuvers off both the dominant and non-dominant leg.

Methods: A series of 45 degree unanticipated side-cutting maneuvers were performed at a maximum effort by 33 pre-pubescent (17 male age 10.4 ± 1.4 yrs, and 16 female age 9.1 ± 1.2 yrs), and 39 post-pubescent (20 male age 21.3 ± 1.9 yrs, and 19 female age 19.5 ± 2.3 yrs) soccer athletes who had no significant lower limb injury in the past 6 months or that required surgery. A timing reaction system was used to guide the athletes to cut either to the left or right of their dominant or non-dominant leg in an unanticipated maneuver, thereby more closely replicating a true game-like situation where this injury is most likely to occur. Muscle activation patterns during the stance phase of the side-cutting maneuvers were analyzed for the following muscles: lateral and medial gastrocnemii, lateral and medial hamstrings, and vastus lateralis and medialis. Mean muscle activation patterns for the stance phase of the side-cutting maneuvers were amplitude normalized to a series of maximum voluntary isometric contractions. For each muscle separately, the participants' individual mean waveforms were analyzed using principal component analysis (PCA), with PC1 and PC2 capturing overall magnitude and timing features (phase shift) in the activation waveforms, respectively. Gender, age, and/or interaction effects were tested for using a two-way ANOVA for each muscle group. Analyses of the dominant leg and the non-dominant leg were each completed separately.

Results: The analysis on the dominant leg revealed that the post-pubescent group had significantly greater ($p<0.05$) muscle activation magnitudes over the pre pubescent group for all muscles examined. The vastus medialis showed gender and age differences, with higher activation magnitudes demonstrated in females compared to males, and post-pubescent males reaching peak muscle activation closer to initial contact (IC) compared to pre-pubescent males. Peak muscle activation occurred earlier for the post-pubescent males compared to post-pubescent females in the vastus lateralis, with trends ($p<0.1$) evident in the vastus medialis.The analysis of the non-dominant leg indicated significantly higher activation magnitudes for the post-pubescent athletes compared to pre-pubescent athletes in the lateral and medial gastrocnemii and the vastus lateralis. Trends of similar differences were also observed in the lateral and medial hamstrings. Greater activation magnitudes earlier in stance or earlier peak activation (phase shift) for the lateral hamstring were observed in males compared to the females. For the medial hamstring, however, greater activation magnitudes

earlier in stance were observed for pre-pubescent athletes compared to post-pubescent athletes. The vastus lateralis showed earlier peak activation for the post-pubescent males in comparison to the post-pubescent females.

Conclusion: Findings that include earlier peak muscle activity for the vastus lateralis and medialis muscles in males may play a role in better stabilizing the knee and decreasing the risk of injury for males (2). Gender differences were more evident in the post-pubescent group and this goes along with findings in the literature that indicate females are more likely to injure their ACL in post-pubescent athletes, with no gender differences in non-contact ACL injuries existing for pre-pubertal athletes (3). Trends or significant age differences in muscle activation magnitudes were found to exist in all but one muscle, with post-pubescent athletes having higher activation magnitudes compared to pre-pubescent athletes. Further research is recommended to determine the role that these age and gender differences may have on the risk of non-contact ACL injury risk.

PO-0115

THE EFFECT OF PERIPHERAL FATIGUE ON KNEE JOINT POSITION SENSE.

N S Relph [1,*] L C Herrington [2]

[1]University of Cumbria, Carlisle, [2]University of Salford, Salford, United Kingdom

Introduction and Objectives: Muscular fatigue is the inability to maintain a power output or force during repeated muscular contractions due to changes in physiological processes. Joint position sense (JPS) is the awareness of position in space. Exercising when fatigued increases the risk of injury, which may be due to a reduction in knee position sense. Indeed, evidence suggests more injuries occur in the final third of sports matches than in earlier periods. The aim of this study was to measure the effect of peripheral muscular fatigue on knee JPS.

Methods: 20 healthy participants provided informed consent. Knee JPS was recorded before and after a fatiguing protocol. The JPS measurements were taken using a previously validated method (Relph and Herrington, 2014a, 2014b). This involved open chain, passive-active reproduction of a target angle into both flexion and extension. Absolute error scores (AES) were taken as the absolute difference between target and reproduction angles. Angles were measured using image capture and manual digitising techniques. Fatiguing protocol was conducted on an isokinetic dynamometer and involved concentrically extensions and flexions of the dominant knee maximally at 60°/s until they reached 50% of their maximum voluntary contraction on three consecutive trials in both flexor and extensor muscle groups.

Results: The mean (±SD) maximum voluntary contraction into knee flexion and extension was 78.7N.m (±22.8) and 177.1N.m (±39.0) respectively. Results of the analysis revealed no effect of the fatiguing protocol on either JPS flexion ($p=0.729$) or JPS extension ($p=0.492$). Knee JPS flexion error scores reduced by 0.17° and JPS extension error scores reduced by 0.14°. Discussion - One viable explanation of the results of this study is the fatiguing protocol was not severe enough to induce a fatigued state. For example the anterior shear loads imposed on the knee joint during isokinetic contraction at 180°/s are equivocal to that of walking and compressive loads equivalent to stair climbing. This suggests studies using isokinetic fatiguing may not create representative fatiguing of the joint as would occur during exercise. The method of measuring fatigue levels using 50% of MVC may also have limitations. It may be more appropriate to use blood analysis techniques to confirm fatigue. However, it would appear peripheral fatigue occurred to some extent as MVC performance did reduce. Another explanation for the lack of JPS decline may be compensatory techniques in the central nervous system, central processing may have adjusted efferent information to ensure continued to provide accurate joint position sense.

Conclusion: In conclusion, peripheral fatiguing protocols may not induce fatigue to an appropriate level to illustrate the effects on knee JPS. Alternatively, knee JPS may not be affected by fatigue and hence a reduction in knee static proprioception may not be a mechanism of the increased risk of injury during the latter stage of exercise and sport. Future research should consider the effect of central fatiguing on knee proprioception. Disclosure -This data is new and has not been submitted elsewhere.

PO-0116

SACROILIAC JOINT CARTILAGES BIOMECHANICAL ANALYSIS AFTER DIFFERENT PERCUTANEOUS SCREW FIXATIONS: A FINITE ELEMENT ANALYSIS

Peng Ye [1,*] tang peifu [1] zhang lihai [1]

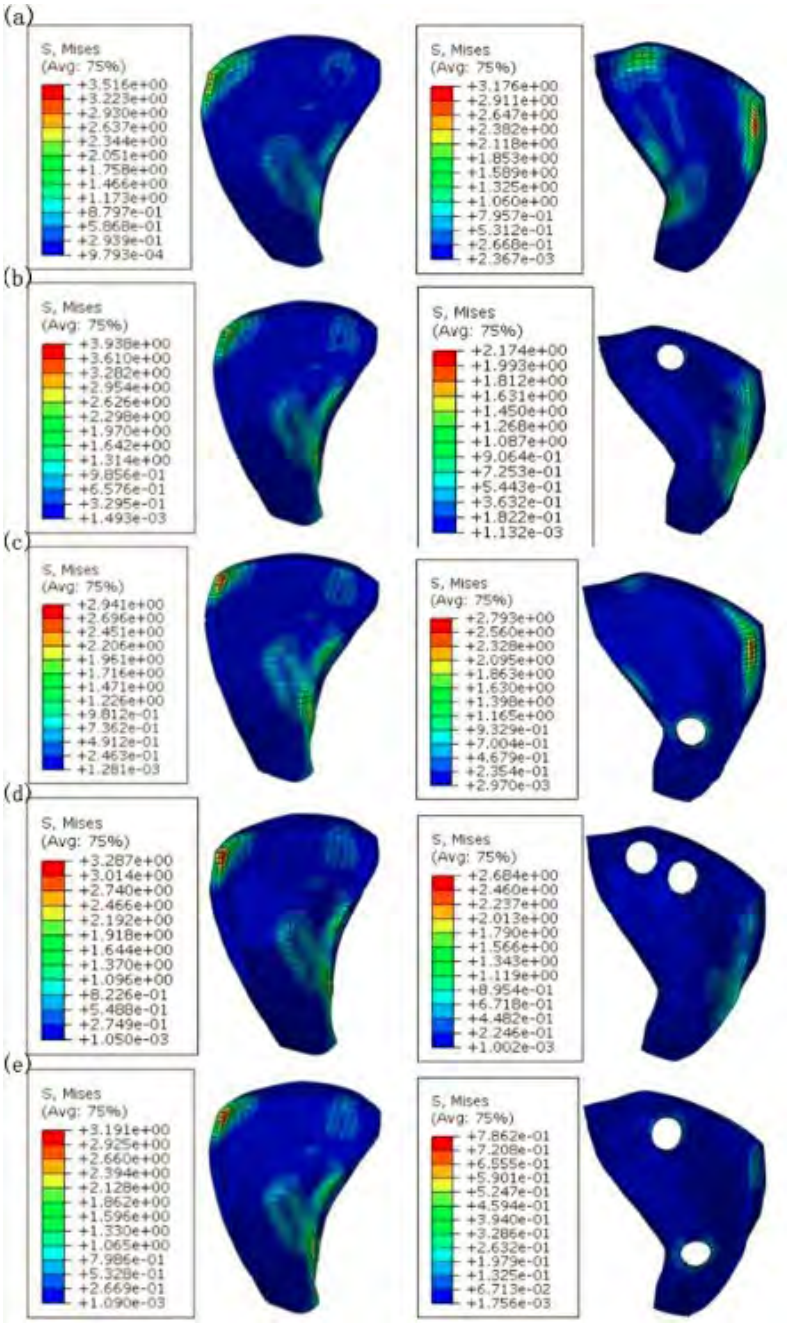
[1]Department of Orthopaedic Surgery, General Hospital of Chinese People's Liberation Army, Beijing, China

Introduction and Objectives: Sacroiliac screw fixation are widely applied in the pelvic fractures and sacroiliac joint dislocations. Many cadaver biomechanical study have been done for the stability of fixations. However, many patients feel uncomfortable and low back pain after fixations which may be cause by the biomechanical change on cartilage. At the same time, the information of stress distribution and changes are difficult to be obtained from cadaver studies. Therefor the three-dimensional finite element model of pelvic was developed for this study to analyze the biomechanical change of sacroiliac joint cartilages after different percutaneous screw fixations.

Methods: Finite element pelvic models reconstructed, bones, cartilages, and ligaments of FE model were developed. The Tile type-B and type C sacroiliac joint disruption were analyzed based on fixation with a single S1 screw (S1-1), single S2 screw (S2-1), two S1 screws (S1-2) and a combination of a single S1 and a single S2 screw (S1-S2). The stress of cartilage and pelvis change were compared and analyzed in bilateral stance.

Results: The largest difference values between both cartilages was in the S1-1 fixation of type C dislocation (2.79Mpa). The smallest difference values between both cartilages was in the S1-2 fixation of type B dislocation (0.51Mpa). The differences of same fixations in type C were larger than in type B. The dislocation more stable, the stress closer between left and right sacroiliac joint cartilages. In the S2-1 fixations, both side of cartilage stress increased (5.25Mpa and 4.45Mpa in type B, 7.68Mpa and 5.10Mpa in type C). In the S1-S2 fixations, both side of cartilage stress is the minimum value (0.79Mpa and 2.94Mpa in type B, 1.07Mpa and 3.06Mpa in type C). The difference of stress in 4 kind of percutaneous fixation in type B disruption and normal pelvis are very small. The normal pelvis stress range from 0-2.347 (Mpa). The S1-1 fixation stress range from 0-2.989(Mpa) in type B and 0-3.234(Mpa) in type C. The S2-1 fixation stress range from 0-2.646(Mpa) in type B and 0-3.945(Mpa) in type C. The S1-S2 fixation stress range from 0-2.854(Mpa) in type B and 0-2.862(Mpa) in type C. The S1-2 fixation stress range from 0-2.832(Mpa) in type B and 0-2.930(Mpa) in type C.

Figure:



Conclusion: The distribution of uninjured side were mainly located at the posterior sacroiliac region and anterior horn. The fixation will increased one side rigidity which will cause the increased wear of the other side. So that, the biomechanical of trans-sacral fixation will be better than the unilateral screw fixations. The differences of same fixations in type C were larger than in type B. The dislocation more stable, the stress closer between left and right sacroiliac joint cartilages. The S2-1 fixation were recommended in type B fractures, and the S1-S2 fixation were recommended in the type C dislocations.

Table:

	Stress of left SIJ cartilage(Mpa)	Stress of right SIJ cartilage(Mpa)	Difference between left and right
Normal	3.18	3.52	0.34
B S1	1.60	3.00	1.40
B s2	5.25	4.45	-0.80
B S1S2	0.79	2.94	2.15

PO-0117

PLAYER LOAD MONITORING IN SPORT: PREDICTING CENTRE OF MASS ACCELERATION FROM BODY-WORN ACCELEROMETRY

Niels J. Nedergaard [1,*] Paulo Lisboa [2] Mark Robinson [1] Jos Vanrenterghem [1]

[1]School of Sport and Exercise Sciences, [2]School of Computing & Mathematical Sciences, Liverpool John Moores University, Liverpool, United Kingdom

Introduction and Objectives: GPS data from units positioned on the upper trunk are frequently used for player monitoring in team sports, yet these devices also include accelerometers and gyroscopes. The accelerometer data can be used to estimate the external load on players (e.g. PlayerLoad™, a cumulative summation of change in resultant accelerations) and to monitor the risk of overuse injuries [1]. The relationship between energy expenditure and PlayerLoad™ has been documented recently [2], but an understanding of the relationship between PlayerLoad™ and the whole-body centre of mass (CoM) acceleration is required to judge how well PlayerLoad™ may relate to the external ground reaction forces. The aim of this study was to investigate the relationship between body-worn accelerometry and whole-body centre of mass (CoM) acceleration during a 45-degree side-cutting task at different intensities.

Methods: Twelve team sports athletes volunteered to participate in this study (age: 23 ± 3 years, mass: 73 ± 11 kg, height: 179 ± 7 cm). All participants completed four anticipated 45-degree side-cutting tasks on their dominant leg at four different approach speeds 2, 3, 4 and 5 m/s (± 5%). Approach speed was measured from photocell timing gates 2 m from where the cut was performed. A 6-degress-of-freedom eight segment model including feet, upper and lower legs, pelvis and trunk was created from kinematic data recorded with 10 optoelectronic cameras (Qualisys AB, Gothenburg, Sweden) sampling at 500 Hz. Trunk acceleration was measured from a triaxial accelerometer within a GPS unit (MinimaxX S4, Catapult Sports, Melbourne, Australian) sampling at 100 Hz. This was positioned as typically worn; on the upper part of the trunk in an elastic vest. Additional acceleration data was collected from three triaxial accelerometers (Noraxan USA Inc., Scottsdale, USA) sampling at 1000 Hz, positioned directly onto the GPS unit, on the hip (between the left and right PSIS) and the anterior tibia.

PlayerLoad™ and resultant peak accelerations were determined during the foot-ground contact and Pearson's correlation coefficients were used to determine any relationships between CoM accelerations and accelerometry data across the different approach speeds.

Results: Stronger relationships were observed between peak CoM acceleration and peak accelerometry data compared to CoM PlayerLoad™ and accelerometry data PlayerLoad™ (Table 1), whereas accelerometry location had little effect on the relationship with CoM acceleration.

Conclusion: Body-worn accelerometers measure the accelerations of the segment they are attached to, while the CoM acceleration represents the accelerations of the whole body, this may explain the moderate relationship. As the acceleration signals were unprocessed, this data may not be best suited to the estimation of external ground reaction forces acting on the players' body in the field. Accelerometer specification, data processing and relative movement of the trunk accelerometer compared to the Catapult trunk accelerometer may explain the difference observed within the trunk.

Further studies and other approaches using body-worn accelerometry are needed to better estimate the peak and accumulated external ground reaction forces acting on the body during team sports in the field.

Table:

	CoM Acceleration	Catapult (Trunk)	Trunk	Hip	Tibia
Peak acceleration (g)					
2 m/s	1.5 (0.3)	2.7 (0.5)	3.6 (1.0)	4.4 (1.1)	8.4 (2.4)
3 m/s	1.9 (0.4)	3.4 (0.7)	4.5 (1.1)	5.8 (1.5)	12.0 (3.9)
4 m/s	2.7 (0.7)	4.2 (1.0)	5.5 (1.5)	8.3 (2.9)	17.1 (4.4)
5 m/s	3.0 (0.6)	4.3 (0.8)	5.7 (1.5)	10.1 (4.3)	19.7 (5.2)
Pearson's r	-	0.732*	0.650*	0.711*	0.709*
PlayerLoad™ (au)					
2 m/s	6 (1)	9 (2)	17 (7)	19 (7)	59 (17)
3 m/s	7 (1)	10 (3)	20 (6)	27 (9)	88 (25)
4 m/s	10 (2)	13 (4)	26 (9)	43 (15)	134 (31)
5 m/s	10 (2)	14 (3)	26 (6)	50 (22)	158 (40)
Pearson's r	-	0.683*	0.658*	0.660*	0.698*
** Denotes a significant correlation, p<0.01.*

VARIABILITY IN THE PEAK OF PLANTAR PRESSURE IN CHILDREN, ADULT AND ELDERLY DURING WALKING

Pedro S. Franco [1 2] Emmanuel da Rocha [1 2] Caio da Silva [2] Gislaine Santos [2] Mariane Figueiredo [2] Renato Azevedo [2] Felipe Carpes [1 2,*]

[1]Graduate Program in Physical Education, Federal University of Santa Maria, Santa Maria, [2]Applied Neuromechanics Group, Federal University of Pampa, Uruguaiana, Brazil

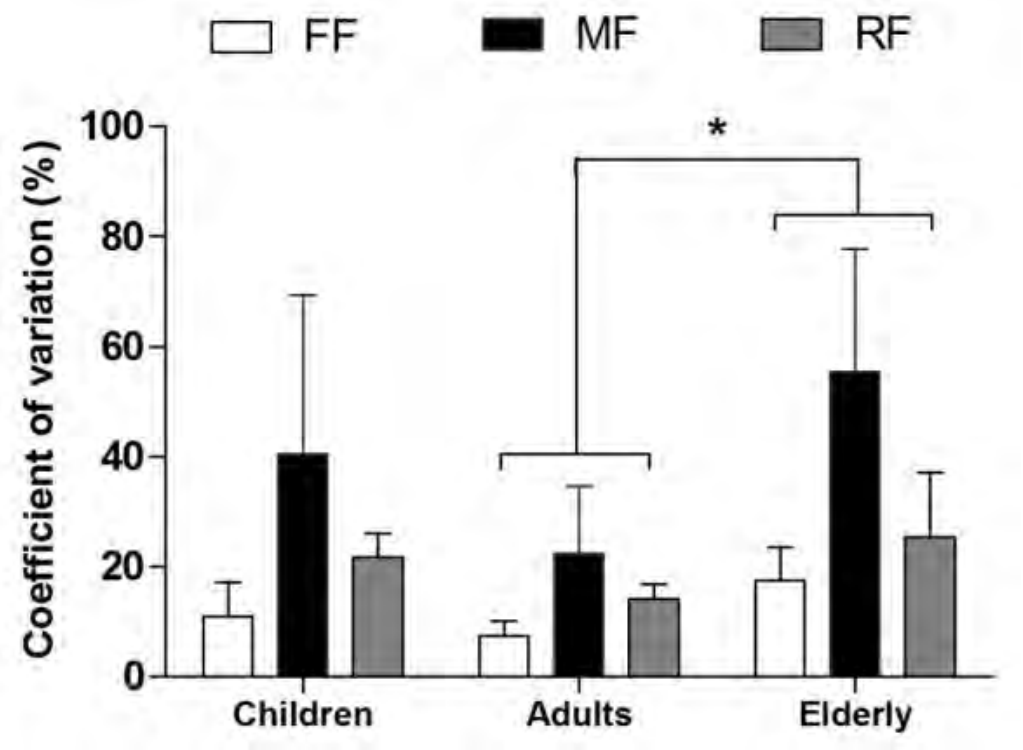
Introduction and Objectives: Plantar pressure is a biomechanical measure commonly used to quantify mechanical loads in the foot during standing and walking. Occurrence of peak pressures on specific foot sites can be related to foot injuries and skin damages. Such conditions are especially investigated in the elderly. Although previous studies addressed average plantar pressures in different foot regions in people of different ages, variability of plantar pressure is briefly considered. Considering that elderly are subjected to foot injuries most likely due to higher plantar pressure, it could be possible that in the elderly a lower variability in the peaks of plantar pressure result in repetitive loads leading to higher risk of injury. Therefore, in this study we quantified and compared the variability in the peak of plantar pressure between able-bodied children, adults and elderly during walking.

Methods: Participants were 7 children (mean age ± SD 10 ± 1 years old, body mass 46 ± 14 kg and height 1.45 ± 0.16 m), 7 adults (age 39 ± 5 years old, body mass 71 ± 21 kg and height 1.64 ± 0.09 m), and 7 elderly (age 74 ± 2 years old, body mass 64 ± 11 kg and height 1.59 ± 0.06 m). For data acquisition, participants walked barefoot in a 9 m walkway. Walking was performed at self-selected speed. Plantar pressure (PP) was recorded at 400 Hz by using a pressure mapping system (Matscan, Tekscan Inc, USA). Data from 5 steps were recorded for determination of the peak of pressures in the forefoot (FF), midfoot (MF) and rearfoot (RF) [1] and normalized by the individual body mass. The coefficient of variation was determined as the ratio between the standard-deviation and the mean. Data normality was verified using Shapiro-Wilk's test. One-way ANOVA for repeated measures was used to compare the coefficient of variation in each foot region between the groups. Tukey post-hoc was applied when suitable. Significance level was set at 0.05 for all analyses using the SPSS 20.0.

Results: We found an effect for the group in all foot regions [FF ($F_{(2)}$=6.729; p=0.007), MF ($F_{(2)}$=3.862; p=0.040) and RF ($F_{(2)}$=4.372; p=0.28)]. Elderly present greater variation in peak of plantar pressure than adults in the FF (p=0.005), MF (p=0.032) and RF (p=0.025), but similar to observed in the children (p=0.083; p=0.439; p=0.623, for FF, MF and RF, respectively). Adults were similar to children for FF (p=0.395), MF (p=0.304) and RF (p=0.152). Results are presented in the Figure 1.

The higher variability in plantar pressure observed in the elderly compared to adults can be resultant of variability inherent to the aged gait and that make them in higher risk of falling [2].Rather, it would be important to identify if such variability is consistent enough to elicit some risk to the elderly health.

Figure:



Caption: Figure 1. Coefficient of variation for the peak of plantar pressure in the elderly, adults and children in each foot region. FF means forefoot; MF, midfoot; and RF, rearfoot. * indicates statistically significant difference ($p<0.05$).

Conclusion: Elderly presented higher variability in the peak of plantar pressure than observed among adults. Next step in this research will be dedicated to verify if such pattern is consistent when elderly are assessed in repeated days.

THREE DIMENSIONAL KINEMATICS OF THE HUMAN METATARSOPHALANGEAL JOINT DURING LEVEL WALKING AND RUNNING

Sivangi Raychoudhury [1,*] Dan Hu [1] Lei Ren [1]

[1]Biomechanics, Mechanical engineering, University of Manchester, Manchester, United Kingdom

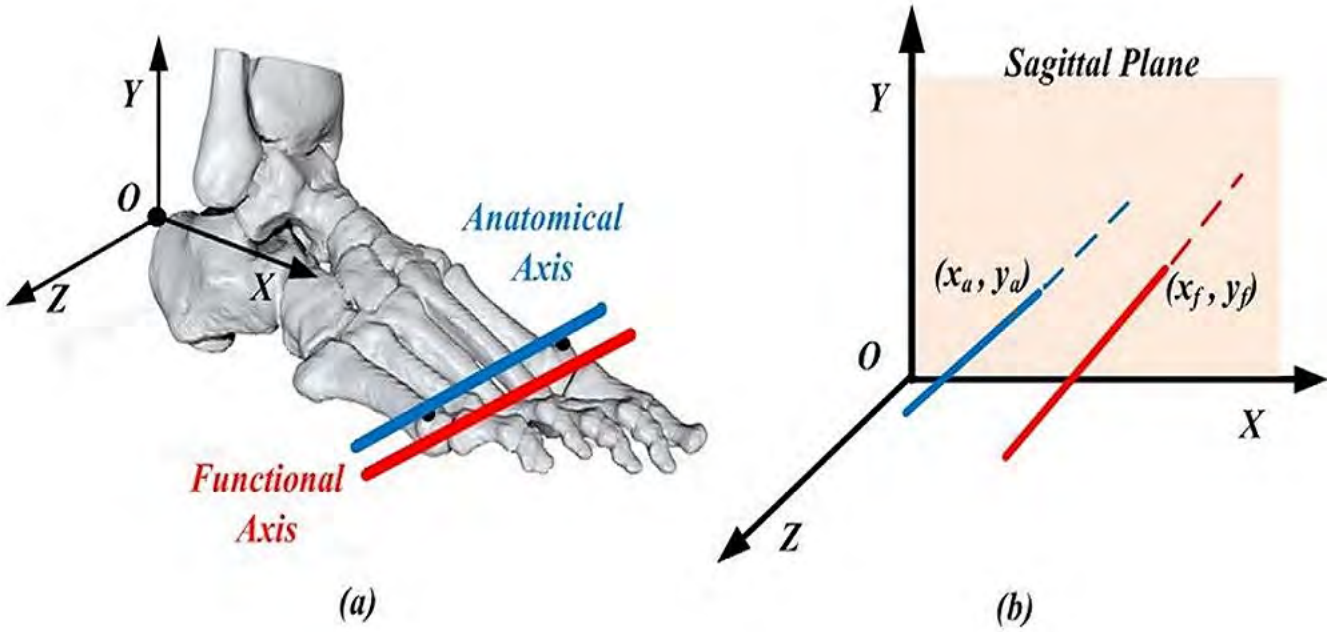
Introduction and Objectives: The human foot plays many important roles in maintaining stability, generating propulsive powers and attenuating ground impacts during locomotion. However, our understanding of the biomechanical function of the forefoot is very limited. So far, little is known about the in vivo orientation and position of the functional rotation axis of the metatarsophalangeal (MP) joint during locomotion and how it changes with varying speed. The objective of this study is to investigate the three-dimensional (3D) kinematics of the functional rotation axis of the human MP joint during level walking and running at different speeds.

Methods: Six male subjects with no medical history of foot injury participated in this study. The subjects walked and ran at their self-selected slow, normal and fast speeds. To record the 3D motions, marker clusters were attached on the foot. A 12 infrared camera motion analysis system (Qualisys, Sweden) was used to capture the motions at 150 Hz. Six force plates (Kistler, Switzerland) were used to record the ground reaction forces (GRFs) and moments at 1000 Hz. A set of static calibration procedures were undertaken to locate the anatomical landmarks. Five rigid segments were defined to represent the lower limb: pelvis, thigh, shank, tarsometatarsi and phalanges. The 3D anatomical coordinate system was defined for each individual segment. We have assumed that the five phalanges form a single rigid segment and the MP joint is a single hinge type joint. The anatomical axis (AA) of MP joint was defined as an oblique line connecting the 1st and 5th metatarsal heads. While the functional axis (FA) was defined as the rotational axis between the hindfoot and forefoot segments (see Figure 1). Raw data were processed using GMAS (Generalised Motion Analysis Software), a MATLAB based software package for 3D kinematic and kinetic analysis of biomechanical multi-body systems. Statistical analyses were conducted using SPSS 20.0 software (IBM, Armonk, New York, USA) to investigate the 3D position and orientation differences between the AA and FA, and the effect of locomotor speed on the axes of MP joint by considering subjects and trials as random effects. Difference between AA and FA, and between each pair of speeds were tested using Fisher's least significant difference multiple comparison based on the least-squared means, considering probability $p<0.05$ as statistically significant.

Results: Statistically significant differences were found for all the orientation and position parameters across all three speeds, except for the vertical position parameter *y* at slow walking speed. The FA of MP joint has a more anterior and superior position than the AA across all speeds. The FA remains anterior to AA with an average distance of about 16% of the foot length. The FA is superior to AA with an average distance about 2% of the foot length during normal and fast walking. The FA shows an anteriorly more medial and more superior orientation than the AA. The joint orientation angle difference is more significant in the sagittal plane than in transverse plane. The joint position in the anterior posterior direction shows statistically significant difference when walking speed changes from slow to fast. The FA moves forward,

towards a more anterior position. Also the FA moves upwards towards a more superior position appreciably with increasing speed.

Figure:



Caption: Figure 1. (a) The FA (red) and AA (blue) of the MP joint (b) The position of the FA is defined by its intersection point (xf, yf) and the location of the AA by (xa, ya) with the XOY plane of the foot coordinate system.

Conclusion: The position and orientation differences found between AA and FA suggests that using AA to represent the MP joint, as normally used in previous studies, may result in overestimated joint moment and power and underestimated muscle moment arms for MP extensor muscles. The joint axis shift towards the GRF vector in the late stance of walking will result in decreased moment arm of GRF and simultaneously increased moment arm of MP extensor muscles, hence will increase the effective mechanical advantage (EMA) of MP extensor muscles. The forward shift of the MP joint axis will result in an increased lever distance to the ankle joint and may moderate the angular velocity increase with increasing speed. The forward and upward FA shift may help to maximise the locomotor efficiency and reduce the risk of injury. This study may help us to better understand the contribution of the intrinsic foot structure to the propulsive function of the foot during locomotion at different speeds. Furthermore, this may also help in improving the design of sports and therapeutic footwears, prosthetic lower limbs and robotic legs.

DIFFERENCES IN LOWER LIMB KINEMATICS AND KINETICS BETWEEN OLDER MALES AND FEMALES WITH OSTEOARTHRITIS

Olivia Zajdman [1,*] Daniel Benoit [1]

[1]Human Kinetics, University of Ottawa, Ottawa, Canada

Introduction and Objectives: Osteoarthritis (OA) is a slow, progressive degradation of articular cartilage and subchondral bone, most commonly found in the knee [6]. OA affects 13% of Canadian adults and is 2-3 times more prevalent in females than males [1]. Differences in strength and muscle activation patterns are present between sexes [4]. These factors will affect the biomechanics of the lower limb and may cause kinematic differences in squatting strategies between males and females. Males with OA have been shown to display lower limb gait kinematics similar to healthy populations, while females demonstrate different biomechanical tendencies [3]. Lower limb kinematics during a counterbalanced and two-legged squat have previously been compared between young, healthy, active male and female subjects [2], but not in an OA population. It is unclear what the kinematic differences between sexes are in an OA population during a two-legged squat despite being an essential activity of daily living. The purpose of this study is to characterize differences in peak sagittal plane hip, knee, and ankle moments (M) and sagittal plane peak knee flexion angle between male and female older adults with osteoarthritis.

Methods: Nine male [62.9 $\pm$ 8.6 years; BMI 24.5 $\pm$ 4.1; KOOS: 72.25$\pm$ 14.8] and eight female [60.3 $\pm$ 8.3 years; BMI 26.8 $\pm$ 3.0; KOOS: 63.94$\pm$ 11.02] adults with knee OA have participated in this study. No subject had a significant lower limb musculoskeletal injury within six months of participation or a BMI ≥40kg/m2. Subjects completed the Knee injury and Osteoarthritis Outcomes Score (KOOS) and affected limb(s) were recorded before data collection. Subjects performed 3 two-legged squats on two force platforms, and were instructed to squat down to 90^{o} knee flexion, if possible, at a self-selected pace. Squat range was not standardized due to range of motion variability within the participant population. Ground reaction force data were recorded from the platform at 1000Hz. Marker trajectories were captured at 200 Hz with a ten-camera infrared Vicon motion analysis system. Lower limb kinetic and kinematic data were recorded and outputted using *Nexus* software. Peak sagittal plane hip, knee, and ankle moments, body weight normalized, and sagittal plane peak knee flexion were determined for the affected leg(s) through custom-made *MatLab* software. A one-way repeated measures ANOVA was performed for peak sagittal plane hip, knee, and ankle moments and sagittal plane peak knee flexion using SPSS at an alpha level of 0.05.

Results: There were significant ($p < 0.05$) differences seen in peak hip moment and knee flexion angle at a self-selected squatting speed between sexes (Table 1). Males exhibited statistically significant larger peak hip moment (M =-0.755 Nm/kg; F= -0.528 Nm/kg) and peak knee flexion angle (M= 102.32 ^{o}; F= 77.61 ^{o}) than females.

Conclusion: Males and females with knee OA exhibited differences in kinetic and kinematic squat parameters. Differences in lower limb mechanics between sexes may cause kinematic variations in squat execution and play a role in the greater incidences of OA in females [1]. Males showed greater peak hip moments, suggesting a more hip dominant squat strategy. This is known to decrease knee loading [2] and may have allowed males to increase peak knee flexion by using

a more efficient squatting technique that was less painful. A similar pattern was seen in adolescents performing single leg squats, where males exhibited greater eccentric hip torque [5]. Knowing the sex differences in joint kinetics and kinematics of a squat could allow for more targeted and successful rehabilitation interventions in persons with OA.

Table:

Variable	Sex	Mean	Standard Deviation	P value
Peak Hip M (Nm/kg)	F M	-0.528 -0.755	0.169 0.169	0.014*
Peak Knee M (Nm/kg)	F M	-0.615 -0.667	0.140 0.180	0.522
Peak Ankle M (Nm/kg)	F M	-0.332 -0.328	0.139 0.124	0.955
Peak Knee Flexion Angle (°)	F M	77.61 102.32	13.18 18.6	0.007*

Caption: Table 1: Males and Females with knee OA show significant ($p < 0.05$) differences in squat parameters (*).

CHARACTERISTICS OF JOINT TORQUE DURING WALKING WITH PUSHING A WHEELCHAIR

Tetsu Yamada, Masami Hidaka

Introduction: Transportation using a wheelchair is a commonly used method for a person with lower limb disorder, an elderly person, and others. Most person who use a wheelchair need support by another person to drive the wheelchair. Although such support to drive a wheelchair is important, there has been little research to investigate the kinetics of walking with pushing a wheelchair.

The purpose of this study was to investigate joint torques of lower limbs during walking while pushing a wheelchair.

Methods: Five healthy male subjects (age: 20.6 ± 1.0 years, height: 1.71 ± 0.07 m, mass: 56.2 ± 5.2 kg) volunteered for participation. All the subjects signed an informed consent form. All experimental protocols were approved by the research ethics board of Hyogo University of Health Sciences.

An 8-camera motion capture system (Vicon MX, Vicon Motion Systems; Oxford, UK) operating at 100 Hz was used to collect all kinematic data. On each subject were attached 34 retroreflective markers, at bony landmarks of the Plug-in-gait model (Vicon Motion Systems; Oxford, UK). Kinematic and kinetic parameters were then calculated by using the Plug-in-gait model.

Analysis of variance (ANOVA) was performed for spatial and temporal descriptors and joint torques. Post hoc analyses for significant parameters were performed using Tukey's multiple comparison test. The level of significance was set at less than 0.05.

Results: Stride time (normal: 1.03±0.05 s; wheelchair: 1.03±0.08 s; weighted wheelchair: 1.10±0.07 s) and stride length (normal: 1.43±0.08 m; wheelchair: 1.39±0.15 m; weighted wheelchair: 1.38±0.16 m) were not significantly different among three conditions. Velocity of walking while pushing the weighted wheelchair (1.25±0.10 m/s) was significantly smaller than that of normal walking (normal: 1.39±0.09 m/s; wheelchair: 1.35±0.13 m/s) ($p < 0.05$).

The patterns of joint torque of the hip, knee, and ankle were mostly similar among three conditions. The peak flexion torque of the hip of normal walking (1.30±0.26Nm/kg) was significantly greater than when pushing a wheelchair (wheelchair: 0.83±0.19Nm/kg; weighted wheelchair: 0.79±0.21Nm/kg), either with or without the weight ($p < 0.05$). The peak extension torques of the hip were not significantly different among three conditions. The peak extension torque of the knee of normal walking (0.74±0.19Nm/kg) was significantly greater than when pushing a wheelchair (wheelchair: 0.55±0.13Nm/kg; weighted wheelchair: 0.40±0.12Nm/kg), either with of without the weight ($p < 0.05$). The peak flexion torques of the knee were not significantly different among three conditions. The peak plantar flexion torque of the ankle of normal walking (1.52±0.15Nm/kg) was significantly greater than when pushing a wheelchair (wheelchair: 1.28.83±0.09Nm/kg; weighted wheelchair: 1.16±0.19Nm/kg), either with of without the weight ($p < 0.05$). The peak dorsiflexion torques of the ankle were not significantly different among three conditions.

The walking velocity and thigh segment angle of the normal walk were great (normal: 63.3±5.3 deg.; wheelchair: 38.2±12.9 deg.; weighted wheelchair: 33.0±13.3 deg.), therefore the hip flexion torque of the normal walk had to been greater than the other conditions.

During walking with pushing a wheelchair, subjects could support part of themselves weight by pushing a wheelchair downward. The peak extension torque of the knee and the peak plantar flexion torque of the ankle during pushing a wheelchair were developed smaller than normal walking, because these support pushing a wheelchair decreased load that need to support by lower limbs.

Conclusion: This study investigated joint torques of the lower limbs during walking while pushing a wheelchair. The hip flexion torque, the knee extension torque, and the ankle plantar flexion torque were developed smaller during the pushing a wheelchair than normal walking. These changes were affected by the support with hands pushing a wheelchair downward.

PO-0123

ISOKINETIC STRENGTH OF LOWER LIMB MUSCLES IN RECREATIONAL RUNNERS WITH CHRONIC LOW BACK PAIN

Congcong Cai [1] Pui W. Kong [2,*]

[1]Physiotherapy, Rehabilitation Department, Alexandra Hospital-Jurong Health Service , [2]Physical Education and Sports Science Academic Group, Nanyang Technological University, Singapore, Singapore

Introduction and Objectives: Back injuries are common among runners but little is known about the strength characteristics of lower limb muscles in runners with chronic Low Back Pain (LBP). This study aimed to compare the isokinetic strength of the hip and knee muscles between chronic LBP and healthy recreational runners.

Methods: Using a retrospective design, 18 [9 males, age = 27.8 (5.6) yr) recreational runners with chronic LBP and 18 [9 males, age = 24.6 (3.5) yr) healthy runners were recruited. Maximum concentric torque of bilateral hip extensors and abductors, and knee extensors were measured using an isokinetic dynamometer at 60˚/s. Peak torques were normalized to individuals' body mass by ratio scaling. A general linear model with repeated measures was used to detect differences in the lower limb strengths between the chronic LBP and healthy runners (between-subject factor: LBP condition, within-subject factor: side of the body, age was used as a covariate).

Results: The LBP runners presented lower knee extensors peak torque than the healthy runners (P = .020, Table 1). There were no significant differences found in hip extensor and abductor isokinetic strength. No bilateral differences were observed in any strength variables.

Runners with chronic LBP are characterized by weaker knee extensor strength compared with healthy runners. In literature, there is no information on lower limb strength in chronic LBP runners but the association between isokinetic knee strength reduction and trunk weakness in patients with disc herniation and other chronic LBP populations has been reported [1,2]. Knee extensor inhibition and trunk muscle endurance reduction as detected by EMG were also found in golfers with chronic LBP.[3] In a study specifically on runners, increased knee joint stiffness during running has been reported in chronic LBP runners comparing to the healthy controls.[4] During running, the quadriceps contract eccentrically following initial contact, playing an essential role as shock absorbers.[5] Weakness and inhibition of the knee extensors may increase knee joint stiffness during running and therefore reducing its capacity for shock attenuation. The shock from ground may then transmit to the low back, increasing lumbar spine stress.

Conclusion: Chronic LBP runners showed lower knee extensor isokinetic strength. Assessing knee extensor strength may contribute to the screening, diagnosis and rehabilitation of chronic LBP runners.

Table:

Torque	Side	LBP	Healthy		*P*-value	
				Condition	Side	Condition × side
Knee extensor (Nm/kg)	D	2.19 (0.43)	2.49 (0.39)	**.020**	.240	.389
	ND	1.96 (0.38)	2.41 (0.36)			
Hip extensor (Nm/kg)	D	1.19 (0.36)	1.43 (0.50)	.223	.615	.734
	ND	1.25 (0.30)	1.43 (0.45)			
Hip Abductor (Nm/kg)	D	1.28 (0.46)	1.30 (0.40)	.437	.051	.235
	ND	1.27 (0.47)	1.39 (0.45)			

Data are in mean (standard deviation). D = dominant, ND = non-dominant.

PO-0124

AN APPROACH TO SIMULATING OVERGROUND ACCELERATIVE LOCOMOTION MECHANICS ON A TREADMILL

Dominic J. Farris [1 2,*] Glen Lichtwark [1] Andrew Cresswell [1]

[1]School of Human Movement & Nutrition Sciences, The University of Queensland, Brisbane, [2]Australian Institute of Sport, Canberra, Australia

Introduction and Objectives: van Ingen Schenau [1] described how the mechanical demands of constant speed treadmill locomotion are the same as for overground. However, the same cannot be said for accelerative locomotion overground vs. treadmill locomotion while the belts are accelerated. As shown by van Caekenberghe et al. [2], on an accelerating treadmill belt one is not required to produce the same propulsive impulse as for overground. This is owing to a component of acceleration coming from the acceleration of the reference frame and not acceleration of the body centre of mass (COM) [2]. This results in a theoretical missing component of fore-aft force. Considering the use of wired measurment systems and the advent of instrumented treadmills for biomechanics research, it would be useful to reproduce the mechanics of accelerative movements on a treadmill.

Therefore, we applied a horizontal force proportional to body mass and belt acceleration via a spring element to participants as they walked and ran on the accelerating belt of an instrumented treadmill. The aim was to induce a net fore-aft impulse and net mechanical work demand similar to what would theoretically be required overground. We hypothesised that providing the additional force would result in more similar mechanical demands to overground acceleration than providing no additional force.

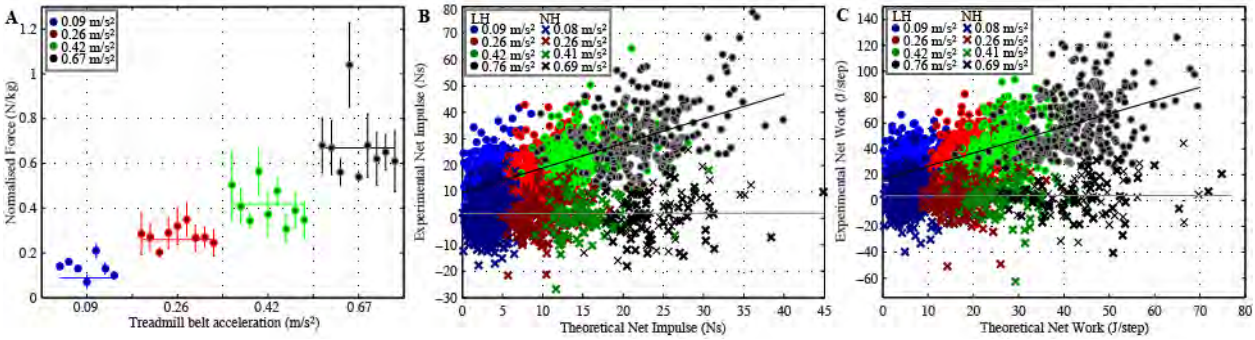
Methods: Nine males (mean ± s.d. age = 26 ± 4 years, height = 1.81 ± 0.5 m, mass = 81 ± 9 kg) participated in the study. Each walked and ran on a fore-aft split belt instrumented treadmill (AMTI, USA) as the belts were linearly accelerated at 0.09, 0.26, 0.42 and 0.67 $m \cdot s^{-2}$ from 0.8 to 2.75 $m \cdot s^{-1}$. For every acceleration the task was completed with and without a horizontal (fore-aft) force applied to participants. This force was applied via a harness worn on the torso and rubber tubing that was anchored to a winch situated 4 m behind the treadmill. A load cell measured the force and the force magnitude was adjusted using the winch to equal the product of body mass and belt acceleration. The instrumented treadmill recorded ground reaction forces (GRF) at 2000 Hz that were filtered using a low-pass cut-off of 25 Hz.

Data were processed on a step-by-step basis. For each step we calculated an experimental value of net fore-aft GRF impulse (I_{net}) and net mechanical work done on the COM (W_{net}). I_{net} was calculated as the integral of the fore-aft GRF and W_{net} as the integral of COM power. COM power was the dot product of the sum of all external forces (including load cell force) and the velocity of the COM. We computed COM velocity as the integral of COM acceleration, which was determined by dividing net external force by body mass. This was an adaptation of the Combined Limbs Method of Donelan et al. [3]. For the trials where a force was applied (LH), the average load cell force (F_{LC}) was also calculated. For comparison to experimental measures, we also computed theoretical values for I_{net}, W_{net} and F_{LC}. Theoretical I_{net} was the product of body mass and the change in velocity of the treadmill belt. Theoretical W_{net} was calculated as: 0.5 x body mass x (final belt velocity^2 - initial belt velocity^2). We multiplied the acceleration of the treadmill belt by body mass to determine

theoretical F_{LC}. Theoretical I_{net} and W_{net} values for each step for all participants were linearly regressed against experimental values from LH and when the harness was not loaded (NH).

Results: The average experimentally achieved F_{LC} at each acceleration rate is compared to the theoretical F_{LC} in Fig. 1A. The experimental F_{LC} proved a reasonable approximation of the theoretical values. Figures 1B & C shows the regressions for I_{net} and W_{net}. For I_{net}, the regression produced a slope of 0.94 (R^2 = 0.41) for LH and 0.003 (R^2 < 0.00) for NH. For W_{net}, a slope of 1.01 (R^2 = 0.44) was observed for the LH condition and only 0.004 (R^2 < 0.00) for NH. Regressions produced highly significant (P<0.0001) correlations between theoretical and experimentally derived I_{net} and W_{net} for LH but, non-significant (P = 0.88 and P =0.90) for NH.

Figure:



Caption: Fig 1. (A) Participant normalised load cell force (o) vs. theoretical force (lines). (B) Regression for net fore-aft GRF impulse - LH (o, black line), NH (x, grey line). (C) Regression for net mechanical work - LH (o, black line), NH (x, grey line)

Conclusion: Our hypothesis was supported by the regression results that showed significant and moderate correlations between theoretical and experimental I_{net} and W_{net} values when an appropriate force was applied, but not when no force was applied. For future experiments this could be improved upon by removing outlying steps where the experimental F_{LC} did not match the theoretical F_{LC} well, or by developing a more accurate method of applying the appropriate force.

THE EFFECT OF GAIT VELOCITY ON JOINT MOMENTS AFTER ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION

Karine J. V. Stoelben [1,*] Mateus Silveira [1] Evangelos Pappas [2] Carlos Mota [1]

[1]Laboratory of Biomechanics, Federal University of Santa Maria, Santa Maria, Brazil, [2]Faculty of Health Sciences, University of Sidney, Sidney, Australia

Introduction and Objectives: Compensatory gait adaptations after an anterior cruciate ligament reconstruction (ACLR) can indicate individual protection mechanisms to avoid overload on the affected knee [1]. Asymmetries generated by these compensatory changes can lead to injuries and degenerative diseases [2].

Even two years after ACLR neuromuscular deficits persist [3]. However, the effect of increasing gait speed in patients who had ACLR at least four years ago has not been investigated. Therefore, the objective of this study was to analyze joint moments of the lower limbs in adults who had ACLR at least 4 years ago while walking at two different velocities.

Methods: Six men between 30 and 45 years old took part in the study. All of them had ACLR between four and eight years ago. KOOS and IKDC questionnaires were completed before the measurement of gait biomechanics. Then, participants were asked to walk on a 10m walkway at two different velocity conditions: their preferred walking speed and 30% faster than the preferred speed.

Six infrared cameras (VICON system) captured the motion of 16 markers (PlugInGait Model) attached to body landmarks with acquisition frequency set at 200 Hz. Two force plates (AMTI) recorded the kinetic data at 1000 Hz sampling rate. Kinematic and kinetic data were filtered by a 4^{th} order Butterworth low pass filter, with cut-off frequency of 6 Hz. Walking speed was monitored during the data collection using two photocells positioned six meters apart but also assessed by tracking the average velocity of one marker attached to the participants' hip. Joint moments were calculated with inverse dynamics equations of motion (NEXUS 1.8.5, VICON).

Three successful trials (total landing of the foot upon the force plate and gait velocity within 5% of target) for each condition were used in the analysis. Joint moment data were normalized to the stance phase of the gait cycle and statistically compared between limbs and velocities at 10% increments of the stance phase of the gait cycle (Fig. 1). Data normality was verified by Shapiro-Wilk test and the limbs (ACLR vs. intact) were compared with independent Student t test or with U Mann Whitney, accordingly. The comparison between velocities was performed with a paired t test or Wilcoxon. The significance level was set at $\alpha = 0.05$ a priori.

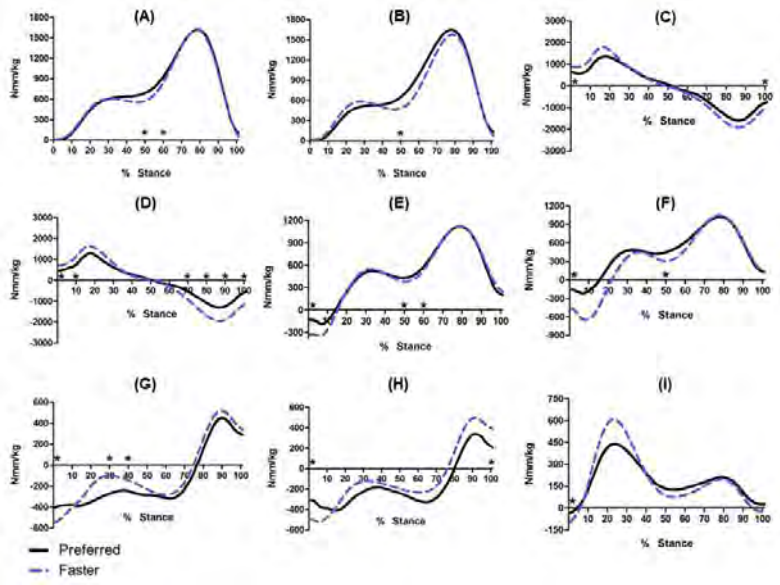
Results: The participants' characteristics were (mean ± standard deviation) age of 36.67 ± 4.57 years; height of 174.8 ± 6.97 cm, mass of 90.82 ± 6.18 kg, time since ACLR of 70.17 ± 15.12 months, IKDC score of 84.48 ± 7.47. KOOS scores were: 85.71 ± 10.71 for symptoms, 92.13 ± 5.42 for pain, 96.82 ± 2.15 for activities of daily living, 85 ± 11.55 for sport and recreation function and 62.5 ± 11.97 for knee-related quality of life. Two subjects had the ACLR on the right limb.

No differences were found between ACLR and intact limb for any moments ($p>0.11$).

In respect to the sagittal plane moment, both ACLR and intact limbs showed higher ankle plantarflexion moments at mid stance ($p\leq0.025$) during walking at preferred speed compared to the fast speed. At the beginning of the stance phase,

larger knee moments were observed at faster speeds for both limbs (p≤0,01). The ACLR limb showed larger knee moments in mid stance at the preferred speed (p=0,019) and the intact limb in the final stance (p=0,018). Larger hip extension moments at the beginning (p≤0,018) and larger hip flexion moments at the end of the stance (p≤0,03) were found when walking faster for both limbs. In respect to the frontal plane moment, there were no differences in ankle moments (p>0,17). In the knee, the intact knee showed larger adduction moments at the beginning of the stance when walking faster (p=0,043). Similarly, hip adduction moments were larger at beginning (p≤0,014) and immediately after heel strike (p≤0,028) when walking with faster velocities for both limbs. Schaefer et al. [4] found more symmetrical gait patterns when young adults without injuries increase their velocities. The current results demonstrate different behavior, with greater compensatory patterns when walking faster. Joint moments at the hip showed larger adduction moments for both limbs, suggesting a possible compensatory mechanism to avoid overload on the ACLR knee.

Figure:



Caption: Figure 1: Joint moments of ankle on sagittal plane (A;B); hip on sagittal (C;D) and frontal (E;F) planes and knee on sagittal (G;H) and frontal (I) planes during walking at preferred and faster speeds. ACLR limb: A;C;E;G. Intact limb: B;D;F;H;I. *Different for p<0.05

Conclusion: Faster walking velocities are associated with increased joint moments (mainly around the hip) suggesting possible compensatory mechanisms that may provide insight into the biomechanical mechanisms of the development of post-traumatic knee osteoarthritis.

PO-0126

GAIT RESPONSE TO AN ACUTE PHYSICAL ACTIVITY STIMULUS IN INDIVIDUALS WITH OSTEOARTHRITIS PAIN.

Katherine A. Boyer [1,*] Carl Jewell [1] Jocelyn Hafer [1]

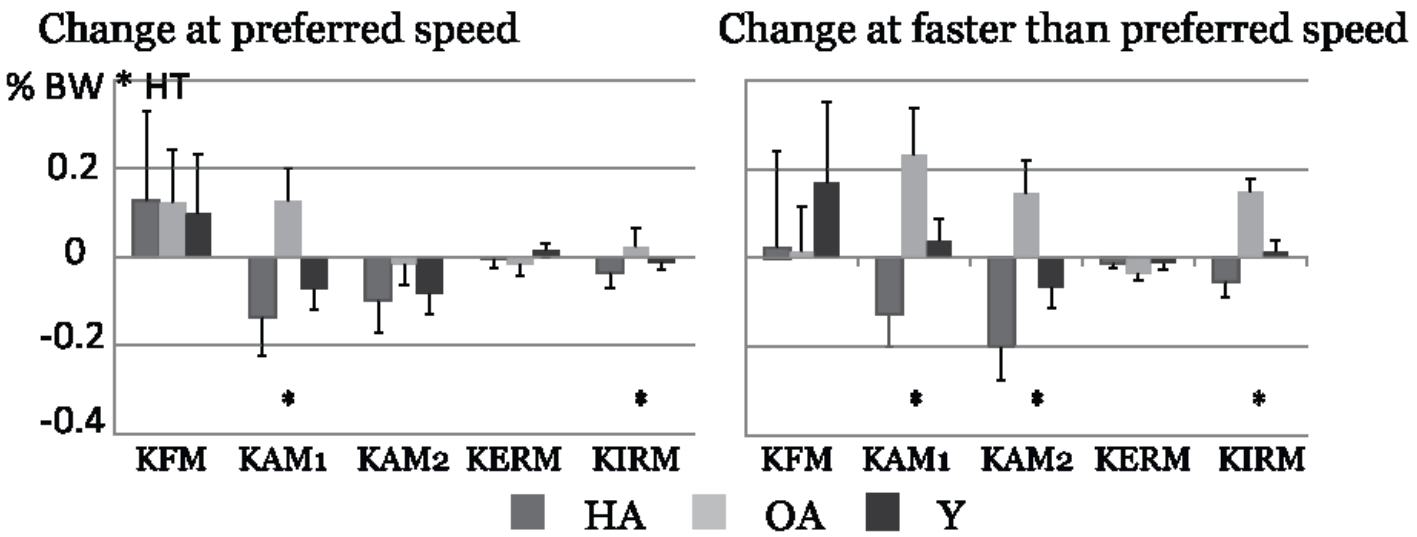
[1]Kinesiology, University of Massachusetts-Amherst, Amherst, United States

Introduction and Objectives: Musculoskeletal pain related to osteoarthritis (OA) is a major cause of disability in older adults. Despite significant effort to improve pain management in OA, there has been limited success as current therapies provide only mild to moderate pain relief.[1] A contributing factor to this variable success may be a lack of information regarding changes in the mechanical environment of the joint with pain. Weight bearing activity is known to exacerbate OA pain on a short term basis [2]; however, very little is known about patient gait compensations to acute flares of OA pain. This acute increase in pain in response to a mechanical stimulus (i.e. weight bearing activities) presents an opportunity to probe the motor system adaptation to pain in the absence of changes in disease severity. The aim of this study was to test the hypotheses that, in response to a 20 minute moderate paced walking stimulus (20MWS), there would be an increase in pain for knee OA patients and there would be a significant difference in the change in ambulatory function and gait mechanics for knee OA patients compared with pain free, healthy younger and older adults.

Methods: Thirty subjects including 14 healthy younger adults (HY) (24.36 ± 3.7 yrs; 23.8 ± 2.8 kg/m^2; 10 healthy older adults (HO) (63.9 ± 5.0 yrs; 22.7 ± 2.8 kg/m^2) and 7 older adults with knee pain (OA) (62.3 +/- 6.2 years; 24.8 +/-2.8 kg/m^2) were enrolled after completing the informed consent process and a Physical Activity Readiness Questionnaire (PAR-Q+). For the OA group, the Knee Osteoarthritis Outcome Score (KOOS) was used to assess knee symptom severity. Gait mechanics data were collected before and after the 20MWS while subjects walked at a preferred and faster than preferred speed over a 20m long walkway with embedded forceplates. External joint moments were calculated for the lower limb using an inverse dynamics procedure. For the 20MWS, subjects walked on a treadmill at a pace similar to the faster than preferred overground speed, or “fitness” pace. For the OA group perceived pain was evaluated on an 11 point verbal numeric pain rating scale (vNRS) in the first and final 2 minutes of the 20MWS. Primary outcome measures were walking speed, stance time, 1st and 2nd peak ground reaction forces (GRF1, GRF2), maximum external knee flexion (KFM), adduction (KAM1, KAM2), external rotation (KERM) and internal rotation (KIRM) moments. Significant group differences in the change in gait outcomes following the 20MWS were tested for using a one-way analysis of variance with least significant difference adjusted post-hoc testing and alpha level of 0.1.

Results: The mean KOOS pain score for the OA group was 62.7 ± 23.1. The initial and final vNRS were 2 ± 1.7 and 2.4 ± 2.2, respectively (p=0.19). At the preferred walking speed there were significant differences in 1st peak KAM between HO and OA and Y and OA and in the stance time for Y and OA in response to the 20MWS (Figure 1). At the faster than preferred speed there were significant differences in the change pre-post 20MWS for the 1st and 2nd peak KAM between the HO and OA and Y and OA (Figure 1). There were also significant differences in the change pre-post 20MWS in the KIRM between the HO and OA and Y and OA for both speeds. No differences in the change in walking speed or GRF magnitudes were found with the 20MWS.

Figure:



Caption: Figure 1: Changes in joint kinetic parameters in response to the 20MWS for the healthy older (HA), knee OA (OA) and healthy younger (Y) groups. * indicate a significant difference with $p<0.1$.

Conclusion: In contrast to the hypothesis, the OA patients did not report a significant increase in pain in response to the 20MWS however, as expected, there were significant differences in the gait response to a 20MWS between the healthy older, younger and chronic knee OA pain groups. While there was a decrease in the KAM magnitude for the healthy groups following the 20MWS, there was an increase in the KAM, as well as the KIRM for the OA group. The KAM is a surrogate measure for the distribution of loading at the knee joint and this OA group response would thus indicate a possible increase in the load acting across the medial compartment of the knee. In response to the 20MWS, mild muscle fatigue in combination with pain-related inhibition of the knee extensor muscles may combine to alter coordination of movement and the ability to maintain a “protective” gait pattern that individuals with chronic pain may have adopted. The changes in joint kinetics could exacerbate an acute pain flare in response to weight bearing activity. This suggests a need for more complex pain adaptation theories for chronic pain conditions such as knee OA[3]. Given that weight-bearing physical activity is often recommended for management of OA, there remains a need to understand the mechanisms of the unexpected changes in gait.

KINECT-BASED LOWER LIMB MOTION ANALYSIS

Shikha Sarkar [1,*] Lina Stankovic [1] Andrew Kerr [2] Philip Rowe [2]

[1]Electronic and Electrical Engineering, [2]Biomedical Engineering, University of Strathclyde, Glasgow, United Kingdom

Introduction and Objectives: This paper investigates the viability of using the Kinect sensor for the purposes of gait analysis in patients recovering from stroke. Use of Kinect has been studied, with little success, for recording of clinical data using analysis [1, 2]. Posture, gait, and mobility data can be produced from 3D point cloud sequence. Physiotherapy programs based on optical movement analysis systems are the norm, and they require large facilities and expensive installations comprising several cameras such as the Vicon. The proposed Kinect based solution, JAFAKEC system, provides a marker-less inexpensive alternative for gait analysis at home or at care homes. Capture of human movements is the primary application of the Kinect but the Kinect SDK does a quick and approximate computation of joint positions, which are not accurate enough for clinical gait monitoring. This paper details the mathematical algorithms applied on the point cloud to improve accuracy of the joint angle calculation.

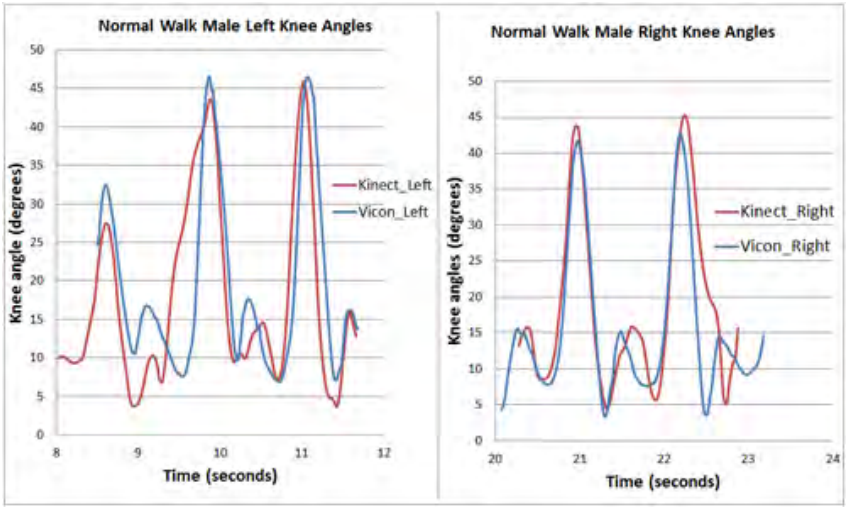
Methods: The proposed approach starts with an investigation of the achievable accuracy and suggests using some low-complexity algorithms as given in table 1 to improve the accuracy of joint positions. The captured depth frame from the Kinect recorder is compressed via run length encoding to allow storage of more frames in a limited memory. The stored point cloud is then used to perform body part labelling and pattern recognition in order to detect the limbs of interest. This process is followed by feature extraction via multiple geodesic distance labelling, shortest path algorithm and model fitting on specific subsets of points once the geodesic distances are attached to the points. With these features attached to each point, points are classified in the space of the features as belonging to specific limbs. Finally, the principal axes of the limbs are computed and the joint angles are calculated as angles between the principal axes.

Experiments:

Two different healthy males and one female were instructed to walk across a 10 meter walkway in the laboratory for the recording using the Kinect at different speeds for the gait data capture of both the left and right legs for approximately 1 to 2 minutes for a few trials. Spatiotemporal data were collected simultaneously using a 12 camera Vicon system with reflective markers placed according to the Vicon requirement.

Results: Experiments were performed to evaluate the proposed system, and results are benchmarked with the state-of-the-art Vicon optical movement analysis system. Figure 1 shows that the calculated angles obtained using the Kinect version 1.8 are a good match with the Vicon results.

Figure:



Caption: Figure 1: Kinect 1.8 vs Vicon, normal person, walking in moderate speed

Conclusion: The joint angles obtained from the skeleton computed by Microsoft Kinect SDK were inaccurate, but the depth frame is shown to achieve better accuracy in capturing the gait cycle of a subject walking at a distance of about 3m from the Kinect sensor. An assortment of geometric algorithms has been used to improve the accuracy of gait capture. Figure 1 shows that the accuracy of Kinect 1.8 results using the proposed JAFAKEC system is within a range of 5 degrees from the angle computed by Vicon. JAFAKEC, using a suite of customised mathematical algorithms, enables marker less gait capture for healthy and post-stroke patients, inexpensive in home application, easy to use GUI and fast. Using the proposed algorithms, the swing phase knee angles in the gait cycle are getting computed accurately but the stance phase knee angles are relatively inaccurate. The system works reasonably well with healthy males but needs to be improved for female gait data as the peak results have a higher difference of gait angle as compared with Vicon.

Table:

Algorithm	Application in JAFAKEC
Geodesic distance labelling	Forming a mesh representing the surface
Shortest path algorithm	Defining features of points for limb classification
3D Convex hull	Assembling the classified points for a single limb into a polyhedron so that point-density does not have an effect on axis calculation
Least-square line fitting	Determining the principal direction of an oblong polyhedron or point-set corresponding to the limbs of interest.
Sectioning of point cloud	Segmenting into sub regions such as for specifying source regions for shortest path and for feature definition.

ASSESSMENT OF POWER LOWER LIMBS IN WOMENS WITH LOW BONE MINERAL DENSITY

Diane Hartmann [1] Sandra Morais [2] Estele C. W. Meereis [3,*] Luiz Fernando Rodrigues [1] Rafael Gobbato [1] Jaqueline Biazus [1] Carla Mai [1]

[1]University Franciscano Center, [2]Federal University of Santa Maria, Santa Maria, [3]Federal University of Rio Grande do Sul, Porto Alegre, Brazil

Introduction and Objectives: Osteoporosis is the deterioration of bone mass, which leads to a growth of bone fragility and a higher risk of fractures. It may happens to both men and women, being more predominant among women. Therefore, this research aimed to verify if the aquatic exercises influence the cases of low bone mineral density (BMD).

Methods: The research had a quantitative almost-experimental approach with pre and post tests. Samples of 14 women, aged 55 to 80 years old. Project approved by the CEP: 162.843. Muscle Strength Test was applying in lower members were done through the dynamometer MIOTOOL® 400. The Hydrotherapy protocol was made in two sessions of 50 minutes a week, in total 8 weeks. For dynamometry analysis was used Wilcoxon test, the data were typed at an Excel data base and the statistics analysis was done in the SPSS Program, version 15.0.

Results: Muscle Strength evaluation showed meaningful improvement on right quadriceps (p= 0,005099) and left quadriceps (p= 0,00004423).

Conclusion: Hence, it was observed that the hydrotherapy protocol has significant influence on the power from osteopenic patient's lower limbs.

PO-0130

COORDINATION VARIABILITY AND OVERUSE RUNNING INJURIES: A PROSPECTIVE INVESTIGATION

Julia Freedman Silvernail [1,*] Katherine Boyer [2] Joseph Hamill [2]

[1]Kinesiology and Nutrition Sciences, University of Nevada, Las Vegas, Las Vegas, [2]Kinesiology, University of Massachusetts, Amherst, United States

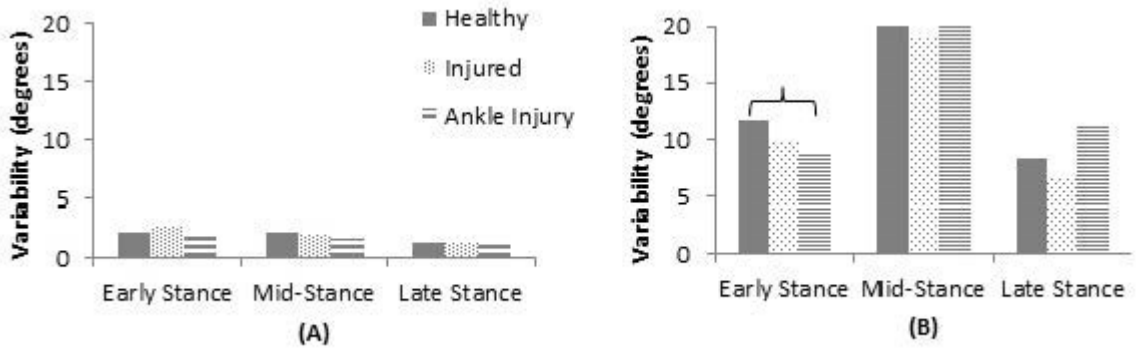
Introduction and Objectives: Coordination variability has been viewed as a metric of musculoskeletal health in human movement research[1]. Both injured and disease states have been tied to lower values of coordination variability compared to healthy individuals [1,2]. It has been suggested that, in a healthy system, variability contributes to adaptability, protecting the individual from injury [1,2]. Yet there is a dearth of prospective research to determine if lower values of variability may lead to injury or is instead a result of injury. Therefore, the purpose of this investigation was to test the hypothesis that prospective running data would show that coordination variability would be greater in individuals who remain healthy compared to those who become injured.

Methods: 110 runners were enrolled to the study after providing informed consent. Participants ran at 3.5 m/s (±5%) in a neutral laboratory shoe while three-dimensional kinematics and kinetics were collected. Runners were tracked for one year after the gait analysis was performed and information on injuries incurred was gathered. Participants were asked via email to report if they had sustained an injury which was defined as anything that forced them to alter their normal training for more than two days. Participants who reported an injury completed a questionnaire clarifying the nature and location of the injury. Eleven participants reported overuse injuries during the data collection period (Table 1). Twenty-five participants who reported remaining healthy over the data collection period were selected as the control group.

Five trials for each participant were used for further analysis. Foot, Shank and Thigh segment angles were calculated relative to the laboratory coordinate system using a cardan sequence (X-Y-Z). Segment angles were time normalized for the stance phase of gait and were divided into sub-phases of early stance (1-33%), mid-stance (34-66%) and late stance (67-100%). A modified vector coding technique [3] was used to determine the movement coordination variability during stance for the following segment couplings: Sagittal plane foot and shank rotation, foot eversion and shank internal rotation, sagittal plane thigh and shank rotation, transverse plane thigh and shank rotation and thigh flexion and shank internal rotation. Trial to trial variability was calculated as the circular standard deviation of the coupling angle calculated at each percentage of stance for each participant. Variability was averaged over each sub-phase of stance and was compared between healthy and injured groups using independent t-tests ($\alpha = 0.05$).

Results: During all phases of stance coordination variability was similar between healthy and injured runners for all measured segment couples ($p > 0.05$).

Figure:



Caption: Figure 1: Coordination Variability of the Foot-Shank Couple: (A) Sagittal plane motion, (B) Foot eversion-Shank internal rotation

Conclusion: It appears that individuals who will become injured do not exhibit overall lower coordination variability when running than individuals who remain healthy. With only a 10% injury rate, this study was limited in the injury data available. Furthermore, the injuries sustained by the participants varied. This suggests that if coordination variability plays a role in injury risk, it is likely specific to the injury location and cannot be generalized to overall changes in variability. To investigate this further, the variability of a subgroup of injured participants (n=4) whose injuries were sustained at the ankle/shank level was analyzed. These individuals had significantly less coordination variability during early stance in the couple of shank internal rotation and foot eversion (Figure 1). With such a small number of participants it is difficult to generalize overall conclusions regarding this information. However, these findings suggest that when looking at applicable segment couplings, individuals at risk may be able to be identified prior to injury.

INTRALIMB JOINT COORDINATION IS AFFECTED BY DIABETES MELLITUS EVEN BEFORE PERIPHERAL NEUROPATHY IS INSTALLED

Liu C. Yi [1,*] Cristina Sartor [2] Francis Trombini-Souza [2] Isabel Sacco [2]

[1]Human Movement Science, Federal University of São Paulo, Santos, [2]University of São Paulo, São Paulo, Brazil

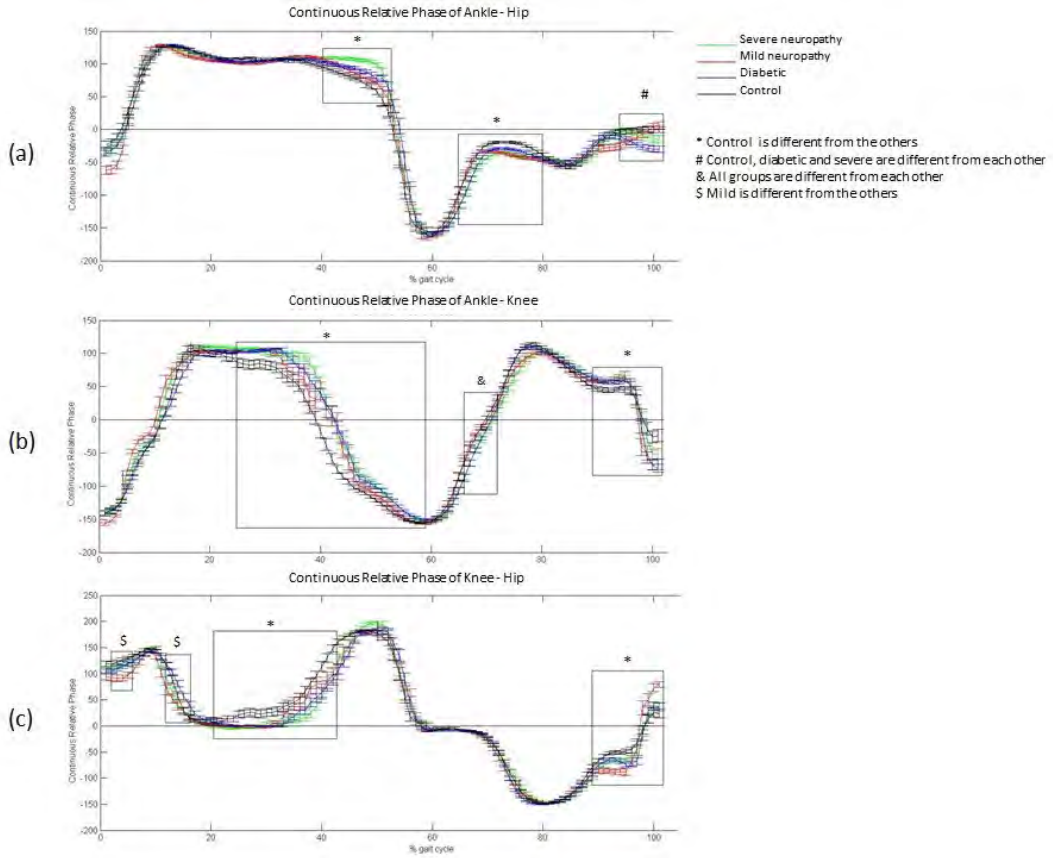
Introduction and Objectives: Diabetes Mellitus (DM) is cause of impairments to stability, mobility and locomotor tasks, especially due to polyneuropathy. It affects distal segment tissues and functions, especially in the ankle. This might induce compensatory mechanisms in intralimb coordination, especially between ankle and hip joints that has seldom been addressed in this population. When associated with increased time-space depreciation and altered loading distribution that are consequences of the disease, they may lead to major comorbidities such as ulcers and falls. Its constant repetition may cause overuse injuries or can be associated with lower mobility and poor capacity of adaptation [1]. Our aim is to describe changes in lower limb coordination in different groups of patients with and without DM to identify how the disease affects the gait cycle. Besides that, we are interested in identify if there would be a pattern of coordination that could distinguish between healthy and different stages of DM installation.

Methods: Sixty subjects between 45 and 65 years-old were evaluated and divided into 4 groups by using Fuzzy Logic Model [2]: Control (CTRL=13, 55±7 years-old, BMI 24±2), Diabetic (DIAB=18, 59±6 years-old, BMI 28±6, DM for 11±7 years, MNSI score 5±3), Mild Diabetic Neuropathy (MILD=7, years-old 56±4, BMI 27±2, DM for 19±7 years, MNSI score 10±3) and Severe Diabetic Neuropathy (SVRE=22, 57±5 years-old, BMI 29±4, DM for 14±8 years, MNSI score 12±4). Patients walked in a 10m walkway, barefoot, in a constant speed monitored by a metronome. Continuous relative phase (CRP) was calculated on each stride [3]. Hip, knee and ankle segmental angular velocities were calculated as the first derivative of segment angular position. Angular position and velocity were normalized to 101 data points. These normalized position and angular velocities vectors were plotted relative to each other for each of the 3 joints. The Phase Angle for hip and ankle joint during gait cycle were calculated ($\theta_{i} = \tan^{-1}[y_i/x_i]$). Afterwards the Relative Phase Angle was calculated, that consist the difference between distal and proximal joint Phase Angle ($\theta_{\text{relative phase}} = \Phi \text{ distal segment} - \Phi \text{ proximal segment}$). CRP was defined for the joint pairs of (a) ankle and hip, (b) ankle and knee and (c) knee and hip, at each instant of the stride. CRP variability was defined as the standard deviation of the CRP at each time point across the trials. The gait cycle was divided in 5 phases: early stance (0-10%), early midstance (11-40%), late midstance (41-60%), propulsion (61-80%) and balance (81-100%). The mean and standard deviation were calculated and one-way ANOVAs between groups were performed to each frame of the resulting time series. One-way ANOVAs between groups were also calculated for standard deviation of the 5 stance phases to compare the CRP variability ($\alpha = 5\%$).

Results: For the ankle-hip CRP, the SVRE presented increased variability in the early stance and remains more anti-phase ratio during late midstance compared to other groups. During propulsion, all diabetic groups remain with more in-phase ration than the CTRL, that also had increased variability. For the ankle-knee CRP, the 3 diabetic groups had more anti-phase ratio than during the early and late midstance, with decreased variability in early midstance. In propulsion phase, the same groups had more anti-phase at the end of balance phase. Finally, for the knee-hip CRP, the MILD

showed more in-phase ratio at the beginning of stance and all the diabetic groups again were more in-phase at early midstance (with lower variability) and at the end of balance phase, especially the MILD that had lower variability than the others.

Figure:



Conclusion: The three CRP were able to distinguish between the control and the diabetic groups, showing that DM can influence on the lower limb coordination during gait. Those differences in coordination were present mainly during the midstance, when the lower limb has to deal with loading transferring in unipedal support. Related to diabetes complications, only the ankle-hip CRP could distinguish the SVRE from the others in late midstance, and only the knee-hip CRP could distinguish the MILD in the beginning and at the end of balance phase. It is expected that the SVRE would have the distal segments more compromised by polyneuropathy, and therefore the hip could deal with the distal insufficiency since it is a more proximal and preserved joint. The low variability and differences in CRP of the MILD was not expected, but could represent an early adjustment of coordination as soon as the disease installation starts to change the sensorimotor intra-limb relations.

PO-0132

RELIABILITY OF ANKLE MUSCLE ACTIVITY IN HEALTHY AND FUNCTIONAL INSTABLE ANKLES DURING PERTURBED TREADMILL WALKING

Antje Reschke [1,*] Steffen Mueller [1] Martin Wolter [1] Tilman Engel [1] Stephan Kopinski [1] Heiner Baur [2] Frank Mayer [1]

[1]Sports & Health Sciences, University Outpatient Clinic Potsdam, Germany, Potsdam, Germany, [2]Health Division, Bern University of Applied Sciences, Bern, Switzerland

Introduction and Objectives: Reflex reaction of ankle muscles can be evaluated by unexpected stumbling trials on a treadmill. In individuals with functional ankle instability (FAI), inter-session reliability of ankle muscular activity during normal (NW) and perturbed walking (PW), performed on a split-belt treadmill, is unclear. The aim of this study was to assess inter-session reliability of ankle muscle EMG amplitude (EMG-A) in adults with and without FAI during NW and PW on a split-belt treadmill.

Methods: Fourteen participants (6 M, 8 F, 26±5 yrs, 1.80±0.09 m, 76±15 kg) were included in a test-retest (M1, M2) design with 6 weeks in between. By means of three criteria (never sprained, score ≥28 pts on “Cumberland Ankle Instability Tool” [CAIT] and ≥80% on “Foot and Ankle Ability Measure” [FAAM], left and right ankle were categorized into healthy ankles (H, n=12). Criteria for functional instable ankles (FAI, n=11) were at least 2 sprains in the past and 1 of 2 scores (CAIT≤27 pts, FAAM<80%). Tests were performed on a split-belt treadmill (WOODWAY): after warm up (walking at velocity of 1 m/s), 30 stumbling stimuli (each 15 left and right belt; time- and side randomized; 100 ms duration [50 ms deceleration to -1 m/s; 50 ms acceleration back to 1 m/s]) were applied 200 ms after initial heel contact (IC). Bilateral sEMG (myon RFTD-32, myon AG, Suisse) was recorded from M. tibialis anterior (TA), M. peroneus longus (PL) and M. gastrocnemius medialis (GM). For EMG-A, RMS was calculated within 200-400 ms post IC, normalized to MVC (%, mean of 15 steps) and presented descriptively (mean±SD of M1 and M2). Reliability was analyzed by ICC (2.1), test-retest variability (TRV, %) and Bland-Altman analysis with bias and limits of agreement (bias±1.96*SD).

Results: EMG-A ranged from 10.1±7.0% (TA, NW) to 93.6±39.4% (PL, PW) in H and from 10.4±4.8% (NW) to 75.7±34.3% (PW) in FAI. For H, TRV varied from 25.8±20.6% (TA, PW) to 57.3±45.2% (PL, PW) and ICC ranged from 0.59 (GM, PW) to -0.24 (PL, PW). For FAI, TRV varied from 35.7±22.3% (GM, PW) to 51.7±45.3% (PL, PW) and ICC ranged from 0.78 (GM, PW) to -0.20 (TA, NW). Bias±1.96*SD ranged from -1.0±24.9% (PL, NW) to -14.8±106.6% (PL, PW) in H and from -2.4±12.2% (TA, NW) to 6.0±97.8% (PL, PW) in FAI (detailed results in table 1).

Figure:

Group	Muscle	NW/ PW	M1, M2 Mean±SD (%)		TRV Mean±SD (%)		Bias	± 1.96*SD	ICC (2.1)
H	TA	NW	10.1	7.0	54.3	44.1	1.6	21.7	-0.03
		PW	70.4	20.3	25.8	20.6	3.6	41.0	0.59
	PL	NW	25.6	12.6	42.7	27.0	-1.0	24.9	0.33
		PW	93.6	39.4	57.3	45.2	-14.8	106.6	-0.24
	GM	NW	46.9	19.2	42.4	48.2	4.3	46.4	0.37
		PW	49.8	27.2	32.9	26.0	13.2	56.9	0.59
FAI	TA	NW	10.4	4.8	48.5	36.1	-2.4	12.2	-0.20
		PW	70.5	22.5	42.0	38.7	-4.6	58.6	0.03
	PL	NW	29.5	19.3	44.7	39.7	4.4	27.4	0.35
		PW	75.7	34.3	51.7	45.3	6.0	97.8	0.12
	GM	NW	37.1	22.6	47.5	57.0	-6.0	29.1	0.69
		PW	46.0	24.0	35.7	22.3	-4.1	28.7	0.78

Caption: Table 1: RMS normalized to MVC (mean±SD, %) of M1 and M2 for both groups (H or FAI), all muscles (TA, PL, GM) and both walking conditions (NW or PW); reliability values of RMS normalized to MVC (%)

Conclusion: Inter-session reliability of ankle muscular activity resulted in poor to moderate values in healthy adults and poor to good values in adults with FAI, depending on walking condition and ankle muscle tested. Large random error and high variation for reliability may reflect the physiological variability in muscle activation during gait and have to be considered with regard to follow-up investigations.

EFFECT OF KNEE TAPING ON LOWER LIMB KINEMATICS IN SIDE-HOPPING TASK

Kuang-Wei Lin [1,*] Yu-Lun Huang [2] Sai-Wei Yang [1] Ying-Fang Liu [3]

[1]Department of Biomedical Engineering, National Yang-Ming University, Taipei, Taiwan, Republic of China, [2]Department of Kinesiology, University of Texas at Arlington., Arlington, United States, [3]Office of Physical Education, Hsin Sheng College of Medical Care and Management, Taoyuan, Taiwan, Republic of China

Introduction and Objectives: Anterior cruciate ligament deficiency (ACLD) is a common injury of knee joint in the sports field. The incidence rate of knee ACL injuries was reported as of 45.4%[1]. In clinical practice, the protective strapping on knee is applied to protect the ACL, however, it is difficult to determine when the ACLD patients are safe to return to strenuous physical activities. Gustavsson et al. (2006) reported that the side hopping task could effectively discriminate the abnormal function of ACL from the normal one [2]. The aim of this study was to biomechanically evaluate the effect of the protective taping on ACLD in kinematics.

Methods: Seven male and ten females (24.65±6.32 years) with one knee ACL injured over 6 months were recruited. Vicon T40 motion analysis system with ten infrared cameras sampled in 100 Hz rate were used. The surface markers were attached on the segments; two force platforms with sampling rate of 1000Hz were used to synchronically record the ground reaction forces during the task.

Before testing, subjects were asked to perform a standard warm up protocol for 20 minutes, then, thoroughly familiarize the experimental procedure with few times of practices. The modified side-hop testing protocol described by Gustavsson et al. (2006) [2] was used. Each subject stood on the injured leg, hopped between two force platforms from side to side, then repeated the same procedure after tapping. The ACL protective strapping method adapted from Anderson et al. (2004)[3]. A static reference measurement was used to measure the locations of the markers (tibial tuberosity, fibular head and both medial and lateral epicondyle) with respect to the cluster markers and to define the neutral joint orientations. Subjects were asked to hop to highest repetition within 30 seconds. The distance of side-hop was determined by the subject's height multiplied by 0.22.

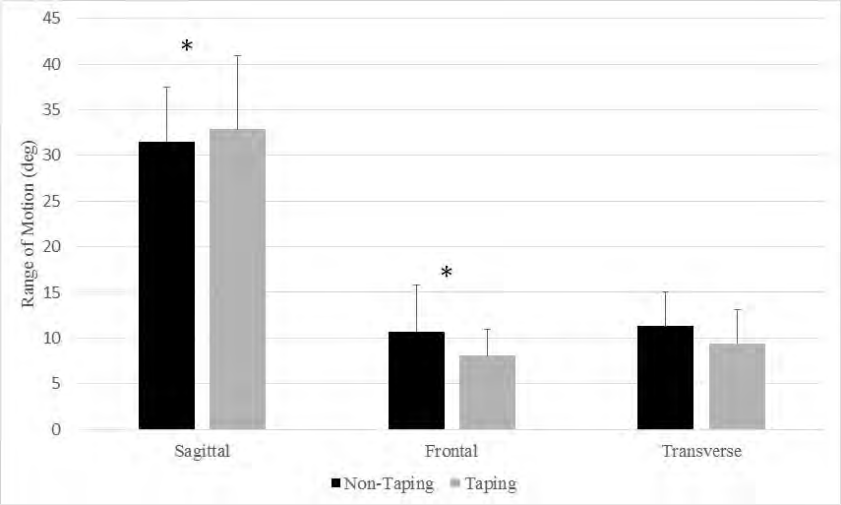
The data reduction of 3D marker trajectories were processed using a MatLab program of 4th order zero-lag Butterworth low-pass filter with a cut off frequency of 8 Hz (The Mathworks Inc., Natick, USA). The calculation of knee Eulerian joint angles was in the rotation sequence of z-x-y. Data were checked the normality first, then used paired *t*-test to discriminate the efficacy of tapping with the significance of the α level 5%.

Results: Table 1 showed the knee joint angles in the frontal and transvers planes of three different phases. In all phases, taping reduced the knee abduction angle significantly; and significantly increased the knee external rotation angle at the initial contact and take-off phases.

ROM of knee joint with taping in sagittal plane was greater than without taping significantly. In fontal plane, ROM of knee joint with taping was smaller than without taping significantly. However, there was no significant difference in transverse plane (Fig1).

Taping technique aims to restrict excessive joint movements. We combined two taping techniques to provide support and stability to the ACL and collateral ligaments of the knee. Anderson et al. (1992) used cadaver specimens to evaluate the effects of taping and bracing, they found the tape and brace combination reduced knee translation and rotation. However, the tape method used individually restricted translation and rotation better than the Stabler brace along[4]. The primary findings of this study were similar to the effects of taping on healthy knee[5]. It reduced abduction angle and led to the tibia rotation externally. In addition, it decreased the ROM of knee joints in frontal plane that could reduce the risk of ACL tear. However, this study did not calculate the forces acting on knee with taping. Future research should also investigate the reaction forces of the knee joint or muscle activation patterns during the side hop task.

Figure:



Caption: Average and standard deviation values for ROM of knee joint in three different planes with and without taping during side hop (* p<.05).

Conclusion: The findings suggest that taping on ACLD knees contributed to limit the knee joint angle of frontal and transverse plane. Moreover, taping may provide restraining capabilities to prevent ACL injury.

Table:

Phase	Direction	Non-taping	Taping	*p*
Initial contact	Adduction(+)/Abduction(-)	-6.77±5.01	-3.14±4.43	.00**
	Internal(+)/External(-) rotation	-3.91±5.35	-7.30±5.51	.00**
Max flexion	Adduction(+)/Abduction(-)	-4.46±7.34	-2.66±6.58	.02*
	Internal(+)/External(-) rotation	-1.42±7.19	-2.46±8.24	.25
Take-off	Adduction(+)/Abduction(-)	-8.83±5.18	-5.45±3.98	.00**
	Internal(+)/External(-) rotation	-3.07±5.13	-6.01±5.75	.00**

PO-0134

REPRODUCIBILITY OF KINEMATICS MEASURED WITH INERTIAL MEASUREMENT UNITS (IMU) DURING TREADMILL RUNNING

Jasmin Gaudel [1,*] Anna Dannemann [1] Doris Oriwol [1] Christian Maiwald [1]

[1]Department of Research Methodology and Data Analysis, Institute of Kinesiology, Chemnitz, Germany

Introduction and Objectives: Over the past few years, use of inertial measurement units (IMU) to measure running-specific features has increased [1, 2, 3]. The advantages compared to stationary kinematic systems (e. g. 3D-motion-capture-systems, force plates) are the possibility to use inertial sensors in field test based on the low weight, small size and wireless mounting [4].

To use inertial sensors in field conditions, data reproducibility should first be tested in a laboratory setting, particularly on the treadmill. Expected variations in the measurement setup and participants must be known to make predictions about kinematic running parameters, e. g. interventions and shoe-specific demands. However, there are currently no scientific studies in this area.

Therefore, the purpose of this study is to analyze the reliability of kinematic parameters during treadmill running and to determine variation ranges.

Methods: Eleven well-trained runners (3♀; 8♂, age: 25 ± 3 y; height: 1.78 ± 0.09 m, weight: 71.4 ± 9.7 kg) performed two running trials over 50 minutes on a treadmill. There was a resting period of 3 days between each trial. On day 1 (MD1), the participants ran at a self-selected, comfortable running speed (10.29 ± 1.08 km/h) with their own running shoes. On day 2 (MD2), the measurements were repeated using the same procedure. Maximum eversion velocity (EVmax [°/ s]) and stride duration (StrD [ms]) were acquired using inertial sensor (Achillex©; 3-axial; acc., mag., gyr.; 400 Hz) at the heel cap on the left side. The first 2000 strides were analyzed minus a warm-up period of 40 strides. The statistical analyses include mean differences ($diff_{mean}$ (absolute); $diff_{norm} = (Mean_1 - Mean_2) / Mean_{all} * 100$ (relative)), limits of agreement ($LoA = \pm 1.96 * SD_{diff}$ (absolute); $LoA_{norm} = \pm 1.96 * SD_{diff} / Mean_{all} * 100$ (relative)) and Bland & Altman plots with pooled standard deviation (SD_{pool}) used as a measure for intra-subject variability.

Results: The data analyses revealed high inter-subject variability for both parameters, which illustrated the high ranges on the two measuring days (Table 1).

EVmax showed high intra-subject variability (Figure 1). Individual running cycles of some participants were clearly beyond the limits of agreement. The inter-subject variation of EVmax will likely be underestimated when only a limited number of stride cycles is available for analysis. Nevertheless, the characteristic of intra-subject variability was similar for all participants, which is illustrated by the pooled standard deviation (Figure 1).

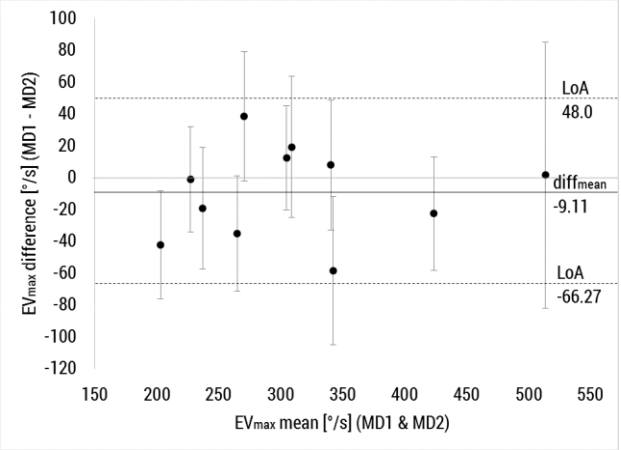
Both parameters, EVmax and StrD, are distributed homoscedastically around the average of the differences. This means that there was no systematic bias between the two measurement days.

During treadmill studies, maximum deviations from a participant's true value between repeated measurements is expected to be up to 57.16 °/ s (EVmax).

For Stride duration, the inter-subject variation range may be up to 32.44 ms, which corresponds to 4.3 % (normalized).

Inertial sensors achieve a high degree of reliability for selected parameters in comparison to stationary and other transportable kinematic systems [5].

Figure:



Caption: Fig. 1. Bland & Altman plot for EVmax with error bar of all participants (SDpool)

Conclusion: Inertial sensors can be used to generate kinematic parameters (e. g. EVmax and StrD) as an alternative to stationary systems. The deviations of the true values of a participant should be noted to make statements about previous differences with regard to interventions, shoe-specific demands, etc.

Table:

	Mean 1	Mean 2	R_1	R_2	$diff_{mean}$ ± LoA	$diff_{norm}$ ± LoA [%]
EVmax [°/s]	307.04	317.05	182 - 514	224 - 512	-9.11 ± 57.16	-2.92 ± 18.3
StrD [ms]	754.18	753.74	692 - 801	690 - 803	-0.44 ± 32.44	0.06 ± 4.3

Caption: Tab. 1. Average value (Mean1; Mean2) and ranges (R1; R2) for MD1 & MD2, diffmean with LoA and diffnorm with LoAnorm for EVmax [°/s] and StrD [ms]

GAIT ANALYSIS FOLLOWING PROXIMAL MEDIAL GASTROCNEMIUS RELEASE – A PILOT STUDY

Alex Humphries [1,*]Aliah Shaheen [1]Derek H Park [2]Daniel McCaffrey [3]Dionysios Trigkilidas [3]Matthew Solan [3]

[1]Mechanical Engineering Sciences, University of Surrey, Guildford, [2]Barnet and Chase Farm Hospital, Royal Free London, London, [3]Orthopaedic department, Royal Surrey County Hospital, Guildford, United Kingdom

Introduction and Objectives: Tightness of the gastrocnemius has been shown to affect dorsiflexion of the ankle [1], leading to increased pain in the forefoot. Gastrocnemius release is shown to improve the dorsiflexion of the ankle [1] and is commonly used in the treatment of gastrocnemius contracture in paediatric patients with neuromuscular conditions [2]. However, relatively little is known about how the surgery affects the kinematics of the foot and the patient's gait.

The study aims to assess the kinematics of the forefoot and hindfoot during walking before and after proximal medial gastrocnemius release surgery, allowing changes in the gait pattern to be identified. This will improve understanding of the effects of the procedure on patients' walking and how it helps in treating conditions causing foot and ankle pain.

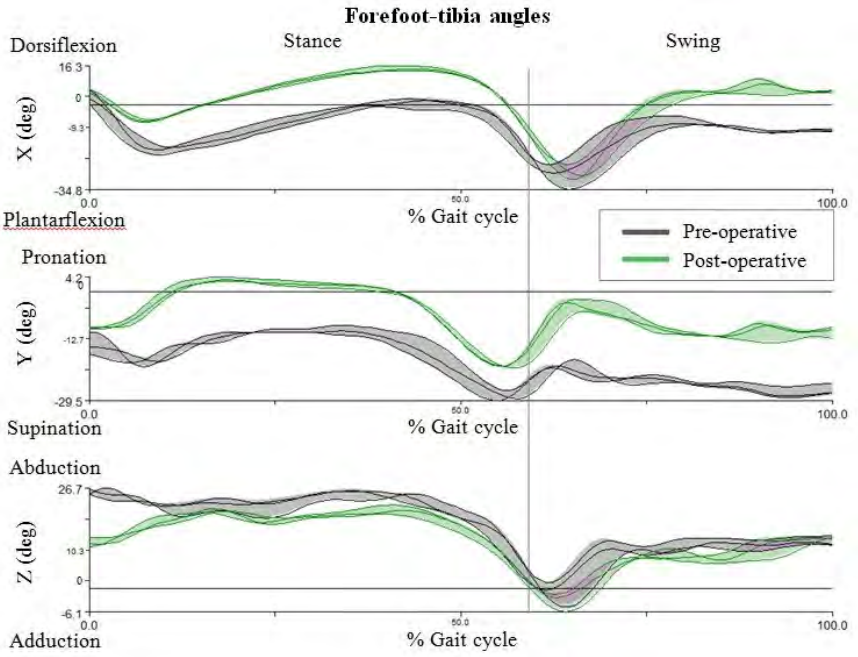
Methods: Four patients were recruited for the study who had been offered a proximal medial gastrocnemius release as part of the routine management of their condition. Patients were excluded from the study if they had neuromuscular or rheumatological conditions or bilateral gastrocnemius contracture. Each patient attended a pre-operative gait analysis session and a postoperative session three to four months after their surgery.

Kinematic data and plantar pressure data were collected during each session for four barefoot 10 metre walks. To minimise the influence of pain on the patient's walk, they were asked to take their regular anaesthesia prior to the sessions. Kinematic data was collected using an optoelectronic system (Qualisys, Sweden), where reflective markers were attached to the patient's skin according to the Oxford foot model [3] on the symptomatic side and a standard 6DoF marker set on the non-symptomatic side. During each walk, ground reaction forces were measured using force-plates whilst pressure data of the symptomatic side was collected using a pressure mat (Tekscan, USA). The data was then used to describe the kinematics of the foot, quantify the loading of the forefoot and to evaluate the temporal-spatial parameters during each session, allowing changes in the gait characteristics to be identified. These included the angles of rotation of the forefoot relative to the hindfoot and tibia, rotation of the hindfoot relative to the tibia, knee kinematics, centre of pressure trajectory, peak forefoot pressure and forefoot loading time. A visual analogue scale (VAS) was collected during each session to obtain a measure of the patient's pain whilst walking during the previous week.

Results: Following surgery there was increased dorsiflexion of the forefoot during stance and swing and increased plantarflexion at toe-off when the forefoot was measured relative to the tibia. Consequently, there was a larger range of ankle dorsiflexion-plantarflexion during stance and swing, where these rotations were comparable to a non-pathological group [4]. Rotations of a patient's symptomatic forefoot relative to the tibia during one gait cycle before and after surgery are shown in the figure with standard deviations, illustrating how gastrocnemius release affects the kinematics of the forefoot. The symptomatic forefoot is also shown to pronate during single stance and has reduced supination throughout the gait cycle following surgery, which is also comparable to a non-pathologic group [4]. These characteristic changes in the kinematics of the foot are also shown when the forefoot rotations are measured relative to the hindfoot. There were

also improvements in the knee kinematics following surgery, showing a reduced abduction during stance and increased adduction during swing. When considering the temporal-spatial parameters there were no differences between the symptomatic and non-symptomatic sides and there were no changes to these measures as a result of surgery. Each patient also reported less pain whilst walking after the surgery compared to their levels of pain before, which was reflected in the patient's VAS score. Forefoot loading was shown to increase following gastrocnemius release, demonstrated by an increased symptomatic forefoot plantar pressure during the toe-off phase of the gait cycle.

Figure:



Caption: Mean rotations of a patient's symptomatic forefoot relative to the tibia before and after surgery

Conclusion: The study shows that gastrocnemius release improves the patient's gait by restoring the range of motion of the forefoot. The reduced pain and increased range of motion following gastrocnemius release could subsequently allow for an increase in loading of the symptomatic forefoot during toe-off. It is important to note that the results presented here are based on a small number of patients, however, these results will help in understanding the effects of gastrocnemius release on gait.

PO-0136

ASSOCIATION BETWEEN THIGH MUSCLE COACTIVATION AND MOVEMENT PRECISION OF LOWER LIMBS ON THE DYNAMIC LEG PRESS

Sophie Rabe [1,*] Konstantina Intziegianni [1] Josefine Stoll [1] Frank Mayer [1]

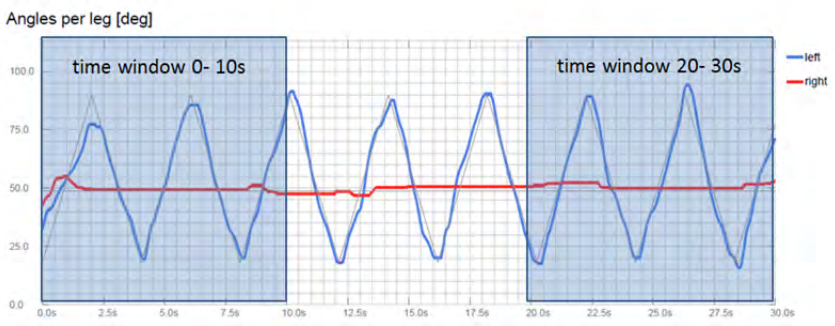
[1]Department Sports & Health Sciences, University Outpatient Clinic Potsdam, Potsdam, Germany

Introduction and Objectives: Muscular coactivation provides joint stability and plays an important role for the coordination of movements. Coactivation has been found to be a motor control strategy for precision of arm movements [1]. The Dynamic Leg Press (DLP) aims to train sensorimotor control and strength of the lower limbs while giving visual feedback to control the movement precision of a task. The user performs extension and flexion movements in a closed kinetic chain at the device. To our knowledge no study before has investigated the association between muscular coactivation and movement precision at the lower limbs on the DLP. This study aimed to test for an association between muscular coactivation and movement precision in a set of exercises for the lower limb on the DLP.

Methods: Nineteen healthy subjects (10 male, 9 female, age 28 ± 3 years, weight 68.2 ± 12.4 kg, height 173.8 ± 8.3 cm,) participated in the study. Subjects had to perform different tasks of 30s in a randomized order on the DLP. Exercises where performed with both legs in an isometric or dynamic movement and differed in terms of load (half/ whole bodyweight) and velocity (slow/ fast). EMG amplitudes were assessed of the agonist M. vastus lateralis (VL) and antagonist M. biceps femoris (BF). RMS of EMG amplitudes were normalised to their MVIC on an isokinetic Leg Press (Con-Trex LP) at a knee angle of 50°. Outcome measure for coactivation was the coactivation index (CI: VL / BF). Movement precision was measured by the deviation of the predefined line (degrees [°]). Data of left/ right leg and time windows of 0-10s/ 20- 30s were analysed for all tasks. Spearman correlation coefficient (ρ) was used to test for a statistically significant association (α≤ 0.05) between muscular coactivation and movement precision.

Results: Taking the different DLP tasks: load conditions, velocity conditions, legs (left/ right) and time windows into account, 48 conditions were investigated. Out of those 4 conditions showed a statistically significant association (ρ= 0.472 to 0.563) between coactivation and movement precision. All 4 significant conditions occurred in the time window of 20-30s. The conditions differed in terms of load, velocity and legs. Averaged CI ratio values were 0.7±0.6.

Figure:



Caption: Figure 1 screen of DLP with deviation of predefined line [°] and analysed time windows

Conclusion: Due to a large majority of not statistically significant results and only 4 moderately significant associations within all 48 testing conditions no association between muscular coactivation and movement precision at the lower limbs on the DLP could been detected in this study. High variability of coactivation values and possible person- and gender-specific coactivation strategies may have influenced the results.

RELATIVE MUSCLE EFFORT OF THE ANKLE AND KNEE JOINTS ACROSS DIFFERENT MODES OF HUMAN LOCOMOTION IN YOUNG AND OLD MEN

Juha-Pekka Kulmala [1,*] Marko Korhonen [2] Luca Ruggiero [1] Sami Kuitunen [3] Harri Suominen [2] Ari Heinonen [2] Aki Mikkola [4] Janne Avela [1]

[1]Department of Biology of Physical Activity, [2]Department of Health Sciences, University of Jyväskylä, University of Jyväskylä, [3]Research Institute for Olympic Sports, Jyväskylä, [4]Department of Mechanical Engineering, Lappeenranta University of Technology, Lappeenranta, Finland

Introduction and Objectives: The force generation requirements of the muscles depend on speed and mode of locomotion and substantially vary between different muscle groups [1]. However, knowledge of operating muscle effort of different lower limb muscle groups during human locomotion is limited and stems predominantly from studies, which have compared joint moments generation during walking in relation to maximum force production in isokinetic dynamometers [2]. The findings of these studies suggest that during walking ankle plantarflexors are working closer to their performance limit compared to knee and hip extensors.

However, switching gait from walking to running has been shown to increase peak joint moments more at the knee (approximately by 3-fold) than ankle level (by 2-fold) [3]. Furthermore, Biewener et al. (2004) reported much greater increase in estimated active muscles volume at the knee extensors compared with ankle plantarflexors as humans changed gait from a walk to a run [4]. On the other hand, our recent study [5] examining age-related changes in locomotion mechanics found that reduced ankle plantarflexor output contributes most to the locomotor decline among old adults, while no age-related deterioration was present in the muscular output of the knee joint. Hence, it can be postulated that despite running increase muscular demands more at the knee than ankle level, it seems that limited muscular output from the ankle rather than from knee may limit the human locomotor performance. Furthermore, assuming that the muscular force production capacity is better in young than old adults, it appears that the knee extensor muscles in young adults are working well within their performance limit even during running and maximal sprinting. However, experimental study of the relative muscular efforts is needed to evaluate these assumptions.

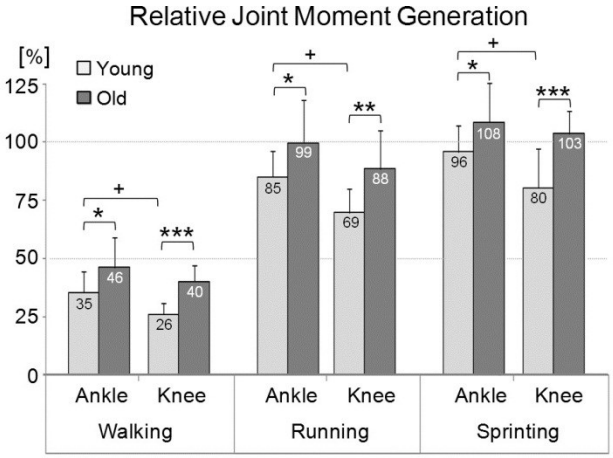
The objective of this study was to investigate relative muscle effort of the ankle plantarflexors and knee extensors during walking, running and sprinting in young and old adults. For that purpose, explosive hopping task was used to quantify maximum effort of the ankle and knee joints which was then used to normalize joint moment generation during locomotion. It was hypothesized that (i) the relative muscle effort would be higher in the ankle versus knee joint in both groups during all modes of locomotion, and that (ii) old adults would demonstrate higher relative efforts in both joints across all measured activities excluding ankle joint during sprinting.

Methods: Eleven young (age 27 ± 6 yr.) and 11 old (age 70 ± 8 yr.) male athletes performed walking trials at 1.6 m/s, running trials at 4 m/s and 60 m sprinting trials at maximal effort. Maximum force generating capability of the ankle and knee joints were quantified during explosive two leg hopping task which has been shown to enable athlete to produce the

greatest mechanical output from the ankle and knee joints amongst several other plyometric exercises [6]. Inverse dynamics was used to calculate joint moments across measured activities.

Results: Within subject comparison showed that relative effort of the ankle was significantly higher compared with the knee in the young group across all measured activities (Fig.1). A trend towards higher ankle effort was observed also in the old group. In addition, between group comparison showed that the old group exhibit higher relative effort in the ankle and knee joint level compared with the young group (Fig.1).

Figure:



Caption: FIG 1. Relative muscle effort across different modes of locomotion in young and old groups.

Conclusion: This study demonstrates that human locomotion requires greater effort from the ankle plantarflexors than knee extensors. It was also found that the old adults exhibit higher relative efforts in the ankle and knee joint level across all measured activities. These findings support previous suggestions that muscular capacity of the ankle plantarflexors plays a key role in locomotor performance as well as help to understand why age-related loss of muscle force capacity first challenges normal function of ankle joint during locomotion. Furthermore, higher muscular effort of the ankle than knee during running may explain why only minor portion of the runners exhibit forefoot striking pattern, which further increases the muscular demand on the ankle joint [7].

Table:

	Walking		Running		Sprinting		Hopping	
	Y	O	Y	O	Y	O	Y	O

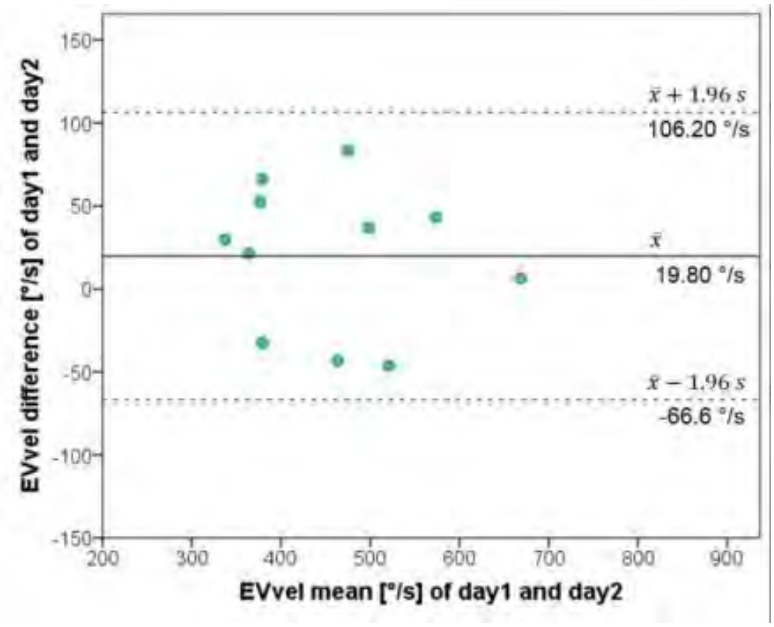
REPRODUCIBILITY OF RUNNING PARAMETERS MEASURED WITH INERTIAL SENSORS DURING FIELD TESTING

Anna Dannemann [1,*] Jasmin Gaudel [2] Doris Oriwol [2] Christian Maiwald [2]

[1]Department of Research Methodology and Data Analysis, Institute of Kinesiology, [2]Department of Research Methodology and Data Analysis, Institue of Kinesiology, Chemnitz, Germany

Introduction and Objectives: Reasons to measure running related features are manifold and include clinical as well as sport related questions. Due to new developments and advancements of measuring systems like inertial measurement units (IMU), data collection is no longer limited to spatial and temporal limitations in a laboratory [1]. This allows for the collection of large quantities of real world data – e. g. of an entire endurance run. However, detecting effects that stem from training, footwear, or injury related mechanisms will only be traceable if a sufficient amount of reproducibility can be attributed to this type of data collection and the amount of natural variance is known. Therefore, the purpose of this study is to determine the variability of biomechanic variables within and across two sessions of outdoor overground running.
Methods: Eleven subjects (3 f.; 8 m., 25.7 ± 2.6 years; 178.5 ±7.5 cm; 70.6 ± 9.8 kg) with running experience performed two fifty-minute endurance runs at an individual, self-selected and constant running speed (3.2 ± 0.5 m/s) at least 24 hours apart. Data were collected using an inertial sensor (Achillex©; 3-axial; acc., mag., gyr.; 400 Hz) fixed at the right heel cap of subjects own running shoes. To avoid any artifacts when initiating the run, the first 40 strides of each run were discarded and analysis was limited to the subsequent 1500 strides. Maximum eversion velocity (EVvel [°/s]) and stride duration (StrDur [ms]) were calculated for each stride interval.
Statistical analyses included mean differences ($diff_{mean,}$ absolute and $diff_{rel}$, relative: $(mean_1 – mean_2) / mean_{all} * 100$), Limits of Agreement (LoA, $diff_{mean} ± 1.96 * SD_{Diff}$) and Bland-Altman plots.
Results: EVvel revealed large inter-subject differences between days (Figure 1). The bias of 19.8 °/s (EVvel) is negligibly small compared to its absolute values. Data of all subjects fell within the LoA and were distributed homoscedastically around the mean difference. However, the range of 172.8 °/s between LoA is substantial and relative differences up to 17.6% were found (Table 1). Data for StrDur was found to be less variable than EVvel. The range between LoA was 86 ms, and relative differences varied from 0.3 % to 6.7 %. It appears questionable whether any type of effect (e. g. based on training or footwear interventions) can exceed the natural variability found in this type of data.
Ultimately, future studies should address the question whether the assessment of means is an adequate way to analyze timeseries of biomechanic data of running, data or whether there is a benefit of non-linear methods [2].

Figure:



Caption: Figure 1: Bland-Altman plot for EVvel

Conclusion: The recording of biomechanic variables in a natural running environment using IMU is advantageous in many ways. Nevertheless, large variances in EVvel can be expected in this type of protocol, whereas StrDur appears to be more reliable even under field testing conditions. The application of non-linear analysis techniques may be beneficial for this type of data.

Table:

	$Mean_{Diff \pm LoA}$	$Diff_{rel}$	$Diff_{relMin}$	$Diff_{relMax}$
EVvel [°/s]	19.8 ± 86.4	11.9	0.9	17.6
StrDur [ms]	-5.1 ± 43.0	1.9	0.3	6.7

Caption: Table 1: Mean differences with LoA; mean, minimal and maximal relative differences of EVvel and StrDur

PO-0139

THE EFFECT OF LIMB PREFERENCE ON KNEE MECHANICS DURING UNANTICIPATED SIDESTEPPING

Kaitlyn Weiss [1,*] Scott Brown [1]

[1]Sports Performance Research Institute New Zealand, Auckland University of Technology, Auckland, New Zealand

Introduction and Objectives: Anterior cruciate ligament (ACL) injuries are the most costly with respect to both the cost of care and the by cost per hour of participation [1]. Previous studies [2, 3] note that 70-84% of all ACL injuries are non-contact in nature and that the majority of these injuries occur during changes of direction, rapid deceleration while running, cutting manoeuvres combined with deceleration, landing after a jump with the knee in or close to full extension, and pivoting on a planted foot with shallow knee flexion [4, 5]. Compared to male athletes, female athletes have been shown [2] to be four to six times more prone to injure their ACL. Additionally, research [6-9] has shown that leg preference is related to the risk of anterior cruciate ligament injury and athletic performance. Most recently, Brown et al. [10] observed important mechanical differences between the preferred and non-preferred legs during planned sidestepping in female footballers (soccer players). While previous research [11] has assessed both planned and unplanned sidestepping and its impact on knee mechanics, to our knowledge, the effect of leg preference on biomechanics during unplanned sidestepping has not been assessed. The purposes of this research were to observe the mechanical differences between the preferred and non-preferred legs during unplanned sidestepping and to assess the magnitude of the mechanical differences between legs during sidestepping.

Methods: Three-dimensional data were collected with 12 female collegiate football and field hockey players during unplanned sidestepping with their preferred and non-preferred kicking leg. Knee kinetics and kinematics were analysed for both legs during initial contact, weight acceptance, peak push-off, and final push-off phases of sidestepping [10].

Results: In comparison to the preferred leg, the non-preferred leg showed moderate decreases in knee flexion angle at initial contact (ES=-0.63); moderate decreases (ES=-0.71) in knee abductor moment and moderate increases (ES=0.75) in knee rotator moment during initial contact, small decreases (ES=-0.52) in knee flexion during weight acceptance, small decreases (ES=-0.51) in abductor moment and small increases (ES=0.58) in rotator moment at peak push-off, moderate decreases (ES=-0.63) in abductor moment and small increases (ES=0.41) in rotator moment at final push-off.

Conclusion: The results of this research indicate that differences exist between the preferred and non-preferred legs during unplanned sidestepping such that the preferred limb was observed to be at a greater risk of knee injury. This increased probability of knee injury is due to differences in knee frontal plane loading experienced by the preferred limb while in a position that decreases stability and the ability to attenuate this increased load. The combination of shallow knee flexion angles of <30 at initial contact and final push-off and greater internal rotation moments make the ACL of the preferred limb more likely to experience greater loading. It is possible that we did not see these mechanics in the non-preferred limb because the non-preferred leg acting as the primary stance leg during various tasks in field sports. The results of this research will augment what is currently known of knee injury in female athletes and can facilitate the design of injury prevention strategies and protocols in the future. Future studies may seek to examine the impact of leg preference on knee mechanics during unplanned sidestepping in males.

GENDER DIFFERENCES AMONG MALES AND FEMALES WHILE PERFORMING ROUTINE TASKS - A PRECURSOR TO OSTEOARTHRITIS RISK

Sudip Paul [1],*Dinesh Bhatia [1]

[1]DEPARTMENT OF BIOMEDICAL ENGINEERING, NORTH-EASTERN HILL UNIVERSITY, SHILLONG, India

Introduction and Objectives: Osteoarthritis (OA) is characterized by the degradation of hyaline cartilage in the joints affecting smooth locomotion. OA is the most common form of arthritis and one of the most important causes of long-term disability in adults. OA mainly affects the elderly population > 60 years and its prevalence > 50%. OA of the knee is also associated with obesity, trauma, history of inflammatory arthritis and certain metabolic diseases. Recently, it has been observed that symptoms of OA are being observed in the younger healthier age group which is an alarming sign. The common sites of joints to develop OA include the knee, hand, hip, spine and foot. Of these, OA of the knee is most commonly found. Patients with knee osteoarthritis often have decreased thigh muscle strength originating from brain centers and spinal cord restricting recruitment of fibers responsible for muscle contraction. This impairs patients' abilities to perform activities of daily living (ADL) and may even contribute to further joint degeneration. Treatment options include various pharmacological and non-pharmacologic interventions but none of them has been successful till date with several side-effects. The most commonly used device available for short-term relief from knee OA pain is the Transcutaneous electrical nerve stimulator (TENS) device. It offers greater relief initially, but is less effective in treating knee arthritis and with time its ability to heal starts diminishing.

The aim of the present study is to understand development of OA symptoms in age group 20-40 years across genders to determine whether there has been a fall in age barrier for OA development in healthier age group. This would aid in understanding predominant factors leading to development of the disease and whether they are related to lifestyle disorders. This would support the development of devices aimed at increasing muscle strength, restoring normal function, and possibly slowing down progress of knee OA to enhance the patient's quality of life plagued with this disease.

Methods: In this study, we conducted the experiments in quadriceps and hamstring muscle for 10 healthy female and male volunteers and 5 paraplegic subjects suffering from UMN as these are prominent muscles leading to OA development as per available literature studies. The study was ethically approved and all subjects gave their written consent. Studies on the right and left leg were done for each of these volunteers and they were asked to perform daily routine tasks such as stepping, normal walking tasks and under voluntary condition. The data was collected by employing 4 channel wireless Biopac Nomadix system available.

Results: As per results, obtained from the experimental data of 10 healthy female for left leg, the EMG values for performing stepping task were 0.011 mV, for normal walking was 0.0076 mV and under voluntary condition was 0.004 mV. The right leg values in these subjects were for stepping task was 0.009 mV, normal walking was 0.006 mV and under voluntary condition was 0.0036 mV. These results were consistent with those available in literature for normal subjects. Again, we have performed with 10 healthy male volunteers for the left leg for the stepping task was 0.0089 mV, for normal walking was 0.0046 mV and under voluntary condition was 0.289 mV. For the right leg for the stepping task was 0.005 mV, for normal walking was 0.004 mV and for voluntary condition was 0.004 mV. It shows that during stepping and voluntary conditions for the healthy male the results show few variations from the normal values. If we look into the paraplegic condition (upper motor neuron paraplegia), we found for the left leg for stepping condition is 0.0034 mV, during normal walking with assistance is 0.0037 mV, and under voluntary condition is 0.0034mV. For the right leg for stepping

condition it is 0.0032 mV, for normal walking with assistance it is 0.004 mV, and under voluntary condition is 0.004 mV. All these values were compared with the MVC values of the respective muscles of the volunteers. Hence, we can say that in, paraplegic condition, the results from both the legs or limbs are almost of equal amplitude during stepping condition however, difference exists during normal walking and voluntary conditions, which shows that their muscle movement is not normal.

Conclusion: We can conclude that this study must be helpful for the understanding the mechanism of muscle functioning during performance of routine tasks. Moreover, it can provide insight for understanding development of osteoarthritis (OA) condition in the knees for this population group at an early age.

PO-0141

CAN HEIGHT AND FLEXIBILITY OF FOOT ARCH MAINTAINED IN OBESITY?

Yuichi Takata [1,*] Yuki Saito [2] Tomoaki Kamiya [2] Takako Chikenji [2] Eiichi Uchiyama [3]

[1]Department of Physical Therapy, Hokkaido Bunkyo University, Eniwa, [2]Sapporo Medicel University, [3]Department of Orthopaedic Surgery, Hitsujigaoka Hospital, Sapporo, Japan

Introduction and Objectives: Overweight may lead to mechanical trauma, degeneration, and eventually posterior tibial tendon dysfunction. Flexibility of the foot arch aids human gait by supporting the body weight against gravity. The tibialis posterior muscle is believed to be the most important dynamic support of the arch of the foot. However, no previous experimental studies have examined the influences of the obesity to the dynamic function of tibialis posterior tendon and *flexibility of the medial longitudinal arch* (FA).The aim of the present study was to investigate the FA which was calculated by the change of the *medial longitudinal arch height* (AH) during cyclic axial loading with obesity compared to the non-obese condition.

Methods: 14 normal fresh frozen cadaveric legs were used. The mean age at the time of death was 82 years (range, 59 to 93). Each leg was cut at the proximal third of the crus. The proximal edge of each specimen was fixed with 2-mm Kirschner wires and mounted by a 5-cm-diameter acrylic tube filled with polymethylmethacrylate resin. The leg was set at the neutral position on the custom jig.

A total of 10,000 cyclic axial loadings of 500 N or 1,000 N (1Hz) were applied to the longitudinal axis of the tibia using the Materials Testing Machine (AG-1, SHIMADZU, Kyoto, Japan). The 32 N dynamic muscle loadings were applied to the tibialis posterior tendon. The experiments were divided into two groups. The 500 N cyclic axial loadings and 32 N dynamic muscle loadings were applied to the tibialis posterior tendon by the servomotor (normal group, n=7). The 1,000 N cyclic axial loadings and 32 N dynamic muscle loadings (obese group, n=7). A 1 mm^2 square red light emitting diode (LED) was attached to the medial aspect of the navicular with minimum disruption. The displacement of the LED light was monitored via a charge-coupled device (CCD) camera (Figure 1) [1] . The image from the CCD camera was converted to the coordinate system. The translational accuracy was 0.06 mm (0.2% full scale).

One cycle was determined that the period of over 5 N axial load applied. The navicular heights with initial 5 N axial load and a peak of axial load were recorded in each cycle. It means that the navicular height with minimum and maximum weight bearing, respectively. The arch change was evaluated using the bony arch index (BAI) [2]. The BAI was determined by the navicular height to foot length ratio. A low arch was defined as a BAI with weight bearing of less than 0.21. The BAI with maximum weight bearing (BAI_{max}) and minimum weight bearing (BAI_{min}) were calculated for each 1,000 cycles. FA was defined as (BAI_{min}- BAI_{max}). Results were expressed as a mean ± standard deviation (SD). We compared BAI with maximum and minimum weight bearing and FA for each 1,000 cycles between normal and obese group by using a t test. A p value of 0.05 was chosen as the level of significance. This study was approved by our institutional review board (IRB).

Results: The height of the navicular decreased with cyclic axial loading. The initial BAIs with maximum weight bearing were 0.242±0.011 (normal group), and 0.234±0.012 (obese group). The BAI of obese group decreased less than 0.21 after 1,000 cyclic axial loadings. On the other hand, the mean BAI of normal group were remained over 0.21. After 10,000 cyclic axial loadings, the mean BAIs with maximum weight bearig were 0.213±0.009 (normal group) and 0.180±0.023 (obese group). The initial BAIs with minimum weight bearing were 0.283±0.007 (normal group), and 0.276±0.018 (obese group). After 10,000 cyclic axial loadings, the mean BAIs with maximum weight bearing were 0.258±0.012 (normal group) and 0.197±0.025 (obese group). The initial value of FA were 0.045±0.011 (normal TP group) and 0.042±0.014 (obese TP group). After 10,000 cyclic axial loadings, FA were 0.046±0.013 (normal TP group) and 0.017±0.006 (obese TP group). Statistical significances were found between normal TP group and obese TP group in the mean BAI with maximum and minimum weight bearing after 1,000 cyclic axial loadings(Figure 2,3) and the FA after 2,000 cyclic axial loadings(Figure 4).

Figure:

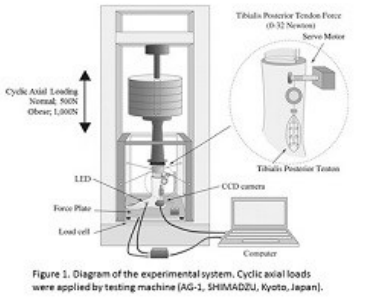

Figure 1. Diagram of the experimental system. Cyclic axial loads were applied by testing machine (AG-1, SHIMADZU, Kyoto, Japan).

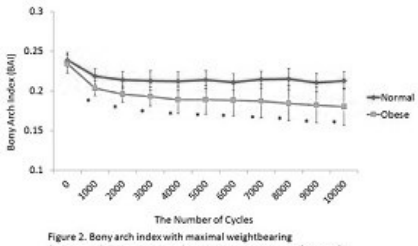

Figure 2. Bony arch index with maximal weightbearing
* The BAI of obesity was significantly lower than normal($p < 0.05$)

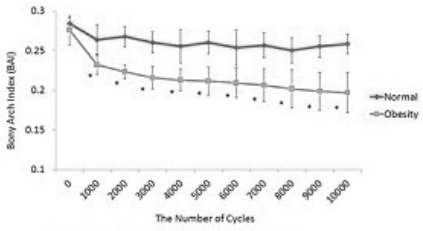

Figure 3. Bony arch index with minimal weightbearing
* The BAI of obesity was significantly lower than normal($p < 0.05$)

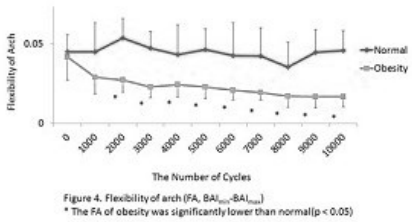

Figure 4. Flexibility of arch (FA, BAI_{min}-BAI_{max})
* The FA of obesity was significantly lower than normal($p < 0.05$)

Conclusion: We investigated the influence of the overweight to the arch height and flexibility during cyclic axial loadings with tibialis posterior muscle force. The present results showed that the BAI with obese group was significantly decreased after 1,000 axial cyclic loading and the flexibility of arch (FA) with obese group was significantly decreased after 2,000 axial cyclic loading. Energy which is received by foot arch is proportional to flexibility (energy=κ*flexibility). Therefore, our results suggested that the decreased flexibility in the obese foot might diminish the energy absorption at the foot arch, and increase the load to the proximal weight bearing joint including ankle joint.

SYMMETRY/ASYMMETRY BETWEEN THE LOWER LIMBS BASED ON GENDER AND DOMINANT LIMB

Alireza Rastegarpanah [1,*] Mozafar Saadat [2]

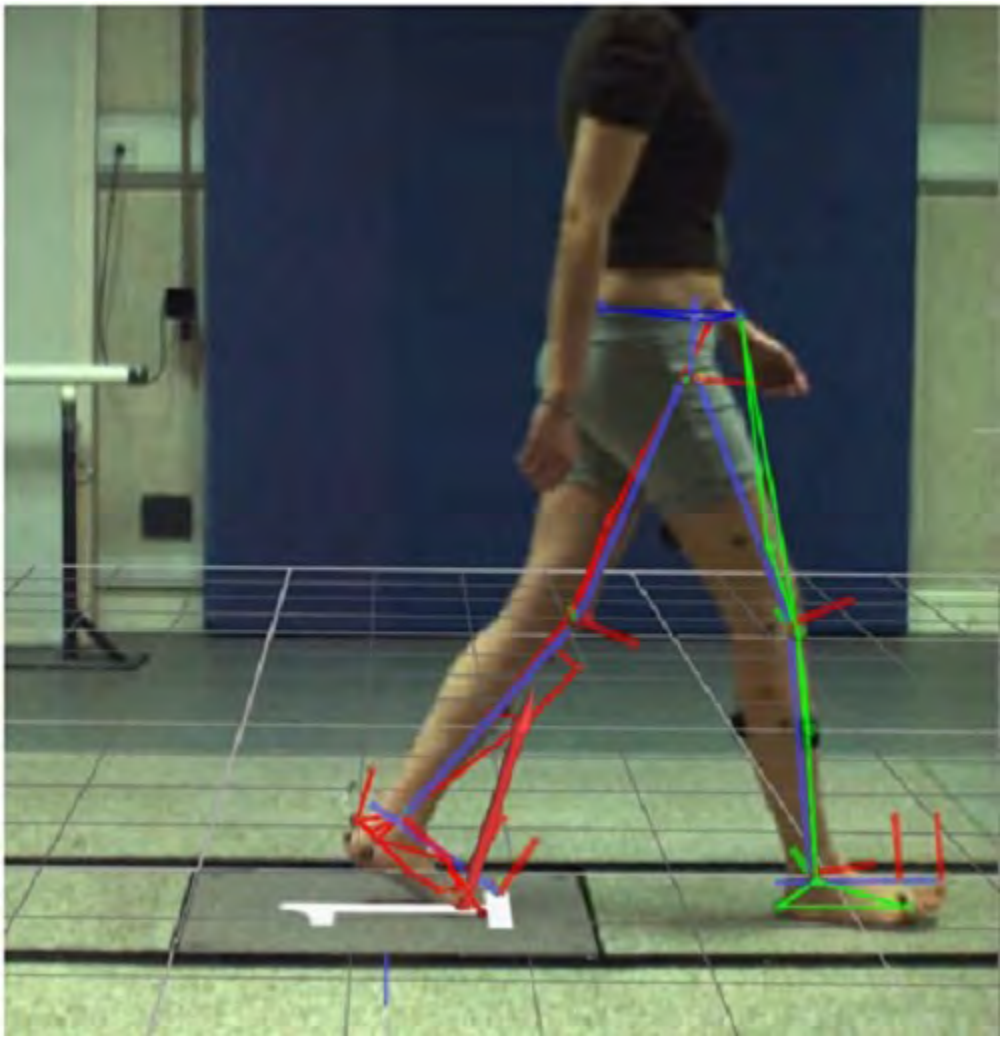
[1]School of Mechanical Engineering, Doctoral researcher - University of Birmingham, [2]School of Mechanical Engineering, University of Birmingham, Birmingham, United Kingdom

Introduction and Objectives: The term “gait symmetry” is used to define the differences between the lower extremities in relation to kinematic parameters and it has been defined as an ideal harmony between the actions of lower extremities[1]. Term of asymmetry often was used by researchers to show structural and functionality disparities, although asymmetries in the brain`s functional map and cytoarchitecture have been associated with asymmetrical behavioural traits such as handedness and footedness[2]. In a number of previous studies asymmetry has been used to show a pathological case, while in many others, gait symmetry has been used for simplifying the data analysis. In this paper experimental gait measurements have been used in conjunction with statistical tests to provide a unique investigation in functional differences between the lower limbs during normal walking.

Methods: As it can be seen in Figure1, gait analysis was performed with anthropometric measurements and measurement of leg segmental motion characteristics of 28 subjects, including 14 male (7 left footers and 7 right footers) and 14 female (7right footers and 7left footers), 7 left female footers, and 7 male right footers. Vicon system was used as the tracking system. The experimentation was performed in two modes: the first part (Normative mode), participants unaware about existence of force plate along the walkway, while the second part, Targeting mode, participants aware of the existence of the force plate. Based on the obtained data, the values for Joints rotations between the first and second foot strikes for each leg were extracted after normalization of cycle time. Statistical ANOVA tests were applied in order to compare the symmetry/asymmetry of angular rotations of the hip, knee and ankle joints using IBM SPSS software. Initially the data between the male and female participants were investigated in two modes. Then, the symmetrical/asymmetrical behaviour of the joints for the male and female was investigated based on the dominant limb.

Results: In this study, force plate has been utilized as a key parameter in determining the effect of laterality on asymmetry/symmetry of angular rotation of the hip, knee and ankle joints between the right limb and the left limb when the brain is not cognizant and does not have any understanding of the existence of an object along the walkway. Therefore, in the Normative mode the context of laterality is modest and no limb predominance observed, specially for males. To study the relation of the these differences, gender investigation was performed and it was concluded that symmetry between the angular rotations of the lower limbs joints appeared in Targeting mode for the right footers females who struck the force plate with their right foot, while asymmetry happened for right and left footers males, with right and left foot strikes, in both Targeting and Normative modes.

Figure:



Caption: Gait analysis and overlay 3D simulation of lower limb

Conclusion: The results suggest that female participants achieved more symmetrical gait motion signatures, between the rotation of the joints of left leg and right leg than their male counterparts in Targeting test. The outcome of this pilot study will provide an improved understanding about human motor function, and will specifically be useful in applications concerned with robotic rehabilitation.

KNEE AND HIP STRENGTH PROFILES CHARACTERISE FUNCTIONAL NEEDS IN RUGBY ATHLETES

Scott R. Brown [1,*]

[1]Sports Performance Research Institute New Zealand (SPRINZ), Auckland University of Technology, Auckland, New Zealand

Introduction and Objectives: Rugby union is an intermittent high-intensity contact sport requiring maximum strength and power performances, interspersed with low-intensity efforts [1]. Rugby forwards utilise strength for success in contact situations such as front-on tackling, rucks, mauls and scrums; whereas backs utilise power for success in high-speed side-on tackling and contact evasion [2]. Unique force-producing attributes are developed in specific joints and angles between the two positions for efficiency. Lower-extremity strength assessment techniques should shift their importance to multi-joint assessments in conjunction with the angles of peak torque for a complete representation of an athlete's lower-extremity strength [3]. Bilateral single-joint or unilateral multi-joint strength deficits may increase risk of lower-extremity injury; especially when unique positional attributes can further accelerate strength differences [4]. We assessed rugby athletes through multi-joint and multi-speed isokinetic actions to illuminate any position specific strength profiles.
Methods: Twenty-nine male academy (development-level) rugby athletes (age 22±4y, body-height 1.9±0.1m, body-mass 97±11kg), separated into forwards (n=15) and backs (n=14), performed bilateral isokinetic strength assessments at the knee and hip with concentric (60°·s^{-1} and 180°·s^{-1}) actions and at the knee with eccentric (60°·s^{-1}) actions. Fourth-order polynomial curve fitting was used to identify peak torque and angle of peak torque. Hamstrings-to-quadriceps (H:Q) ratios and knee flexion-to-hip extension (KF:HE) ratios were calculated.
Results: Backs were smaller in stature (MDiff=-0.032m; ES=-0.45) and lighter in body-mass (MDiff=-13kg; ES=-1.3) compared to forwards. Strength comparisons at the knee showed small decreases in strength of the backs compared to forwards during concentric knee extension and flexion at 60°·s^{-1} (MDiff=-19N·m; ES=-0.37 and MDiff=-11N·m; ES=-0.48 respectively) and small to moderate decreases at 180°·s^{-1} (MDiff=-23N·m; ES=-0.59 and MDiff=-15N·m; ES=-0.85). Eccentric peak extension and flexion torques showed unclear and small decreases in strength of backs compared to forwards (MDiff=1.07N·m; ES=0.018 and MDiff=-10.7N·m; -0.30). Compared to forwards, backs showed moderate decreases in peak concentric flexion angles at 60°·s^{-1} and 180°·s^{-1} (MDiff=-10°; ES=-1.004 and MDiff=-3.3°; ES=-0.65) and moderate to small changes in peak eccentric extension and flexion at 60°·s^{-1} (MDiff=-5.7°; ES=-0.78 and MDiff=4.4°; ES=0.58). At the hip, strength comparisons between forwards and backs showed unclear to small decreases in strength during hip extension and flexion at 60°·s^{-1} (MDiff=-10N·m; ES=-0.12 and MDiff=-11N·m; ES=-0.33) with differences between the groups unclear at 180°·s^{-1} (MDiff=4.2N·m; ES=0.046 and MDiff=-5.0N·m; -0.16). Backs showed a small increase in angle of peak torque during 60°·s^{-1} hip extension (MDiff=1.1°; ES=0.29) and a large decrease during hip flexion (MDiff=-2.7°; ES=-1.2) compared to forwards.
Conclusion: It was not surprising that forwards had greater peak torque values at the knee and hip compared to backs considering the conceptual positional requirements of each group [2]. Strength differences between forwards and backs were similar to those reported for professional rugby athletes [1]; with the exception of an overall decrease in strength,

likely a result of the age, competition level and strength training history. Backs possessed more desirable angles of peak torque during extension and flexion actions (i.e. larger extension and smaller flexion angles) and speeds given the types of movement patterns they use in match play. Adequate strength at long muscle lengths are more desirable in sports with sprinting bouts as hamstring injuries are suggested to occur near full knee extension [5]. Forwards and backs showed substantially smaller H:Q ratios (0.54 vs 0.67 forwards; 0.53 vs 0.64 backs) and KF:HE ratios (0.39 vs 0.58 forwards; 0.37 vs 0.61 backs) compared to professional rugby athletes [1]; most likely resulting from overactive quadriceps and/or weak hamstrings. Meaningful strength differences were present in academy rugby forwards and backs at the knee and hip which became more substantial during faster assessment speeds. While rugby forwards had superior lower-extremity strength compared to backs, their associated angle of peak torque occurred at inferior degrees; potentially lending way to lower-extremity injury. Bilateral single-joint and unilateral multi-joint lower-extremity strength assessments can facilitate more informed recommendations on whether athletes would be more advantaged to perform specific movements aimed to improve strength at longer muscle lengths.

PO-143

DEFINING A CUT-OFF THRESHOLD FOR JOINT POSITION SENSE IN INDIVIDUALS WITH PATELLOFEMORAL PAIN

Ambreen Chohan [1,*] Michael Callaghan [2] Denis Martin [3] Jim Richards [1] James Selfe [1]

[1]Allied Health Research Unit, University of Central Lancashire, Preston, [2]Arthritis Research UK, Institute of Inflammation and Repair, University of Manchester, Manchester, [3]Health and Social Care Institute, Teeside Univeristy, Middlesborough, United Kingdom

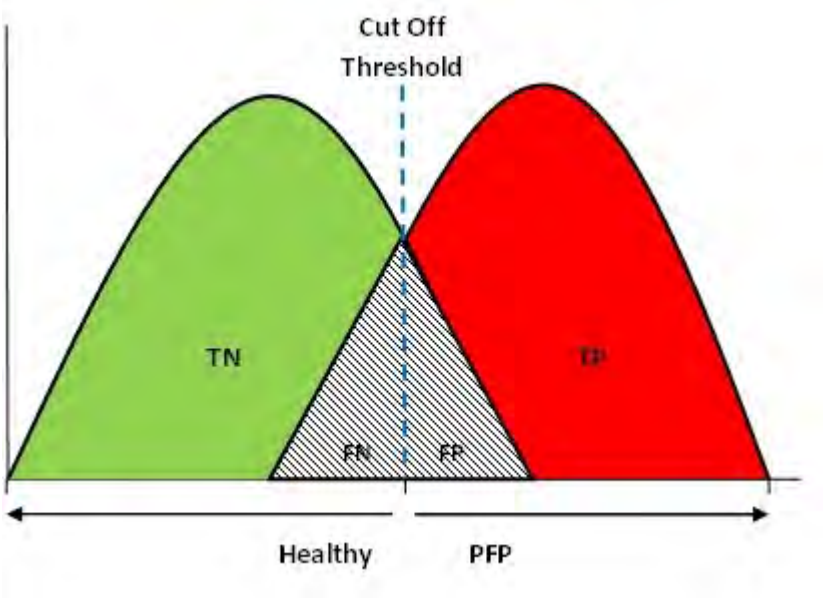
Introduction and Objectives: The importance of measuring proprioception status has increased to help explain the clinical effect of interventions such as knee braces, patellar taping and exercise. In the absence of a reference standard, various measurement techniques have been used for joint proprioception. The most common is joint position sense (JPS) using active angle reproduction (AAR). To date there has been no consensus defining a threshold above or below which proprioception status can be classified. Cut-off thresholds can be based upon the absolute difference between the target angle and achieved angle during AAR testing. To date studies on either healthy people or those with knee pathology had a target angle for JPS tests of absolute difference of ≤5 degrees to differentiate good/poor proprioception though this had no supporting evidence. If a JPS test such as AAR is to be used it is necessary to set a cut-off threshold, below and above which people would be considered to have good/poor proprioception respectively. Defining the threshold may help in the sub-classification of knee conditions such as patellofemoral pain (PFP) and knee osteoarthritis and help decide appropriate treatment if proprioceptive deficits are found.This study aimed to determine the optimum cut-off threshold and test angle that most accurately classifies those with poor proprioception using target angles of 20° and 60° in individuals with and without PFP and explored the possible use of AAR tests as a diagnostic test for PFP participants with poor proprioception.

Methods: Twenty healthy adults (26.8±8.2years old) and thirty adults with PFP (32.1±11.2years old) were recruited. The study was performed in accordance with the 2008 Declaration of Helsinki and appropriate ethical approval was gained from all relevant bodies. JPS was assessed through AAR using an Isokinetic Dynamometer. An ipsilateral position matching activity was performed at target knee flexion angles of 20° and 60° as studies have suggested that functionally these angles are clinically important when assessing patellofemoral disorders. The lever arm passively extended the leg to a target angle of 20° or 60° of knee flexion, without resistance and was held for 10 seconds to enable participants to memorise the position. After the limb was passively returned to 90° there was a 5-second pause before participants actively moved the limb at a self-selected speed, to the target angle, stopping when they thought the target had been perceived. Participants were not permitted to correct the angle. The absolute difference between the perceived angle and the target angle was calculated for each trial. AAR testing was repeated 5 times at each angle in accordance with previous recommendations. The Diagnostic Odds Ratio (DOR) has been determined as a good single indicator of test performance, to define an optimum cut-off threshold. Fig.1, illustrates a cut-off threshold below which tested participants may be determined as healthy, or with good proprioception and above which are individuals with poor proprioception and PFP. An optimum cut-off threshold was determined by maximising the True Negative and Positives (TN, TP), whilst

minimising the False Negatives and Positives (FN, FP). A minimal grey overlap is the ideal situation, minimising the percentage chance of being wrongly classified through AAR testing. Performance of the DOR for AAR testing was compared to the cut-off threshold determined by the Youden's index. Both DOR and Youden's index determine the strength of association between proprioception and a diagnosis of PFP.

Results: For AAR joint position sense testing at 20° there was an agreement between the two test performance indicators (DOR and Youden's index) for a 2° cut-off threshold. However, at 60°, results were similar but not identical (DOR=10°,Youden's Index=11°). Taking each of the test angles separately, at 20° a 2° cut-off threshold shows 62% accuracy and a 38% chance of falling into the "grey area" requiring further assessment, sub-classification or sub-grouping. The previous arbitary threshold of ≤5° would lead to this figure being 52%. At 60°, a 10° cut-off threshold shows lower accuracy at 58%, leaving a larger chance of incorrect identification of PFP through this form of proprioceptive testing.

Figure:



Caption: Graphical representation of a cut-off threshold

Conclusion: Proprioception status has been shown to play an increasingly important role in the effect of clinical interventions. This study suggests that independent tests for proprioception may not be solely relied upon for accurate diagnosis of proprioceptive deficit and PFP. A cut-off threshold for JPS testing may help to optimise treatment in light of proprioceptive deficits. It is suggested that for adults with PFP the previously used arbitrary cut-off threshold of ≤5° is revised to 2° and that 20° is the more clinically appropriate test angle as a greater degree of accuracy is required when approaching full extension in order to optimise control of the knee joint.

ACUTE EFFECTS OF WHOLE BODY VIBRATIONS ON LANDING LOAD DURING DROP JUMPS FROM A 40 CM HEIGHT

I.Lin Wang [1,*] Sheng-Wun Siao [2] Tzu-Chieh Chang [2] Yuan.Mei Sun [2] Mu.San Chang [3] Li.I Wang [2]

[1]National Dong Hwa University, Department of Life Science and the Institute of Biotechnology, [2]National Dong Hwa University, Department of Physical Education and Kinesiology, [3]Tzu Chi University, Center of Physical Education, Hualien, Taiwan, Republic of China

Introduction and Objectives: Drop jumps (DJ) are a common plyometric exercise, and many studies have confirmed that drop jump task training can improve sports performance [2,8]. However, drop jump task movements carry a potential risk of injury [1,9]. The proper use of drop jump tasks to effectively train and reduce the risk of injury is an important issue given that enhanced muscle strength may help to reduce the loading during landing [11]. Whole body vibrations (WBV) could stimulate the muscle spindle and increase muscle action to enhance muscle strength and provide power immediately [4,10]. Hence, the purpose of this study was to investigate the acute effects of WBV on landing load.

Methods: Fifteen male college students from the physical education (19.47±0.59 yrs, 1.73±0.04 m, and 64.67±4.22 kg) from the physical education department voluntarily participated in the study. Subjects were excluded if they experienced any lower body orthopedic injuries or musculoskeletal injuries within the past six months. The Institutional Review Board approved this study.

A standard warm-up was performed before testing. The subject performed a pre-test involving a drop jump from a 40 cm drop height (pre-DJ40). All subjects were subject to a WBV process (1 min*3set, 30Hz, 3 mm) [3,6]. A 4-min rest time after WBV occurred [7] before the post-test involving a drop jump from a 40 cm drop height (post-DJ40).

The Qualisys Track Manager (QTM) motion capture system with 8 infra-red cameras (200 Hz) was used to capture motion data. Two AMTI (60 cm×90 cm) force plates (1000 Hz) were used to collect ground reaction forces. The data were analyzed by using the Motion Monitor analysis software.

The SPSS 14.0 statistical program was used for statistical analysis. A repeated measures *t*-test was used to compare the difference between the pre-DJ40 and post-DJ40. The significance level was set at α=0 .05.

Results: The results of this study are shown in Table1. The peak VGRF and vertical loading of post-DJ40 were significant less than pre-test ($p<.05$). The knee joint angular displacement of post-DJ40 was significantly greater than the pre-DJ40 during landing phase ($p<.05$). There were no significant different in ankle and hip joint angular displacement during landing phase between pre- and post-DJ40 ($p>.05$).

Conclusion: In summer, we conclude that WBV reduced the landing load acutely during 40-cm drop jump tasks. WBV could be applied during plyometric training with drop jump to reduce the risk of injury.

Table:

Group	pre-DJ40	post-DJ40	*p*-value
Peak VGRF (BW) *	2.98±0.78	2.66± 0.65	0.005
Loading Rate (BW/s*)	83.80± 61.43	69.49±42.31	0.039
Ankle joint angular displacement during landing (degree)	40.94±5.73	40.87±4.69	0.931
Knee joint angular displacement during landing (degree) *	43.80±9.57	47.01±10.03	0.029
Hip joint angular displacement during landing (degree)	15.70±7.09	17.07±6.80	0.171

* Significant differences between pre-DJ40 and post-DJ40 , $p<0.05$

PO-0144

QUANTIFYING WARFIGHTER PERFORMANCE ON A TARGET ACQUISITION AND AIMING TASK USING WIRELESS INERTIAL SENSORS

Steven P. Davidson [1,*] Stephen M. Cain [1,2] Ryan S. McGinnis [3] Rachel V. Vitali [2] Noel C. Perkins [2] Scott G. McLean [1]

[1]School of Kinesiology, [2]Department of Mechanical Engineering, University of Michigan, Ann Arbor, MI, [3]MC10, Inc., Cambridge, MA, United States

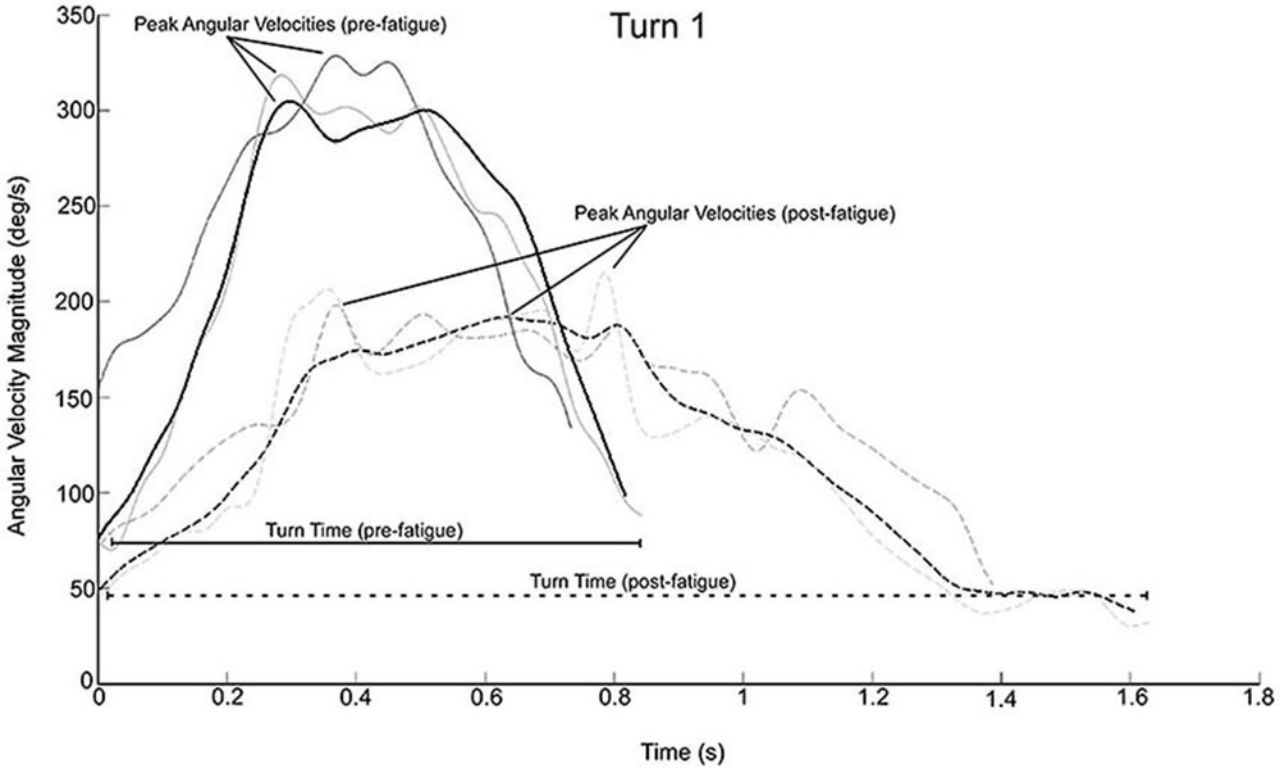
Introduction and Objectives: In a combat scenario, the performance of a warfighter is paramount to the safety and success of a mission. In these situations however, a warfighter is expected to carry over 18kg of advanced armor, weapons, ammunition, and support gear, while simultaneously maneuvering through a complex and often random environment. These additional load constraints often restrict/alter key movements and increase fatigue rate, contributing to a rapid decay in warfighter performance. A key aspect of warfighter performance is the ability to aim a rifle and to successfully acquire and hit a target. Overall aiming performance rests on the ability to react, identify, and stabilize on a target before accurate shot execution. It is understandably a challenge to quantify overall aiming performance, particularly given the random (real) environments that a warfighter negotiates. However, a promising means to do so is summarized herein by employing an array of wireless inertial measurement units (IMUs) that measure 3D rifle and body segmental movements in in simulated combat environments. By employing IMUs, this study aims to quantify explicit warfighter aiming performance metrics pre- and post-fatigue in a simulated target acquisition (TA) task.

Methods: Thirteen participants (7 Male/6 Female, 20.4±1.5 years old) were recruited from an athletic collegiate student population. Participants were outfitted with three IMUs (Yost Engineering), attached to the barrel of a mock rifle, the sacrum, and the sternum. Participants wore a military issue generation III improved outer tactical vest (IOTV-III) equipped with mock-ballistic plates and mock- tactical assault panel attached to the IOTV-III anteriorly. A mock-M4 assault rifle outfitted with a laser aiming system provided visual confirmation of target acquisition. The TA task consisted of two targets (6.35cm black circles on white sheets of paper) spaced 11.6m apart and 0.9m high. At the beginning of the TA task, the participant was verbally commanded to pick up the rifle and stabilize the laser within the black circle of one target. Once stabilized, the participant was instructed to perform a 180° turn and stabilize the laser within the black circle of the second target. The participant performed a final 180° turn, again stabilizing the laser in the circle. The participant then performed a fatiguing circuit (~5 minutes) before repeating the task. The fatigue circuit consisted of vertical jumps, box step ups, and modified shuttle run requiring two standing to prone transitions between runs. Participants continued to perform the TA task and fatigue circuit until maximum fatigue, defined by a drop in vertical jump height equal to 70% of the subjects' maximum non-fatigued weighted vertical jump height. Kinematic measures of aiming performance (deduced from the IMU array) were compared between the first (pre-fatigue) and final (post-fatigue) TA task trials. Specifically, maximum angular velocity (MAV) and total turn time (TT) of the rifle, sacrum, and sternum IMUs were compared (Figure1). Significant differences between pre- and post-fatigue performance were revealed using paired t-tests (α=0.05).

Results: Fatigued MAV was significantly less than pre-fatigue levels during turn 1 by an average (±std) of 64.87±46.43deg/s, 54.98±54.48deg/s, and 80.83±62.03deg/s, for the sternum, sacrum, and rifle IMUs, respectively.

Similarly during turn 2, fatigued MAV was significantly less for the sternum (56.49±39.45deg/s), sacrum (50.54±33.23deg/s) and rifle (53.48±43.93deg/s) IMUs, respectively. Fatigued TT was significantly longer during turn 1 for the sternum, sacrum, and rifle IMUs by an average of 0.372±0.282s, 0.471±0.404s, and 0.256±0.304s, respectively (Figure1). However, fatigued TT was significantly longer in Turn 2 only for the rifle sensor by an average of 0.139±0.195s.

Figure:



Caption: Figure1: Representative data from a single trial, showing maximum angular velocity and turning time differences in the first turn of a target acquisition task before and after fatigue.

Conclusion: Fatigue-induced decreases in MAV for the rifle, sacrum and sternum sensors evident for both turns likely represent a decreased ability to successfully react and perform the given task. The associated increase in TT may be particularly critical for warfighter performance, suggesting an increased vulnerability during the movement and an inability to react quickly for an extended period. Additionally, decreased MAV during the turning motion suggests a reduced ability to maneuver the body when fatigued; leading to low shot success even if a target is visually identified and acquired. Current outcomes suggest that fatigue associated with realistic warfighter movements under load degrades the ability to acquire and aim at a target in the battlefield, therefore reducing warfighter performance and increasing risk. The study also confirms the promise of IMU arrays as a means to quantify warfighter performance in realistic warfighter environments.

PO-0145

BIOMECHANICAL RESPONSE OF SCAFFOLD ON MECHANICAL LOADING.

Jana Anděrová [1,*] František Lopot [1] Karel Jelen [1]

[1]Anatomy and Biomechanics, Charles University in Prague, Prague, Czech Republic

Introduction and Objectives: Many authors encounter problems associated with insufficient mechanical properties, as the formed tissue is actually not strong enough/resistant, or even earlier, when the cells are not forming optimally or do not grow adequately. This is caused by number of factors, such as suboptimal chemical - biological properties of the scaffold as well as its mechanical properties.

While electrospinning the nanofibers, many parameters can be adjusted, affecting the final properties of the nanofibers (manufacturing solution viscosity, voltage, collector type ....)

The properties of the scaffolds are also adjusted by the post-production processes, such as. cross-linking ect. It is evident from the available literature, that there is not a linear dependence on the properties of the nanofibres and the complex nanofibrous structure. These are characterized by their rheological inhomogenity and the available approaches used to study deformations omit detailed structural changes inside the material.

The aim of this work is the detection of mechanical properties through basic viscous, plastic and elastic components with a clear physical interpretation, and effects of hydration on the properties of the scaffolds.

Methods: The research subject were polyvynilalcohol scaffolds produced by electrospinning technology NanospiderTM 2nd generation. The molecular weight of a solution of 40 kDa, 220 kDa, and for measuring the scaffolds were produced with the following ratios of solutions: 1:3, 1:2, 1:1, 2:1, 3:1.

A single-axis tensile test was utilised, where controlled variable was displacement, velocity 1,5mms^{-1}. Evaluation of the measured data takes place by evaluating the measured software stress-strain response curve. A lateral deformation had been detected by HD camera recording, which was used for the calculation of Poisson's ratio.

Samples were adjusted to the dimensions of 70x20 mm. The thickness of the samples was very small due to substantial non-uniformity of the materials and measurement difficulties. Instead of the cross-section area, the width of the sample was determined to be the standardized dimension. By default, the normalization values of the material applied relative to the initial cross-sectional samples. However, since one of the cross-sectional dimensions of the test scaffolds approaching zero as a limit, is not only for the purpose of this work is designed to standardization initial width sample b_0 [mm]. This approach introduced stiffness and damping coefficient unit, for which the following equation:

$K = K' / b_0$ [N / (mm_x.mm_b)]

$B = B' / b_0$ [Ns / (mm_x.mm_b)]

where the index x indicates mm in the length direction and the index b mm in the width direction of the sample. Measured data passed the evaluation software, and the force deformation response curve was fitted by equation of selected rheological model. The monitored parameters were the damping coefficient and normalized stiffness in areas of small deformations (units %) as well as large deformations (from 20%).

Samples were measured in a dry and hydrated state (Ringer's solution).

Results: The data was processed into the visual charts comparing the ratios for individual production solutions for the samples measured in dry and hydrated state.

As for the dry samples, it has been found that the damping coefficient and the stiffness in both fields retain deformation character. Large deformations led to an increase in standardized damping coefficient values, on average by 30%, and an increase in standardized stiffness values in average by 43%.

For wet samples large deformation led to a very significant increase in normalized damping coefficient values on average by 278%. Large deformations do not cause significant change, an increase on average of 7% has been recorded.

The smallest changes in both parameters for the dry measurement have been observed for the solution ratio of 1:1. The highest increase in damping coefficient values for the hydrated state had been detected also at the solution ratio of 1:1, on the contrary the smallest change of stiffness has been recorded.

Conclusion: Detection of the scaffolds mechanical parameters can be used to stabilize the production conditions, and their adaptation of specific usage and application of scaffolds.

There is no linear relationship between the manufacturing solution rations and monitored parameters.

Hydration sample causes a value decrease in damping coefficient and decrease stiffness values.

Ratio 1:1 solution constitutes a landmark from which have values for other ratios of solutions either increase or decrease in value, both when measured in the dry and wet state. Also while simply observing macroscopically, the Poisson points change indicates that the structure of the samples scaffolds changes under strain.

Only just detailed analysis of changes in the internal organization of the influence of deformation is the key to the generally applicable methodology for measuring nanofibrous structures.

MOTION AXIS OF SUBTALAR JOINTS

Takahiko Fukumoto [1 2,*] Kenrin Shi [3] Kazuomi Sugamoto [2]

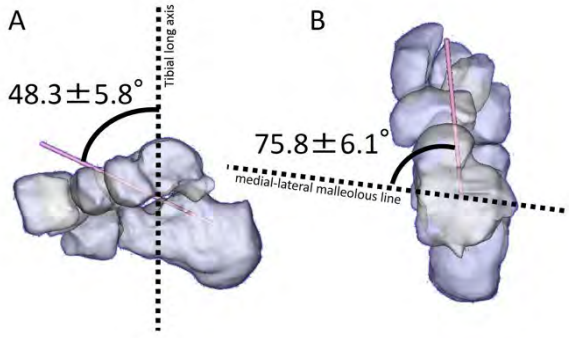
[1]Department of Physical Therapy, Faculty of Health Science, Kio University, Nara, [2]Department of Orthopedic Biomaterial Science, [3]Department of Orthopedic Surgery, Osaka University Graduate School of Medicine, Osaka, Japan

Introduction and Objectives: There have been many studies on the kinematics of the subtalar joint accompanying the ankle motion. It is reported that the subtalar joint is associated with varus-valgus among foot parts. And it is reported that the motion axis internally rotates for the long axis of the foot part. Most of these studies were cadaveric studies. Alternatively, it was the in vivo study that rotated the ankle joint in varus-valgus. However, the movement of the subtalar joint is unclear when an ankle dorsi-plantar flexion. The purpose of this study was to analyze the subtalar joint kinematics during plantar-dorsiflexion of the ankle, using multi-positional low-dose CT imaging.

Methods: After informed consent, 20 ankle joints of 10 healthy male volunteers (age, 32.5±5.0 years; height, 170.9±3.2 cm; weight, 65.3±2.1 kg) underwent low-dose CT in 3 positions (40° plantar flexion, neutral, and 20° dorsiflexion). 3D pose of the fibula relative to the tibia in each position was analyzed by our originally developed software, and was calculated by Euler's method. Then 3D motion of the ankle was visualized in animation.

Results: When the ankle was in plantar flexion, the calcaneus was rotated varus in all case. The rotation angle of the calcaneus against the talus were varus; 5.1±1.7°, plantar flexion; 1.0±0.8°, external rotation; 0.8±0.7°. The motion axis were 48.3±5.8° for a tibial long axis (fig.A) and 75.8±6.1° for a medial-lateral malleolous line (fig.B)

Figure:



Conclusion: When an ankle dorsi-plantar flexed, the subtalar joint turned a foot part varus-valgus. The motion axis internally rotated from the anterior-posterior axis of the foot part. This motion axis is similar with a conventional report very much. The subtalar joint seems to make a constant move regardless of the movement of the ankle joint like a midcarpal joint makes a constant move regardless of the movement of the wrist. This is very useful for orthopedics and physical therapy.

EFFECTS OF INTERNAL AND EXTERNAL ATTENTION ON GAIT IN ELDERLY

Jonathan De Melker Worms [1,*] John Stins [2] Erwin van Wegen [3] Peter Beek [2] Ian Loram [1]

[1]School of Healthcare Science, Faculty of Science and Engineering, Manchester Metropolitan University, Manchester, United Kingdom, [2]MOVE Research Institute Amsterdam, Faculty of Human Movement Sciences, VU University Amsterdam, [3]Department of Rehabilitation Medicine, MOVE Research Institute Amsterdam, VU University Medical Center, Amsterdam, Netherlands

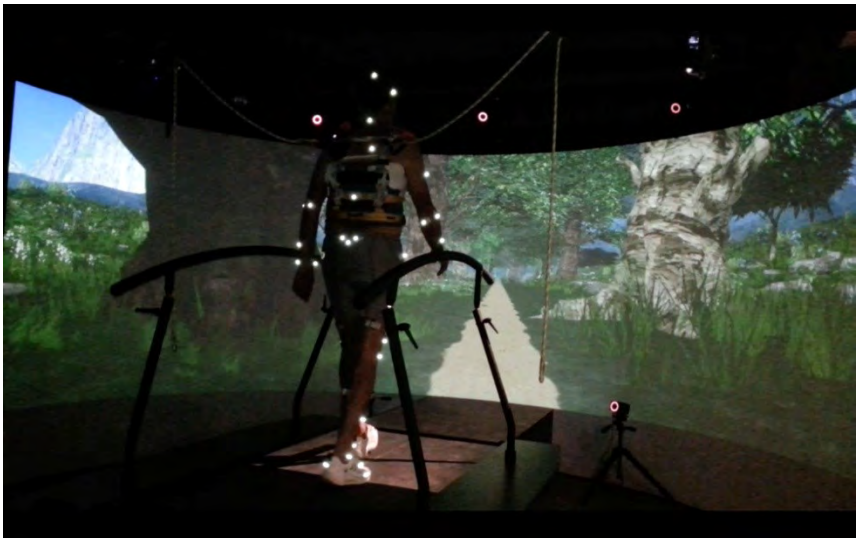
Introduction and Objectives: The aging population is confronted with the problem of mobility loss. It has been suggested that individuals with increased fear of falling have heightened conscious attention to their own movements (e.g., control of locomotion), which otherwise would require little attentional control. The process of switching from a more automated implicit form to a more conscious form of motor control has been termed reinvestment [1]. Using the Movement Specific Reinvestment Scale (MSRS), Wong et al. have found higher reinvestment scores in elderly with a history of falling compared to elderly non-fallers [1]. Related to reinvestment, one might distinguish between external and internal focus of attention during motor performance. Based on a growing body of literature [2], an external focus of attention appears to facilitate performance on challenging motor tasks, as it allows more 'automatic' or 'efficient' control mechanisms to come into play, compared to an internal focus of attention. To assess walking stability as a function of attentional focus one could study kinematic properties of walking. We studied whether an external focus of attention leads to a temporary less variable gait pattern (indicative of greater stability) than internal attention. Effects of gait perturbations, fall history and falls efficacy on spatiotemporal gait parameters and fear of falling were studied as well.

Methods: 28 healthy older adults (8 males, 20 females) aged 65 or above were recruited. Participants walked on the Gait Real-time Analysis Interactive Lab (GRAIL) system (Motek Medical b.v., Amsterdam, The Netherlands). The GRAIL system consists of an instrumented split belt treadmill in combination with a Virtual Environment (VE) projected on a 180° semi-cylindrical screen (see the figure). Temporary unilateral treadmill decelerations at random time intervals were used to perturb gait. Using Motek Medical's Human Body Model (HBM) and D-flow software full body kinematics was collected. In this abstract reported data is limited to unperturbed gait episodes. Perturbation data is analysed at the time of abstract submission. Participants filled out Dutch versions of the Falls Efficacy Scale International (FES-I), the Movement Specific Reinvestment Scale (MSRS, consisting of 2 subscales) and details about their fall history. 5 Minutes of unperturbed and two 5-minute trials of perturbed gait were recorded, one internal and one external attention condition, in counter balanced order. For the internal attention condition participants received the verbal instructions: "Look ahead at the screen and concentrate on the movement of your legs". For the external attention condition the instruction was: "Look ahead at the screen and concentrate on the movement of the treadmill". Instructions were repeated every 30 seconds during the trials using a speaker system. We calculated variability (coefficient of variation [CV]; SD/mean × 100) for the following gait parameters: step width, step length, swing time and stance time.

Results: 12 out of 28 participants had experienced a fall within the last 12 months and were labeled as fallers, while the remaining subjects were labeled as non-fallers. A one way ANOVA with FES-I and MSRS scores as dependent variables

and fall history as independent variable showed significantly higher FES-I scores for fallers, $F_{1,28} = 7.15$, $p < 0.05$. MSRS scores were not significantly different between fallers and non-fallers, $F_{1,25} = 0.74$, $p = 0.40$ (MSRS part 1) and $F_{1,25} = 0.61$, $p = 0.44$ (MSRS part 2). For the CVs of step width, step length, swing time and stance time no significant difference was found between conditions, neither for fallers, nor for non-fallers.

Figure:



Caption: Virtual walking environment.

Conclusion: Variability of our selected gait parameters did not show a significant difference between internal and external attention. Possible limitations of conventional spatiotemporal gait parameters are the strong emphasis on location of the feet, neglecting the rest of the kinematic chain. Currently we are analyzing centre of mass velocity and body segment angular velocity time series as described by Bruijn, S.M., et al. [3]. With this multivariate analysis of the perturbation response a more detailed assessment of stability in perturbed gait could be produced. However, our results of spatiotemporal gait parameters indicate that effects of internal and external attention on motor control, as observed in other studies with challenging motor tasks, are not found in healthy elderly gait.

Table:

	Step width	Step length	Swing time	Stance time
External	34.2 (13.9)	12.4 (2.5)	6.3 (1.7)	14.4 (4.2)
Internal	35.3 (10.4)	11.3 (3.1)	6.4 (2.1)	14.3 (4.9)
Difference	1.1 (8.1)	-1.1 (3.9)	0.1 (1.5)	-0.1 (2.9)

Caption: Mean coefficient of variation of spatiotemporal parameters (SD) per condition, and for the difference between conditions.

PO-0148

FORCE CONTROL STRATEGY FOR ACCURATE GENERATION AND RELAXATION

Chiaki Ohtaka [1,*] Motoko Fujuwara [2]

[1]Department of Human Sciences, Graduate School of Human and Sciences, Nara Women's University, [2]Faculty of Human Life and Environment , Nara Women's University, Nara, Japan

Introduction and Objectives: All physical movements consist of the coordination of muscle contractions and relaxations, and a wide variety of movements is possible by changing their amplitudes, velocities, and directions. To move as intended, it is essential to accurately control both the generation and relaxation of the force, which is considered a basic and key element.

However, the vast majority of studies have focused on force generation. Although a previous study reported that controlling the force relaxation is more difficult than controlling the force generation, the reason and a motor strategy for controlling the force relaxation remain to be elucidated.

Therefore, the purpose of this study was to investigate a motor strategy for force generation and force relaxation, utilizing grading tasks during isometric force control. A comparison of the force generation and force relaxation strategies is used to elucidate the difficulty of force relaxation.

Methods: Fifteen healthy right-handed subjects participated in the study. They accurately controlled the force of their isometric elbow flexion response to a go signal to reach a target force level as quickly as possible.

They performed the following two tasks: a generation task, in which they increased their force from 0% maximum voluntary contraction (MVC) to 20% MVC (0–20%), 40% MVC (0–40%), or 60 %MVC (0–60%), and a relaxation task, in which they decreased their force from 60% MVC to 40% MVC (60–40%), 20% MVC (60–20%), or 0% (60–0%). The subjects performed the tasks under two conditions: a simple reaction (SR) condition, and choice reaction (CR) condition. The force output by each subject was recorded, and the following items were analyzed. The difference between the peak force and each target force level was evaluated using the absolute error, constant error, and variable error. The time element was evaluated using the reaction time (RT), adjustment time (AT), and total adjustment time (TAT). The velocity of the force control was calculated using the peak velocity (Peak V) and time needed to reach the Peak V (time to Peak V).

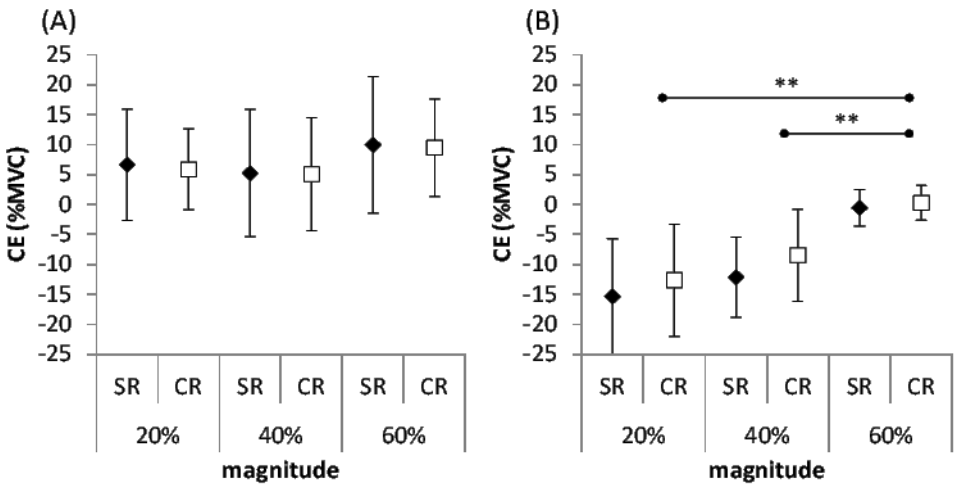
To determine the difference in the mean value for each magnitude of force controlled (20%, 40%, and 60%) and each condition (SR and CR), a two-way repeated measures analysis of variance (ANOVA) was conducted for all the parameters in both tasks.

Results: In the generation task, no difference in the error was observed among the three magnitudes of force controlled (following the 20%, 40%, or 60% magnitude). Under the relaxation task, the error for 20% and 40% was greater than that for the 60% magnitude (Fig.1).

As for the time, under both tasks, AT increased with the magnitude, whereas RT tended to decrease with an increase in the magnitude.

With regard to the strategy (Peak V, time to Peak V), under the generation task, as the magnitude increased, Peak V and the time to Peak V both increased. On the other hand, under the relaxation task, as the magnitude increased, Peak V was increased, although the time to Peak V was constant. A comparison showed that, Peak V was greater for the relaxation task than the generation task under all the magnitudes, and the time to Peak V was greater for the generation task than the relaxation task under the 60% magnitude.

Figure:



Caption: Fig. 1. Mean and standard deviations of constant error for the generation task (A), and relaxation task (B). *: a significant level of difference between magnitudes, **: p< .01.

Conclusion: The result of this study showed that it is difficult to accurately of control the force relaxation with a slight magnitude, and under both force generation and relaxation the adjustment time depended on the magnitude of the force controlled.

Moreover, in relation to the strategy, under the force generation, Peak V came in the latter half of the adjustment time. On the other hand, under the force relaxation, Peak V came at an early stage of the adjustment time and was greater than that under the force generation. Therefore, this suggested a factor in the difficulty of force relaxation compared with force generation: when the force control speed was great and the peak velocity was reached quickly.

MULTI-OBJECTIVE OPTIMAL CONTROL STRATEGIES OF THE LOCOMOTOR SYSTEM DURING OBSTACLE-CROSSING IN PATIENTS WITH PARKINSON'S DISEASE

Hsuan-Lun Lu [1,*] Bing-Chang Wu [1] Tung-Wu Lu [1 2]

[1]Institute of Biomedical Engineering, [2]Department of Orthopedic Surgery, School of Medicine, National Taiwan University, Taipei, Taiwan, Republic of China

Introduction and Objectives: Locomotor changes are one of the most obvious clinical symptoms of Parkinson's disease (PD). It can be a great challenge to patients with PD to perform daily activities such as walking and obstacle crossing. A successful obstacle-crossing requires not only sufficient toe clearance but also the body stability provided mainly by the stance limb. Failure to cross the obstacle can lead to falls and serious injuries [1]. Previous motion analysis studies of obstacle-crossing in PD have focused mainly on individual joint variables such as joint angle and moments. However, it is not clear how the overall control strategy is affected by the disease. The purposes of this study were to study the overall control strategies of obstacle-crossing in healthy older adults and older patients with PD.

Methods: Fifteen healthy older adults (NO) and 15 patients with 1st stage PD participated in the current study with informed written consent. The motions of the body segments were meaureed using a skin marker-based motion capture system when they crossed obstacles of 10%, 20%, and 30% of each subject's leg length.A 7-link sagittal-plane model of the whole body was developed, including the feet, shanks and thighs of both the stance and swing limbs, and the pelvis, upper torso, head, neck and hand as a single segment. The joints were modeled as frictionless hinge joints. Inertial properties of the segments were determined using Dempster's coefficients.The obstacle crossing cycle was discretized into twenty time instances. During each time instance, given the kinematics of the stance limb, the positions of the swing ankle in space and thus the motions of the swing limb were determined by solving a multi-objective optimal control (MOOC) problem with 3 objectives, anmely energy expenditure (f1), toe clearance (f2), and heel clearance (f3) [2]. The weighting method was ued to convert the MOOC problem into a single objective one with the new objective as the weighted sum of the original objectives, i.e., (W1f1 + W2f2 + W3f3), where W1, W2, and W3 were weighting factors satisfying the condition W1 + W2 + W3 = 1 [2].The best-compromised solution to the MOOC problem was one that minimized the root-mean square error (RMSE) between the model predicted ankle trajectories and those experimentally measured. The corresponding weighting set is called the best-compromised weighting set, which indicates the control strategy adopted during obstacle-crossing [2].A two-way ANOVA was used for statistical analysis. Once a significant main effect was found, the Duncan's post-hoc test was used to compare the differences in the best-compromised weighting sets between groups and heights. The significance level was set at 0.05. All statistical analyses were performed using SPSS 13.0 (Chicago, USA).

Results: The energy expenditure weighting for the older group was 0.54 (0.01), much smaller than 0.68 (0.07) for young subjects previously reported [2], suggesting that the older people adopt a more conservative strategy with increased emphasis on foot clearance but reduced emphasis on energy expenditure, which was helpful for reducing the risk of tripping over the obsacle. The energy expenditure weightings in PD were significantly smaller than those in NO,

suggesting that patients with PD increased their emphasis on toe and heel clearances more than the healthy older people did for successful obstacle crossing.

Conclusion: Patients with PD were found to have adopted a control strategy significantly different from that of the healthy older people as expected, with more emphasis on the foot clearance than energy expenditure. These between-group differences were not affected by obstacle height. The findings of the current study provide a better understanding of the control of obstacle crossing in patients with PD from a system-level perspective, which will be helpful for the rehabilitation and design of fall prevention strategies for this patient group.

Table:

Group	Obstacle Height	Energy Expenditure	Toe Clearance	Heel Clearance
Healthy control	10%	0.52	0.24	0.24
	20%	0.51	0.24	0.24
	30%	0.53	0.23	0.24
PD	10%	0.49	0.26	0.26
	20%	0.46	0.27	0.27
	30%	0.49	0.26	0.26
Height Effect		p=0.55	p=0.72	p=0.74
Group Effect		p=0.03	p=0.02	p=0.02

Caption: Average values of the best-compromise weightings for healthy older group (NO) and patients with PD (PD) when crossing obstacles of different height. The last two rows show the P-values for height and group effects, respectively.

ANODAL MOTOR CORTEX TRANSCRANIAL DIRECT CURRENT STIMULATION IMPROVES FORCE STEADINESS IN POST-STROKE HEMIPARETIC PATIENTS

Rafael Montenegro [1 2,*] Adrian Midgley [2] Wendell Bernardes [1] Renato Massaferri [1] Paulo Farinatti [1]

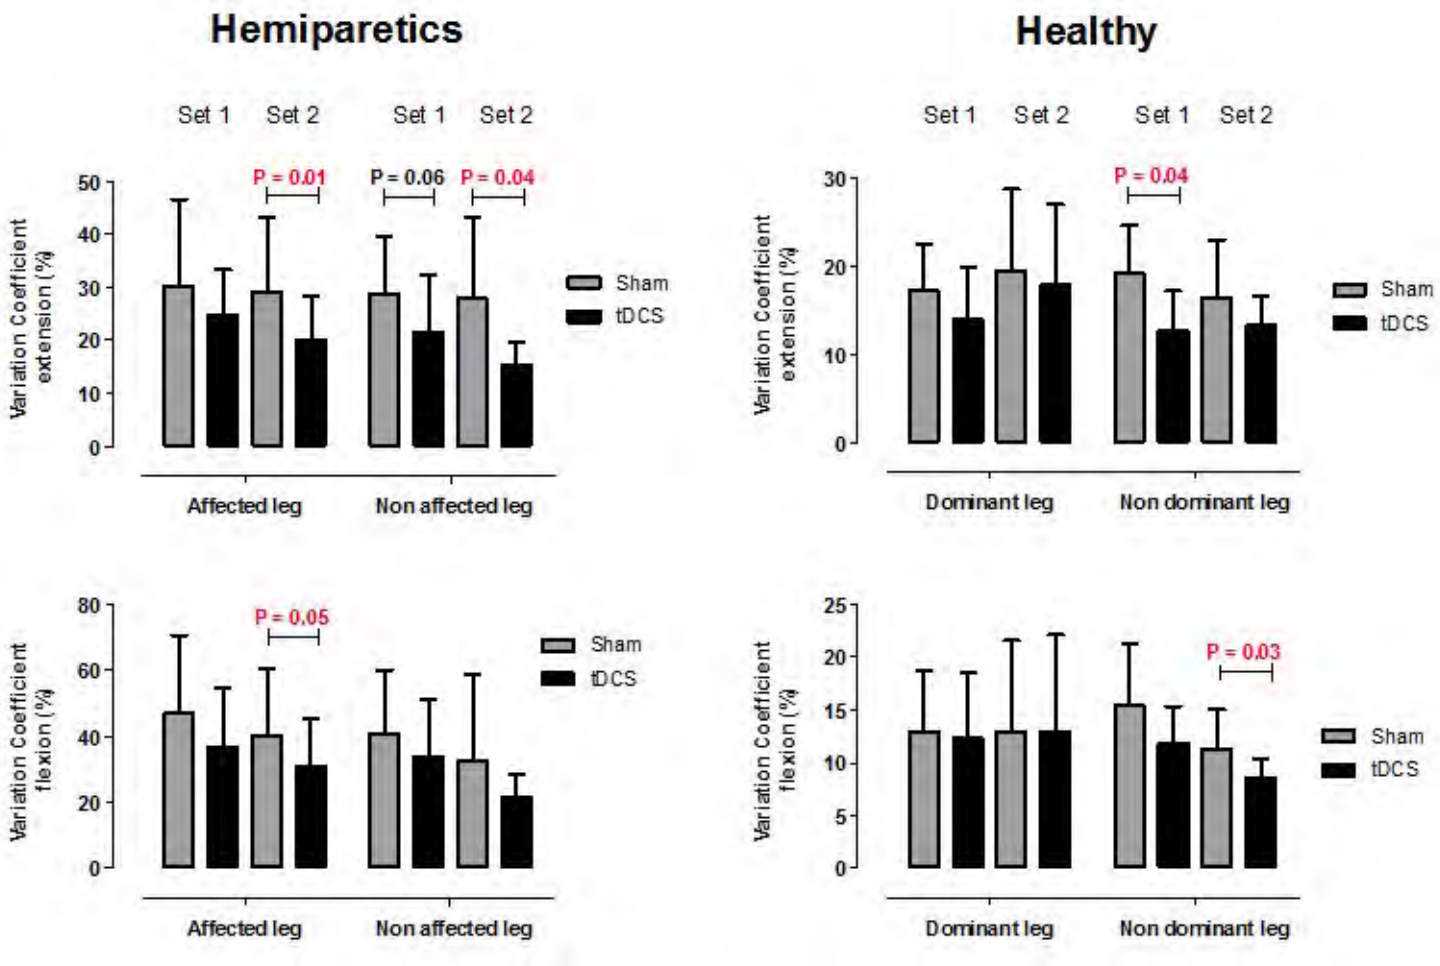
[1]Physical Activity and Health Promotion Laboratory, State University of Rio de Janeiro, Rio de Janeiro, Brazil, [2]Department of Sport and Physical Activity, Edge Hill University, Ormskirk, Lancashire, United Kingdom, Ormiskirk, United Kingdom

Introduction and Objectives: Relative imbalance in interhemispheric motor cortex excitability is observed in post-stroke patients due to an ipsilesional motor cortex hypo-excitability with concomitant contralesional motor cortex hyper-excitability. As a consequence, high coefficient of variation of muscle strength induced by high force variability was showed in stroke patients while performing submaximal dynamic strength exercises. Transcranial direct current stimulation (tDCS) is a simple and non-invasive technique widely used in neurological rehabilitations programs. Enhances in affected motor cortex plasticity as well as improvements in maximal and isometric submaximal strength exercise performance in hemiparetics and healthy subjects have been showed when bi-hemispheric motor cortex tDCS is applied. The main purposes were to investigate and compare the acute tDCS effects on peak muscular torque as well as the force steadiness during maximal and submaximal dynamic leg isokinetic exercise protocols, respectively, in hemiparetic and healthy subjects.

Methods: In a double blind, crossover, randomized sham controlled experimental design, 10 chronic stroke hemiparetic patients and 09 healthy subjects performed bilateral knee extension and flexion isokinetic tests at submaximal and maximal workloads [2 sets of 10 repetitions at 50% peak torque and 1 set of 3 reps at 100% peak torque, respectively] with and without bihemispheric tDCS over motor cortex [2mA during 20 min]. First of all, the participants were invited to perform one or, if necessary, two familiarization sessions aiming to avoid apprehensible behavior and learning effect within experimental protocols. The range of motion varied between 0° to 90° with execution speed fixed in $60°.s^{-1}$ for maximal and $120°.s^{-1}$ for submaximal exercise tests. The peak muscular torque and the coefficient of variation between repetitions and sets were used as an indicator of force production and force steadiness, respectively. All participants got information to keep their food diet routine normally prior to perform the visits but were discouraged to consume ergogenic beverages like coffee and soft drinks.

Results: After tDCS the peak torque in stroke patients increased only for the knee extension in the non-affected leg ($P = 0.008$), while no difference was found in the affected leg ($P > 0.05$). For healthy subjects, no difference was found for the peak torque in both dominant and non-dominant legs ($P > 0.05$). The force steadiness reflected by the coefficient of variation during the knee extension phase decreased in tDCS *vs.* sham condition in both affected ($P = 0.01$) and non-affected legs ($P = 0.04$). However, in the knee flexion phase, the coefficient of variation after tDCS decreased only in affected leg ($P = 0.05$). For healthy subjects, the force steadiness during both knee extension and flexion phases decreased in tDCS *vs.* sham condition only in non-dominant leg (Knee extension phase: $P = 0.04$; Knee flexion phase: 0.03).

Figure:



Caption: Variation coefficient (Mean ± SD) between two sets of 10 repetitions at 50% of peak muscular torque) after anodal motor cortex tDCS (black bars) or sham condition (gray bars) in both hemiparetics and healthy subjects

Conclusion: A single session of bihemispheric tDCS might enhance the maximal strength in chronic stroke patients but not in healthy subjects. Furthermore, the force steadiness might be attenuated in both chronic stroke and healthy individuals. These findings warrant additional research to ratify the potential role of bihemispheric tDCS to improve motor performance in stroke patients.

PO-0151

DIFFERENTIAL EFFECT OF VISION GUIDING ON ARCHIMEDES SPIRAL DRAWING BETWEEN PATIENTS WITH ESSENTIAL TREMOR AND PARKINSON'S DISEASE

Kai-Hsiang Chen [1] Yu-Jung Chen [2,*] Po-Chieh Lin [2] Bing-Shiang Yang [2]

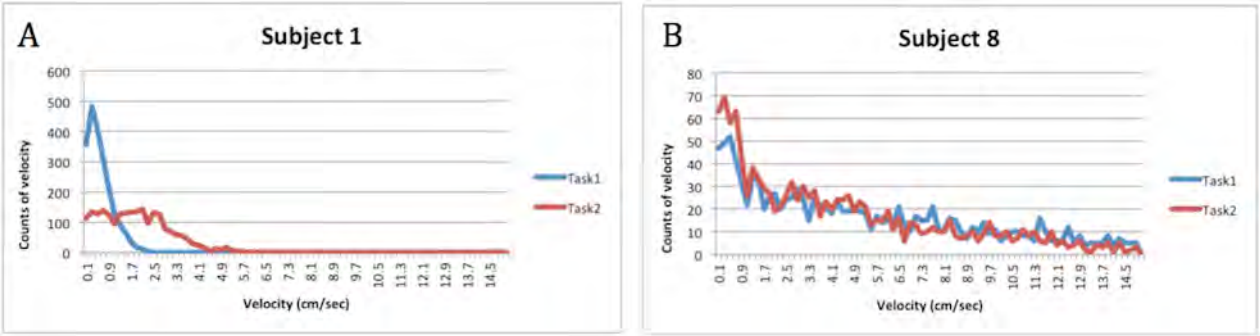
[1]Neurology, National Taiwan University Hospital, Hsinchu Branch, Hsinchu, [2]Mechanical engineering, National Chiao Tung University, Taiwan, Hsinchu City, Taiwan, Republic of China

Introduction and Objectives: Tremor is the most common movement disorder seen in general neurological outpatient clinics. There are many diseases that could have tremor as a main clinical phenotypes, including Parkinson's disease (PD) and essential tremor (ET). Because of the similar symptom, it is usually difficult to differentiate between PD and ET in an early stage using current clinical assessments, which could result in inappropriate diagnoses or treatments. Therefore, the aim of this study was to develop a clinical assessment to better distinguish tremor between patients with PD and ET.

Methods: Archimedes spirals are commonly used in the evaluation of patients with pathologic tremor. Thus, we employed a digitizing tablet with sampling rate 50 Hz to quantify the performance of drawing Archimedes spirals. Six patients with ET (ages: 73.8±6.64) and three with PD (ages 71.6±3.51) signed informed consents to participate in the study. Spiral drawing was recorded under two tasks - *task 1*: patients were instructed to draw the spiral along printed spiral loops from inside to outside; and *task 2*: patients were instructed to follow a guiding point with a constant velocity (3cm/sec). Drawing velocities were quantified during each test.

Results: Figure 1 shows the distribution of drawing velocity in one typical PD and one typical ET patents during the two tasks. We found that distributions of task 2 were significantly different between ET and PD, with the mean velocity as 1.94±1.34 in PD cm/sec, and 2.77±2.33cm/sec in ET($p<0.05$). Besides, Jaccard's similarity coefficients of PD patients are less than 0.4, while those of ETs are more than 0.5 (Table 1).The interquartile range the velocity distribution of guiding task is about three times as the non-guiding task in PD, but less than two times in ET patients (Table 1).

Figure:



Caption: Figure 1 Distribution of velocity in task 1 and 2. The Jaccard's similarity coefficient defined as the size of the intersection divided by the size of the union of the sample sets. A: data from one PD patient. B: data from one ET patient.

Conclusion: A visual guiding could bring different performance in ET and PD in spiral drawing. Patients with ET have the similar distribution of velocity between the guided and non-guided tasks. However, the velocity distribution of PD patients is significantly changed during the guiding task ($p<0.05$). In addition, the Jaccard's similarity coefficient and interquartile range of velocity indicate that frequency profile of drawing velocity between two tasks in ETs are with more similarity than those in PD patients. It appears that patients with PD were affected by the guiding point. These findings can be used to develop a standardized test for early diagnosis for patients with tremor, to distinguish essential tremor from Parkinson's disease, in clinical environment.

Table:

	Jaccard's similarity coefficient	Interquartile range of velocity		
		Task 1	Task2	Ratio (Task1/Task2)
PD (N=3)	0.34±0.05	0.67±0.08 (cm/s)	1.93±0.17 (cm/s)	2.87±0.17
ET (N=6)	0.64±0.14	3.08±1.88 (cm/s)	3.34±1.33 (cm/s)	1.29±0.55

N=number of subject

Caption: Table 1 Jaccard's similarity coefficient, interquartile range of velocity and the ratio between task 1 and task 2 in PD and ET patients.

LOW OBSTACLE INCREASES VARIABILITY OF GAIT TEMPORAL PARAMETERS IN APPROACHING PHASE IN PATIENTS WITH PARKINSON'S DISEASE

Lucas T. B. Simieli [1,*] Fabio Barbieri [2] Diego Orcioli-Silva [1] Paulo Cezar Rocha Santos [1] Victor Spiandor Beretta [1] André Macari Baptista [1] Vinicius Alota Ignacio Pereira [1] Lilian Teresa Bucken Gobbi [1]

[1]Department of Physical Education, Univ Estadual Paulista "Julio de Mesquita Filho" - Rio Claro, Rio Claro, [2]Department of Physical Education, Univ Estadual Paulista "Julio de Mesquita Filho" - Bauru, Bauru, Brazil

Introduction and Objectives: The literature reports that obstacles change gait parameters during gait of elderly people, mainly in individuals with Parkinson's disease (PD) (1,2). Variability of temporal parameters is an important factor on gait during obstacle crossing (4). Patients with PD present alterations on gait, such as longer double support phase (1,3) and greater variability (4), which seems to indicate a deficit on programming, mainly during challenging tasks, such as crossing an obstacle (1,4,5). These modulations during obstacle crossing may explain the greater number of falls in this population. However, there is little information in the literature about the effects of different obstacles height on gait parameters, mainly related to approaching to the obstacle (approaching phase) (5). Therefore, the aim of this study is to investigate the influence of three different obstacle heights during the approaching phase in patients with PD and neurological healthy elderly (control group).

Methods: Fifteen patients with PD (70.61±9.82 years) and 13 neurological healthy elderly (70.5±15.4 years) participated in this study. All subjects performed ten trials for each condition: gait without obstacle, gait with low obstacle, gait with intermediate obstacle and gait with high obstacle. The conditions were randomized by block, but the first condition for all participants was the gait without obstacle. The obstacle heights were customized according to leg length (low = ankle height; intermediate = (low obstacle height + high obstacle height)/2; high = knee height/2). The obstacles were positioned in the middle of a pathway (8 meters). The temporal parameters were recorded by a carpet with sensors of pressure (GAITRite® (CIR System, Clifton, NJ, USA). The parameter analyzed was the variability (standard deviation) of step time, double support time, swing time, stance time and single support time of the STEP BEFORE OBSTACLE CROSSING.

Results: MANOVAs with factor for group and condition were performed, with repeated measures for condition, to answer the questions of the study ($\alpha = 0.05$). The groups were similar at age ($t_{1,26} = 0.70$), mental status ($t_{1,26} = 0.76$), body weight ($t_{1,26} = 0.98$) and body height ($t_{1,26} = 0.20$). The MANOVA revealed main effects of group ($p = 0.001$) and condition ($p = 0.001$) and interaction ($p = 0.001$) between group and condition. About the interaction, PD group showed a greater variability of all temporal parameters than control group, mainly in low obstacle condition. Low obstacle changed the approaching phase of PD group, increasing the variability of step time ($p<0.001$) and swing time ($p<0.001$) compared to other conditions and with control group ($p = 0.001$).

Conclusion: Interesting, these findings were against our initial hypothesis: high obstacle will increase the variability of temporal gait parameters compared to other conditions, mainly for PD group. Less attention driven to the obstacle seems to explain the greater variability during approaching phase in low obstacle condition (5). This behavior induces the individuals to adjust gait parameters during obstacle approaching, increasing the variability. In addition, patients with PD

needs more time to process environmental information and seems to judge this incorrectly, which could also explain the greater variability. In conclusion, the presence of obstacle increased variability of temporal parameters on approaching phase of individuals with PD, regardless its height. In addition, low obstacle influenced the temporal gait variability of patients with PD more than other obstacle height.

Table:

THE INFLUENCE OF BODY WEIGHT SUPPORT ON COORDINATION OF LOWER LIMB IN STROKE PATIENTS WITH SLIGHTLY PARALYSIS DURING TREADMILL WALKING

Takuma Yawata [1] [2]Hitoshi Makabe [1,*]Shinjiro Saito [3]

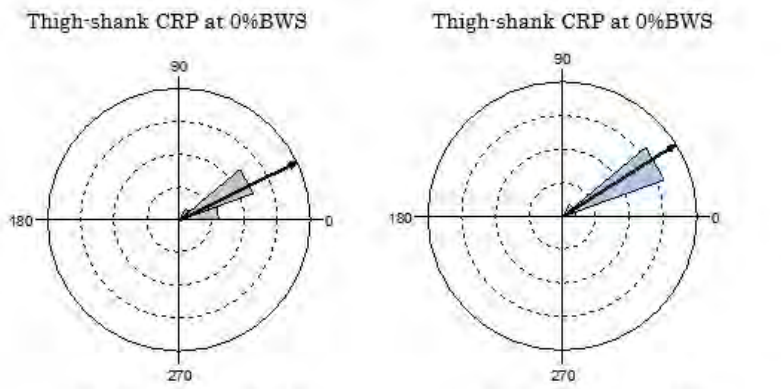
[1]Physical Therapy, Yamagata Prefectural University of Health Sciences, Yamagata, [2]Physical Therapy, Oizumi Kinen Hospital, Shiroishi, [3]Yamagata City Hospital SAISEIKAN, Yamagata, Japan

Introduction and Objectives: On discharge from rehabilitation, 60% to 80% of stroke patients walk at insufficient speed and poor inter-limb coordination [1]. It is known that body-weight supported walking training on a treadmill (BWSTT) improve walking performance [2]. However, it is not clear whether or not the BWSTT is effect to coordination of lower limb. The purpose of this study was to investigate the influence of body weight support (BWS) on the coordination of lower limb during treadmill walking in stroke patients with slightly paralysis.

Methods: Subjects were 10 healthy individuals (control group: age = 64.3±7.5 years, height = 166.9±7.2 cm, weight = 71.7±11.7 kg) and 10 stroke patients (patients group: age = 64.8±8.2 years, height = 163.2±8.6 cm, weight = 64.6±11.4 kg, NIH stroke scale=0~2). Experimental task was walking on treadmill with body weight support (BWS) system. BWS was set in 0%, 10%, 20%, and 30% of the body weight. The subjects walked at a comfortable speed estimated on the basis of Froude velocity for 30 seconds. Kinematics of walking was recorded by 3D motion analysis system (Vicon). Muscle activities of lower limb and trunk acceleration at L3 level were recorded by wireless EMG and acceleration system (Trigono Wireless System). Continuous relative phases (CRP) of thigh-shank and shank-foot, %EMG (vastus medialis = VM, lateral hamstring = LH, tibialis anterior = TA, and gastrocnemius = GAS; ratio of RMS EMG to 0% BWS,), and %ACC (ratio of RMS acceleration to 0% BWS) at L3 level were calculated from 10 stride data. Means and variance of relative phase were calculated by circular statistics (Oriana 3.0). Analysis of variance was used to determine the effect of BWS (R ver.2-8-1). Significant level was set at $p < .05$. This study was undertaken in accordance with the Declaration of Helsinki Ethical approval and all participants gave informed consent. The present study was approved by the Institutional Review Boards of the Yamagata Prefectural University of Health Sciences and the Yamagata City Hospital Saiseikan.

Results: Thigh-shank CRP of the stroke patients at heel-contact during 10%, 20%, and 30% BWS were significantly greater compared with that of the healthy individuals at heel-contact during 0% BWS. Shank-foot CRP of the stroke patients at toe-off during 0% BWS were significantly greater compared with that of the healthy individuals at toe-off during 0% BWS. Shank-foot CRP of the stroke patients at toe-off during 10%, 20%, and 30% BWS decreased to the value of the healthy individuals at toe-off during 0% BWS. %EMG of VM and TA for the stroke patients during 10%, 20%, and 30% BWS were significantly lower than those for the stroke patients during 0% BWS. No significantly difference was in %ACC between the healthy individuals and the stroke patients.

Figure:



Healthy subjects (n=10)
(Mean± SD=26.6±9.8)

Stroke subjects (n=10)
(Mean± SD=32.3±9.7)

Thigh-shank relative phase of stroke patients at toe off during 0%, 10%, 20% and 30% of body support weight.

Shank-foot CRP of the stroke patients at toe-off during 0% BWS were significantly greater compared with that of healthy individual at toe-off during 0% BWS.

Conclusion: BWS for the stroke patients with slightly paralysis made thigh-shank CRP at heel-contact delay and made shank-foot CRP at toe-off fast. These changes may result from reducing muscle effort around knee and ankle joints during treadmill walking with BWS. We need to use the treadmill walking with BWS for the stroke patients with slightly paralysis in consideration of the merit and demerit of the treadmill walking with BWS.

PO-0154

NEUROMUSCULAR CONTROL OF FREELY CHOSEN CADENCE DURING SUBMAXIMAL CYCLING

Karl Grainger [1,*] Lee Romer [1] James Martin [2] Thomas Korff [1]

[1]Centre for Sports Medicine and Human Performance, Brunel University, London, United Kingdom, [2]College of Health, The University of Utah, Salt Lake City, United States

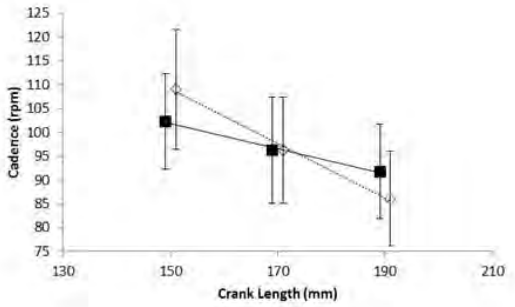
Introduction and Objectives: Previous research has shown that crank length has little effect on metabolic cost and joint power distribution once the effects of pedal speed (the mathematical product of cadence and crank length) are accounted for. Pedal speed (PS) is indicative of muscle shortening velocity, and it would be intuitive to hypothesise that the central nervous system would seek to preserve this variable when perturbed by changes in crank length. Alternatively, the central nervous system may seek to preserve cyclic velocity when crank length is changed. Cyclic velocity (CV) is the product of pedal speed and pedalling rate, and it is therefore a measure which is indicative of both muscle shortening velocity and activation/deactivation dynamics. The purpose of this study was therefore to determine the effect of crank length on freely chosen cadence (FCC), PS and CV during submaximal cycling. Based on previous research [1] [2], it was hypothesized that PS would be preserved across crank lengths.

Methods: Ten volunteers (6 male and 4 female) cycled at 90% of ventilatory threshold using three different crank lengths (150-, 170- and 190-mm), and a range of set cadences and FCC. ANOVAs were performed to examine differences in FCC, PS and CV across crank lengths. In addition, we predicted the FCC for the extreme crank lengths based on the cadence chosen at a crank length of 170 mm assuming that PS would remain constant. Similarly, we predicted FCC at the extreme crank lengths based on the assumption that CV would remain constant. The predicted values were then correlated with the actual values for FCC by means of a linear regression with a forced zero intercept.

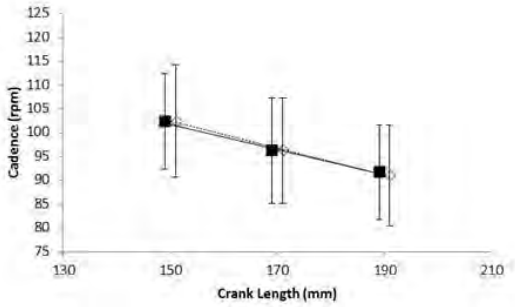
Results: As predicted by our hypothesis, increasing crank length resulted in significantly reduced FCC ($p < .001$). However, contrary to the hypothesis, increasing crank length resulted in a significant increase in PS ($p < .001$), but had no significant effect on CV ($p = .805$). FCC was strongly correlated with FCC predicted from CV ($r = .992$) but less strongly with FCC predicted from PS ($r = .708$) (Figure 1, Table 1).

Figure:

A



B



Caption: Cadence (modeled and freely chosen) - crank length comparison for submaximal cycling. A = pedal speed model, B = cyclic velocity model. Note: ◊ MPC, ■ FCC. Error bars show FCC and model predicted standard deviation. Points are offset horizontally so that error bars are visible.

Conclusion: Contrary to our hypothesis, the participants did not select FCC to preserve PS but rather to preserve CV. These results suggest that when perturbed, the central nervous system does not solely seek to preserve muscle shortening velocity. They further suggest that it is a combination of muscle shortening velocity and activation/deactivation dynamics which is important in the selection of FCC. These results lead us to speculate that FCC is selected to find an optimal trade-off between the minimisation of metabolic cost and neuro-muscular stress. From an applied perspective, our findings add to the body of evidence that crank length is not an important determinant in submaximal cycling performance.

Table:

Crank length (mm)	Actual cadence (rpm)	Pedal speed model predicted cadence (rpm)	Cyclic velocity model predicted cadence (rpm)
150	102.3 ± 9.5	109.1 ± 12.6	102.4 ± 11.8
170	96.2 ± 11.1	96.2 ± 11.1	96.2 ± 11.1
190	91.8 ± 9.4	86.1 ±9.9	91.0 ± 10.5

DEVELOPING CONCUSSION TESTING IN A COMPUTER ASSISTED REHABILITATION ENVIRONMENT (CAREN)

Matthew Pain [1,*] Louise Burnie [1] Glen Blenkinsop [1]

[1]School of Sport, Exercise and Health Sciences, Loughborough University, Loughborough, United Kingdom

Introduction and Objectives: Concussion is becoming accepted as a major problem in many sports, e.g. American football, ice hockey, soccer, rugby, judo, road cycling, and better testing methods are needed to track and improve rehabilitation. Neurocognitive deficits may be observed following a concussion and can be used to help diagnose concussion and monitor recovery. Previous research, using visual only virtual reality (VR) systems, has shown that athletes can pass common test but fail when taking visually based VR tests. With the CAREN system we can also add movement perturbations to the sensory input or require the athlete to take the test using actual whole body movements as the control method. This latter format would replicate the real world needs of athletes where decision making, cognitive function and movement control are needed simultaneously in many instances. The purpose of this project was to develop a neuropsychological testing procedure using a motion sensing CAREN system to assess cognitive function whilst incorporating simultaneous balance assessment and whole body motion as the controller to develop a more sensitive and sport specific concussion testing, monitoring and rehabilitation methodology.

Methods: Variants of standard neuropsychological tests were created using D-Flow software that allowed the tests to be taken using a video games controller or via two force plates with an immersive 2D screen. CAREN based tests were: word memory, pattern memory, reaction time and pattern recall, visual-motor processing speed, colour response and Stroop test, letter recall and trail making. These were variants or adaptations of standard paper and computer based neuropsychological tests. Validity, reliability and test-retest reliability, including using the Reliable Change Index (RCI), were determined against “gold standard” pen and paper tests for a total of 17 healthy subjects. The effect of taking the test in two different conditions, controlled via force plates and games controller, or only a games controller was investigated. To examine if just standing, as needed for the force plate tests, would alter performance subjects took the games controller only tests both standing or seated at a regular computer screen was investigated. Test order was randomised across subjects. Practise and retention effects with test – retest intervals of 10 minutes and 1 week were also assessed. Pearson’s product correlation compared pen and paper tests to CAREN tests. One-Way Anova with Bonferroni correction compared test scores in different conditions, significance at $p < 0.05$. Subjective feedback from the subjects was also recorded.

Results: The CAREN tests had moderate to strong correlations with the pen and paper equivalents. There were no significant differences between standing and sitting for games controller only. There were significantly different scores between force plate control and games controller for time based scores. Pen and paper showed a large number of significant differences for test-retest, while the CAREN tests showed less. RCI measures only gave a significant result on one pen and paper test on the retest interval of 10 minutes, Hopkins verbal learning test. There was no difference in subjective ranking of difficulty of the pen and paper tests or the CAREN tests.

Conclusion: The motion sensing CAREN based tests are a reliable and repeatable set of tests whilst allowing: balance metrics to be simultaneously analysed, postural movements as a controller, visual and physical perturbations to be introduced for greater diffuse sensory input during testing. The next step is to begin testing of concussed subjects with this system to determine an overall system scoring system for assessing concussion, and then to introduce further refinement via introducing perturbation affects during testing.

THE EFFECTS OF PAIRED ASSOCIATIVE STIMULATION -INDUCED BRAIN PLASTICITY CHANGES ON VISUOMOTOR LEARNING TASK

Janne Avela [1,*] Susanne Kumpulainen [1] Jussi Peltonen [1] Ilona Ruotsalainen [1]

[1] Department of Biology of Physical Activity, University of Jyväskylä, Jyväskylä, Finland

Introduction and Objectives: Brain can adapt in response to motor learning by changing its neuroanatomical and functional properties. A simple repetitive motor activity does not; however induce this reorganization (representational map plasticity). Instead, skill acquisition, learning or practice of a novel motor task does induce map plasticity. Thus, specific patterns of motor activity are required to produce functional motor cortex plasticity. One proposed model for these changes is long lasting enhancement of synaptic strength called long-term potentiation (LTP) (Hebb 1949). LTP-like changes in motor cortex are possible to induce artificially with paired associative stimulation (PAS). Some evidence exists that PAS can enhance specific types of motor learning (Ziemann et al. 2004). The aim of this study was to examine the effects of PAS-induced LTP-like plasticity on early acquisition phase of brief visuomotor learning task.

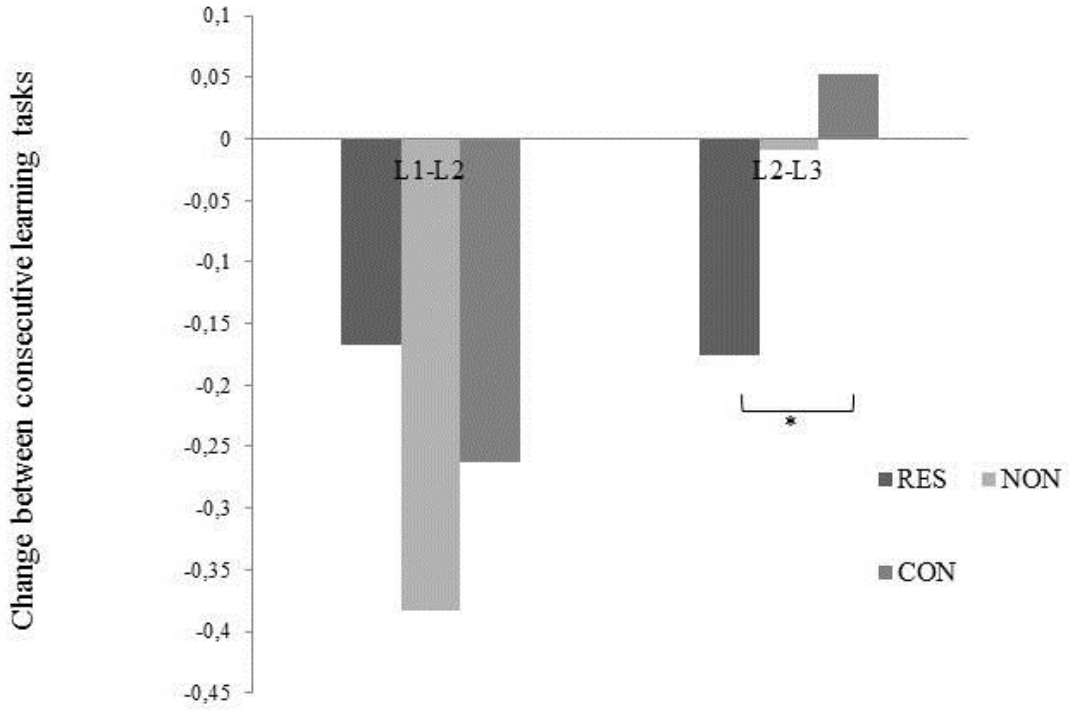
Methods: Twenty healthy volunteers (8 females, 12 males; age = 26.6 ± 4.3; height = 174.4 ± 8.7; weight = 75.5 ± 12.5) participated in this study. The measurements were conducted during two separate sessions. During the first session, measurements of maximal isometric plantarflexion contractions (MVC), motor evoked potentials (MEP), maximal compound muscle action potentials (Mmax) and H-reflexes preceded the PAS intervention (PAS). Five minutes after PAS, learning task one (L1) was conducted. There was a 15 minutes break between the next two consecutive learning tasks (L2 and L3), during these breaks MEPs, Mmax and H-reflexes were measured (POST1, POST and POST3).

PAS consisted of 200 electrical stimuli delivered to the posterior tibial nerve at popliteal fossa, paired with a single TMS pulse of the soleus area over the contralateral M1. The rate of paired stimulation was 0.2 Hz. The interstimulus interval between electrical stimuli and TMS was calculated as the latency time of the sensory evoked potential + 18ms (Kumpulainen et al. 2012).

Learning task performance was calculated as a magnitude of an average error throughout the task. Subjects were divided into three different groups: control group (CON, n=6), group of responders (RES, PAS induced MEP facilitation, n=8) and group of non-responders (NON, PAS did not increase MEP size, n=6).

Results: All groups improved their learning task performance between L1 and L2 as expected (figure 1). However, there was an additional improvement between L2 and L3 for the RES group only. This improvement was significant when compared to CON and close to significant when compared to NON. MEP amplitudes following PAS increased in the RES group by 138.0 ± 98.6 % (POST1), 227.8 ± 130.2 % (POST2, $p < 0.022$) and 228.4 ± 152.9 % (POST3, $p < 0.012$). In the NON group MEP amplitudes were 83.0 ± 35.2 % (POST1) 70.7 ± 21.7 % (POST2, $p < 0.020$) and 72.0 ± 15.5 % (POST3) when compared to PRE. There were no changes in MEP size in CON when compared to PRE measurement. Both the H-reflex and Mmax did not change significantly between the conditions in neither of the groups.

Figure:



Caption: Change in average errors between consecutive learning tasks L1-L2 and L2-L3. Asterisk represent a significant ($p < 0.05$) difference between RES and CON groups. Data expressed as mean.

Conclusion: The present findings showed that PAS-induced LTP-like plasticity did not improve visuomotor learning immediately after the PAS intervention (between L1 and L2). However, as the learning proceeded PAS might have had a beneficial effect on learning (between L2 and L3). This could be due to delayed effects of PAS, which was shown as significantly higher MEP values in POST2 and POST3 than in POST1. This is in line with some previous experiments which have shown that is usually takes some 10 to 15 minutes for LTP to evolve after PAS (e.g. Kumpulainen et al. 2012). Since there were no changes in H-reflexes or Mmax between the different conditions in neither of the groups, it is very likely that the changes took place at the cortical level. However, since the visuomotor learning alone (CON) did not affect the MEP amplitudes, it is difficult to identify the cortical networks that could have affected the visuomotor learning.

HIGH-DENSITY SEMG FOR THE OPTIMIZATION OF MOTOR EVOKED POTENTIAL DETECTION ON TIBIALIS ANTERIOR MUSCLE DURING TRANSCRANIAL MAGNETIC STIMULATION

Niklas König [1,*] Navrag Singh [1] Marco Gazzoni [2] Nicole Wenderoth [3] William Taylor [1]

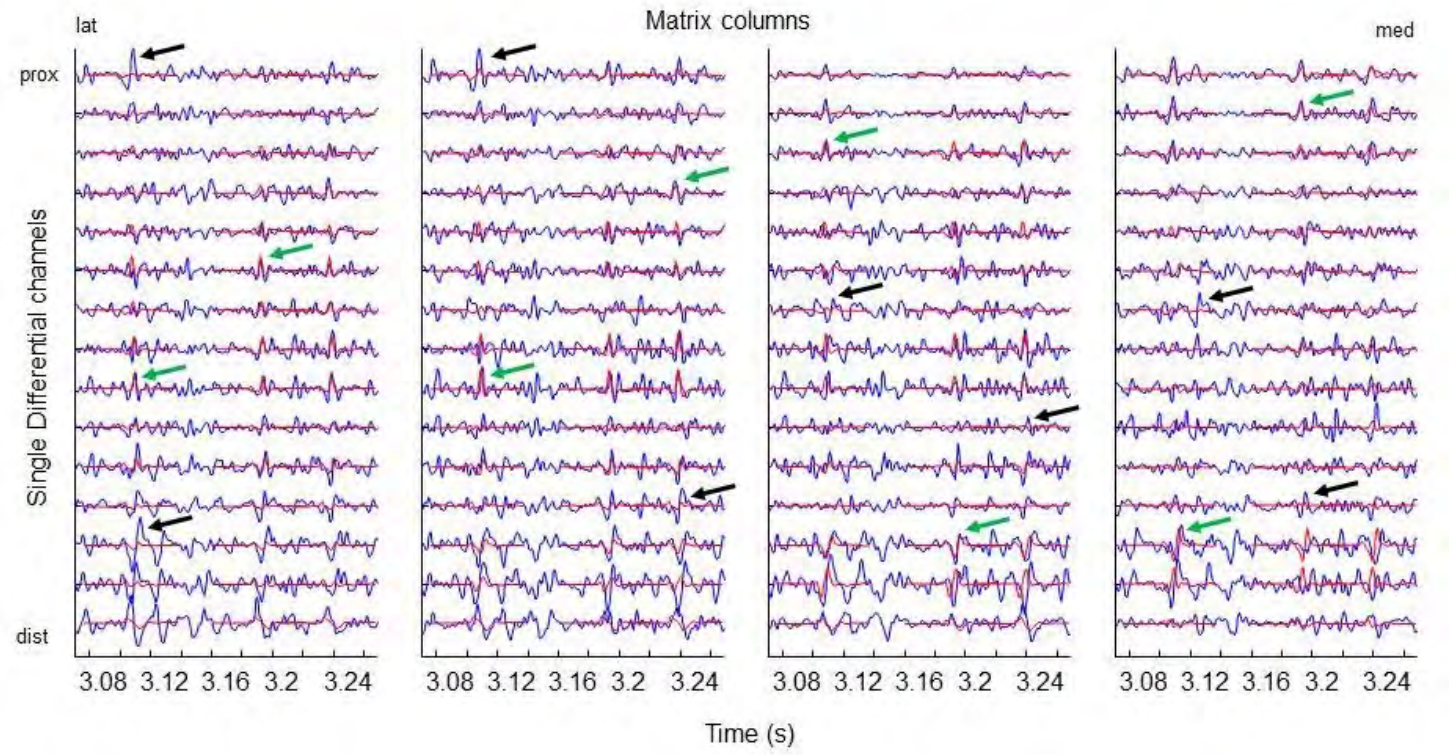
[1]Institute for Biomechanics, ETH Zürich, Zürich, Switzerland, [2]Laboratory of Engineering of Neuromuscular System and Motor Rehabilitation , Politecnico di Torino, Turin, Italy, [3]Neural control of movement laboratory, ETH Zürich, Zürich, Switzerland

Introduction and Objectives: Integrated effects of central & peripheral neuromotor entities are required for effective motor control [1]. Transcranial magnetic stimulation (TMS) is a tool for assessing the causal influence of cortical areas on motor control by evaluating changes in task performance in response to induced neural perturbations [2]. Until now TMS has been used primarily to investigate upper limb function due to limited magnetic field penetration depth. However, recent developments in coil designs provide accessibility to lower extremity muscle representations [3]. TMS application requires determination of subject-specific parameters based on evoked responses measured via surface EMG. Typically, lower limb muscles are large, allowing for variability in positioning the EMG electrodes during TMS. Furthermore, bipolar EMG amplitude is sensitive to electrode location, with locations over the muscle innervation zone resulting in significantly lower EMG amplitudes [4]. The rest motor threshold (RMT) is defined as the lowest stimulation intensity (%maximum stimulator intensity [MSO]) needed to evoke 5/10 motor-evoked potentials (MEPs) with an amplitude > 0.05mV [5]. Thus, the RMT is dependent on the EMG amplitude. However, for application of TMS to lower limb muscles, it remains unclear whether location of the surface EMG can alter the subject-specific RMT. Therefore the aim was to assess if optimised EMG location would result in decreased RMT.

Methods: Five subjects (29±5yrs, 70±13kg, 171±10cm) were seated relaxed with their knees and ankles at 90°. Bipolar EMG (Delsys, USA) was placed on the right tibialis anterior muscle belly after preparing the skin. MEPs were induced with a double-cone coil connected to a Magstim 200 stimulator (Magstim, UK) while EMG responses were sampled at 4kHz (CED, UK). Initially, the coil location resulting in the largest and most consistent MEPs was determined. Firstly the RMT for each subject was determined using the bipolar EMG located centrally on the muscle belly (RMT_Norm) [5], followed by 20 MEPs recorded at 130% RMT_Norm. A high-density surface EMG (HD-sEMG) with a grid of 16x4 electrodes (LISiN, Turin) was then attached covering the whole muscle surface. This HD-sEMG grid was connected to a 64 channel amplifier (W-EMG, LISiN-Bitron). A 15s ramp isometric contraction was then recorded, as well as 20 MEPs at 130% RMT_Norm. The electrode pair resulting in the largest MEP amplitude was identified and the corresponding location was marked on the muscle. Finally, the HD-sEMG was replaced by a bipolar electrode located at the identified optimised muscle location before RMT was again evaluated (RMT_Opti) and 20 MEPs recorded at 130% RMT_Opti.

Results: The RMTs remained unchanged when the bipolar sEMG was located at the centre of the muscle belly compared to the optimal location. The change of MEPs between MEP_Norm and MEP_Opti was inconsistent with 3/5 subjects revealed lower MEPs at MEP_Opti. Cross-correlation of amplitude and shape between the action potentials in the ramped contraction and the MEPs in a revealed that TMS only recruits a fraction of motor units within the pool (Figure 1).

Figure:



Caption: Cross-correlation between motor-units during ramped contraction and the MEP during TMS. Blue traces: ramped contraction. Red traces: MEP template. High (green arrows) and low (black arrows) correlation between both signals

Conclusion: The RMTs were insensitive to the location of the bipolar EMG. Although in a small sample size, a comparison between action potentials during the ramped contraction and the MEP showed that TMS at 130% RMT innervated only few motor units. The amplitudes at MEP_Opti were not larger than at MEP_Norm, which is in contrast to the increased MEPs identified for the optimised location in the HD-sEMG. This might be due to differences in the electrode geometry, or that the TMS quasi-randomly innervates motor units [6], which would result in the optimal location moving with every iteration. Finally, it appears that although the average MEP_Opti was reduced in 3/5 subjects, the RMT remained stable, which implies that the central effect in the primary motor cortex is larger than the local effect of amplitude change on the muscle. In conclusion, the current RMT method is a robust measure to assess subject-specific TMS intensity irrespective of local muscular effects. The effects of TMS on motor unit recruitment are interesting but require further investigation.

Table:

Subject	RMT_Norm [%MSO]	RMT_Opti [%MSO]	MEP_Norm [mV]	MEP_Opti [mV]
1	44	44	0.49	0.86
2	37	39	0.91	0.50
3	43	43	0.48	0.15
4	32	32	0.45	0.35
5	34	34	0.21	0.24

PO-0158

EVIDENCE FOR SPINAL CORD ACTIVATED MOTOR UNITS IN SPASTIC MUSCLES AFTER STROKE

Kathrin Koch [1,*] Catherine Disselhorst-Klug [1]

[1]Rehabilitation and Prevention Engineering, RWTH Aachen, Institute of Applied Medical Engineering, Aachen, Germany

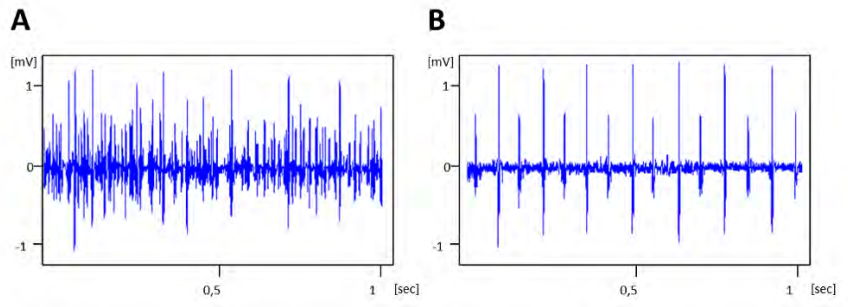
Introduction and Objectives: About 15 million people suffer from stroke each year worldwide and approximately 10% subsequently remain with spastic impairments. A spastic impaired muscle shows a velocity dependent increase in muscle tone. The changes in the muscular activation are caused by the lesion in the cerebral tissue after the stroke incident, whereas the muscle structure itself is not impaired.

Since the insult the regulating effect of the brain, which controls the activation of the muscle, is missing and changes in the activation of motor units can be expected. Spasticity is often linked with hyperreflexia what leads to the suggestion that the activation of the spastic muscle is now controlled by mechanisms on spinal cord level. In order to get evidence for a spinal cord controlled activation of spastic muscles, the activation of single motor units is analyzed with surface electromyography.

Methods: For an evaluation the changes in the activation of the smallest excitable units (motor units) of a muscle will be analyzed. By measuring muscular activation on motor unit level important information about the recruitment and firing strategies can be gained. The activation of motor units is measured with grid electrodes in combination with a two-dimensional Laplacian filter (high spatial resolution electromyography) which was used already for the distinction between different neuromuscular disorders. Measurements have been performed at the abductor pollicis brevis of 10 stroke patients at maximum voluntary contraction for one second. From the measured data the number of action potentials per time, the firing frequency of all motor units and the distance between peaks were extracted, which describe the special characteristics of spastic muscles.

Results: The HSR-EMG signal of patients who suffer from stroke shows significant changes compared to the signal of healthy subjects. The most dominant feature is a constant appearance of action potentials (Figure 1). The constant firing is a common feature for all patients with spasticity. The main frequency of the firing rate is about 8 to 16 Hz. The distance between single peaks is extraordinarily uniform. Additionally the shape of the repeated, isolated peaks is similar. Further characteristics of the HSR-EMG signal of spastic muscles are sparsely distributed, isolated peaks and rarely background activity. The total number of peaks per second is much less than in healthy muscles.

Figure:



Caption: Figure 1: HSR-EMG signals of a healthy muscle (A) and spastic muscle (B)

Conclusion: The activation of single motor units in spastic muscles shows constant firing rates. The underlying mechanism for this activation pattern might be an autonomously oscillating circuit on spinal cord level. A trigger frequency which is developed after central lesions could be responsible for the special firing frequency. Additionally it could contribute to the increased muscle tone in spastic muscles. A sparse appearance of action potential indicates less active motor units than in a healthy muscle. After the brain insult the innervation of the complete pool of motor units is no longer possible, so the compensation strategy of this deficit results in less active motor units activated at a constant frequency. The regular activation strategies for force generation of a muscle controlled by the brain, like increase of firing rate and increase of activated motor units, cannot be provided by the mechanism on spinal cord level.

In conclusion possible evidence for muscle controlling mechanisms on spinal cord level can be found in the activation pattern of spastic muscles.

PO-0159

INVESTIGATION OF A CAUSAL MODEL LINKING CORTICOMUSCULAR COHERENCE TO MOTOR PRECISION INCLUDING ANTAGONIST MUSCLE EFFECTS

Nikhil V. Divekar [1,*]

[1]Exercise Science and Sports Medicine, University of Cape Town, Cape Town, South Africa

Introduction and Objectives: The relationship between cortico-muscular-coherence (CMC) and motor-precision is unclear: a within-task direct relationship [1] and a between-task inverse relationship [2 3] were found previously. The latter was explained using a proposed causal model: higher beta (15-35-Hz) CMC induces higher beta oscillations in the agonist electromyogram (EMG) which cause higher beta and low-frequency (<5Hz) fluctuations in joint-torque (leading to lower precision). We aimed to examine this proposed causal model in the within-task scenario to control for the confounding task factor. Furthermore, previous studies applied to agonists only, but antagonist muscles would also affect precision and hence were also included.

Methods: EEG, EMG and wrist-joint-torque were recorded from 15 subjects performing 10 repetitions of 2 isometric tasks (wrist flexion, extension) using multiple co-contracting agonists-antagonists. Data was segmented, re-ordered and bifurcated into high-precision (HP) and low-precision (LP) groups within each task.

Results: Within both tasks, both beta CMC and beta EMG of certain agonists and antagonists were significantly higher for HP; while both beta and low-frequency (<5Hz) fluctuations in wrist-joint-torque were significantly lower for HP.

Conclusion: Hence contrary to the causal model, lower joint-torque fluctuation (higher precision) was found despite the higher beta EMG that was induced by the higher beta CMC. We propose the annulled task confound and also co-contraction of agonists-antagonists to have facilitated this result. We hence confirm a direct CMC-precision relationship and also reveal the significance of antagonist CMC in this relationship. An extra observation suggests the extent of the CMC-precision relationship varies with the role (ant/agonist) of certain muscles.
